A Celebration of a Great Partnership: Teledyne Webb and RU COOL

2010-2025

“Work Hard, Have Fun, and Change the World”
Quoting Doug Webb in Baiona, Spain, 2009
At the Celebration for the First Underwater Glider to Cross an Ocean Basin

Progress in ocean science, while tightly connected to innovating new technologies, is only possible through partnership of like-minded dedicated people working together for a vision of what could be. This partnership with the leaders-engineers-scientists at Teledyne Webb has been a shining example of what great partnerships can be. This partnership took a vision first articulated in Henry Stommel’s 1989 science fiction hope in *Oceanography,* to then, in 1999, successfully demonstrate for the first time a glider working in the coastal waters offshore New Jersey. From that initial flight, gliders have been widely adopted by the ocean community to build a globally distributed network spanning our planet.

Autonomous gliders are now a transformative technology serving diverse stakeholders that use and live with the ocean. Gliders were first included in the World Ocean Database (WOD) 2018 holdings (WOD18) and by the 2023 WOD23 glider collected data accounted for 15.9% of all ocean data holdings, second only to the historical Ocean Station Data (OSD) at 17.5%, which goes back to 1974. Gliders will likely surpass that dataset in the next WOD update and will represent the largest source of data to the WOD. Taking a moment to reflect on another aspect of this partnership, this collection of science literature published over the last decade illustrates the impact of gliders on a wide range of research questions and technical achievements. But even while taking this moment to look back, most of our energy is focused on the great adventures to come.

In celebration of Doug Webb’s contributions to humanity, we are so excited and honored with the start of the Sentinel mission in 2025 where our partnership will together navigate a glider around the world’s ocean. This book documents our science enabled by Teledyne Marine gliders. We look forward to our continued partnership and the discoveries to come. Looking forward, let’s go and “Smell the sea and feel the sky. Let your soul and spirit fly.” (*Van Morrison)*

Your friends and partners at RU COOL

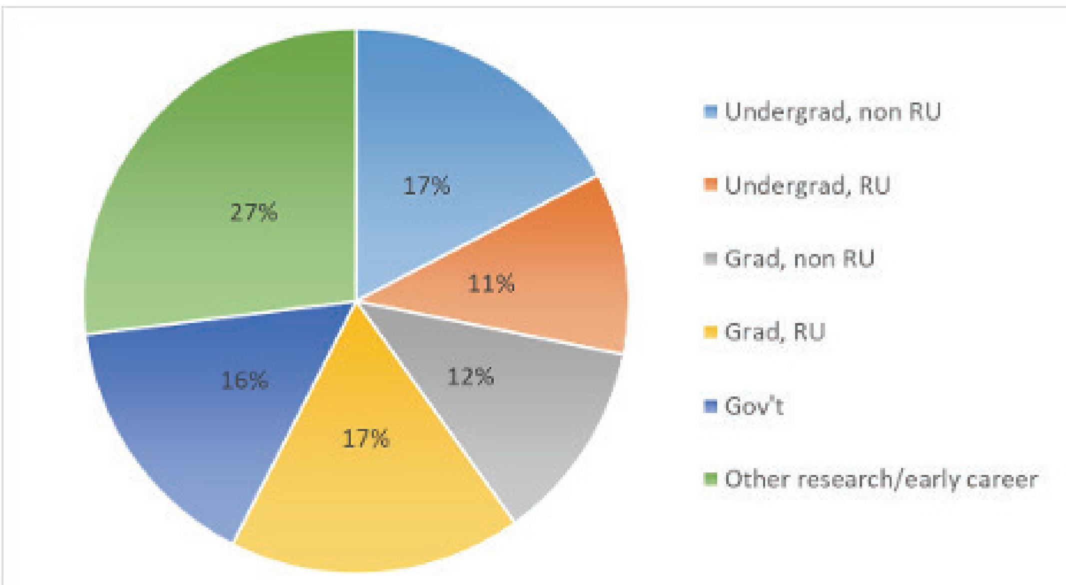
Teledyne Webb has helped educate a new generation of scientists through generous contributions of graduate fellowships. Their funding has supported a wide range of science spanning the physics of extreme storms to the seasonal migration of the Antarctic krill. Here is the current list of the 11 Ph.D. theses supported by Teledyne Webb.

Teledyne Marine and Doug Webb Graduate Fellowship at Rutgers			
Ph.D. Grad Student	**Graduation Year**	**Thesis Title or Topic**	**Post-Graduation Position**
Travis Miles	2014	Observations and Modeling of the Coastal Ocean Beneath Tropical and Extra-Tropical Cyclones	Tenured Rutgers Associate Professor
Filipa Carvalho	2017	Coupled Physical and Phytoplankton Dynamics in Antarctica's Coastal Seas	National Ocean Centre (NOC)
Nicole Couto	2017	Circulation and hear Transport on the West Antarctic Peninsula Continental Shelf	Scripps Institute of Oceanography (SIO)
Clifford Watkins	2021	Mixed Layer Dynamics: Exploring the Impact of Storms in the Mid Atlantic Bight	Naval Research Lab – Monterey
Schuyler Nardelli	2022	Seasonal Dynamics of Plankton Ecology in Coastal Antarctica	US Geological Survey (USGS)
Michael Chen	2024	Spatial and Seasonal Controls on Eddy Subduction in the Southern Ocean	Oceana Inc.
Lauren Cook	Expected June 2025	Exploring fish carbon cycling off the coast of New Jersey	Faculty @ St. Mary's College, MD
Teemer Barry	Expected July 2025	Deoxygenation in coastal New Jersey bottom water	Applied for Knauss Fellow
Leah Hopson	Ph.D. Candidate	Upper ocean mixing in hurricanes	
Jacob Kuenzil	Grad Student	Distribution and habitat use of sharks in the Mid Atlantic	
Becca Horwitz	Grad Student	Marine heat waves and cold spells in the coastal ocean	

Working together Rutgers and Teledyne Webb have trained a new generation of glider operators. The people who have taken the training have spanned from the Navy, Universities, Federal Laboratories, and students. Over the last 20 years over 165 have been trained between February 2005 and June 2024. The demographics of the training is provided below.

Participant Category	Number	Percentage
Undergraduate	46	28%
Graduate Students	48	29%
Government (Navy, NOAA, etc)	45	27%
Other Researchers	26	16%
Total	**165**	**100%**



Given the adoption of glider technology across the marine communities, increasing the pool of technical expertise for the community is critical. Rutgers established in 2020, a Masters of Operational Oceanography program. Since its establishment 35 students have taken the program of which 11 of the students' projects were focused on various aspects of glider technology.

Automated Sensor Networks to Advance Ocean Science

Oceanography is evolving from a ship-based expeditionary science to a distributed, observatory-based approach in which scientists continuously interact with instruments in the field. These new capabilities will facilitate the collection of long-term time series while also providing an interactive capability to conduct experiments using data streaming in real time.

The U.S. National Science Foundation has funded the Ocean Observatories Initiative (OOI), which over the next 5 years will deploy infrastructure to expand scientists' ability to remotely study the ocean. The OOI is deploying infrastructure that spans global, regional, and coastal scales. A global component will address planetary-scale problems using a new network of moored buoys linked to shore via satellite telecommunications. A regional cabled observatory will "wire" a single region in the northeastern Pacific Ocean with a high-speed optical and power grid. The coastal component will expand existing coastal observing assets in order to study the importance of high-frequency forcing on the coastal environments.

These components will be linked by a robust cyberinfrastructure (CI) that will integrate marine observatories into a coherent system-of-systems. This CI infrastructure will also provide a Web-based social network enabled by real-time visualization and access to numerical model information, to provide the foundation for adaptive sampling science. Thus, oceanographers will have access to automated machine-to-machine sensor networks that can be scalable to increase in size and incorporate new technology for decades to come. A case study of this CI in action shows how a community of ocean scientists and engineers located throughout the United States at 12 different institutions used the automated ocean observatory to address daily adaptive science priorities in real time.

Connectivity Between Observations and Models

During its 5-year construction period, the OOI is committed to engaging the ocean sciences community. To fulfill this goal, researchers are developing a useful CI by using a "spiral design strategy" so that the oceanography community can provide input throughout the construction phase.

An example of this strategy was conducted in fall 2009 when the OOI CI development team used an existing ocean-observing network in the Mid-Atlantic Bight waters (MAB, spanning offshore regions from Massachusetts to North Carolina) to test OOI CI software. The objectives of this CI test were to aggregate data from ships, autonomous underwater vehicles (AUVs), shore-based radars, and satellites and then make the aggregated information available in real time to five different data-assimilating ocean forecast models. Scientists use these multimodel forecasts to automate future underwater glider missions so that they can study quickly developing and fast changing characteristics of nearshore marine environments. Scientific interests spanned from the formation of the winter phytoplankton bloom to the role of storms that induce sediment resuspension from the seafloor. The test demonstrated the feasibility of two-way interactivity between the sensor web and predictive models.

Specifically, this effort tested the CI planning and prosecution software, which enables operators to monitor and control individual components within an ocean-observing network. The CI software coordinates and prioritizes the shared resources, allows for the semiautomated reconfiguration of asset tasking, and thus facilitates an autonomous execution of observation plans for both fixed and mobile observation platforms. For this effort, numerical model ocean forecasts, made interoperable by standard Web services, allowed scientists to simulate potential robot trajectories. This was used to guide scientists' decisions about whether desired target areas could be reached by autonomous vehicles.

For example, the software allows a scientist to determine if any available underwater glider could be redirected to map a surface plume of turbid water that had been identified in an ocean color image within a 24-hour period. The software then could determine the optimal path to map the turbid plume. Such efforts were coordinated through a Web portal that provided an access point for the observational data and model forecasts. Researchers could use the CI software in tandem with the Web data portal to assess the performance of individual numerical model results, or multimodel ensembles, through real-time comparisons with satellite, shore-based radar, and in situ robotic measurements.

Testing CI Outputs

To try out the CI's capabilities, scientists investigated the program's ability to remotely coordinate the mission of an array of AUVs that were acoustically networked. Scientists on shore in New Jersey used satellite data to define an operations area, which was forwarded to planners at the NASA/California Institute of Technology's Jet Propulsion Laboratory (Pasadena), who in turn e-mailed hourly AUV deployment instructions back to

Ocean Science cont. on page 346

cont. from page 345

at-sea teams on boats off New Jersey. Each AUV was equipped with an acoustic modem that enabled underwater communications with other AUVs. A gateway buoy allowed real-time communication with science personnel on a ship. This system enabled AUV reports of status information such as position, speed, heading, and scientific sensor readings to be published on Google Earth™ and distributed to scientists around the United States in real time. These AUVs were outfitted with software that enabled them to access the available onboard data to autonomously adapt to the environmental features measured by scientific sensors.

Another test of the CI was to try to coordinate sampling between underwater gliders and the space-based Hyperion imager flying on the Earth Observing-1 (EO-1) (http://eo1.gsfc.nasa.gov) spacecraft. Hyperion images have a footprint of 7.5 × 100 kilometers, with a spatial resolution of 30 meters. This small spatial footprint makes it difficult to ensure that instruments closer to the ground are present for in situ verification measurements. The Hyperion swath can be adjusted to survey different regions, and therefore there is a possibility to mobilize in situ assets and simultaneously adjust the satellite sampling region to be coincident. During the field experiment, observational data and multimodel forecasts were analyzed to determine an optimal redirection for the satellite. These new coordinates were used by the EO-1 Web-based capability to change the spacecraft's surveying patterns (http://ase.jpl.nasa.gov). A 48-hour model forecast was then used by the CI software to colocate any gliders and plan their paths within the new EO-1 Hyperion swath. Two gliders were successfully moved to the swath; other gliders, which were not capable of reaching the swath, were diverted to accomplish other science missions.

Improving the Ease of Science

OOI's CI represents a major technology breakthrough in simultaneously coordinating satellite and underwater assets guided by multimodel forecasts. It provides a machine-to-machine interactive loop driven by a geographically distributed group of scientists.

As the number of ocean observatories increases globally, a sophisticated and scalable CI will be required. The OOI CI will provide functionality, allowing scientists to manage the complex networks while optimizing the science data being collected. The CI will also provide pathways to link other ocean networks, allowing more distributed groups to interact. The resulting global sensor net will be a new means to explore and study the world's oceans by providing scientists with real-time data that can be accessed via any wireless network.

Growing a Distributed Ocean Observatory: Our View From the COOL Room

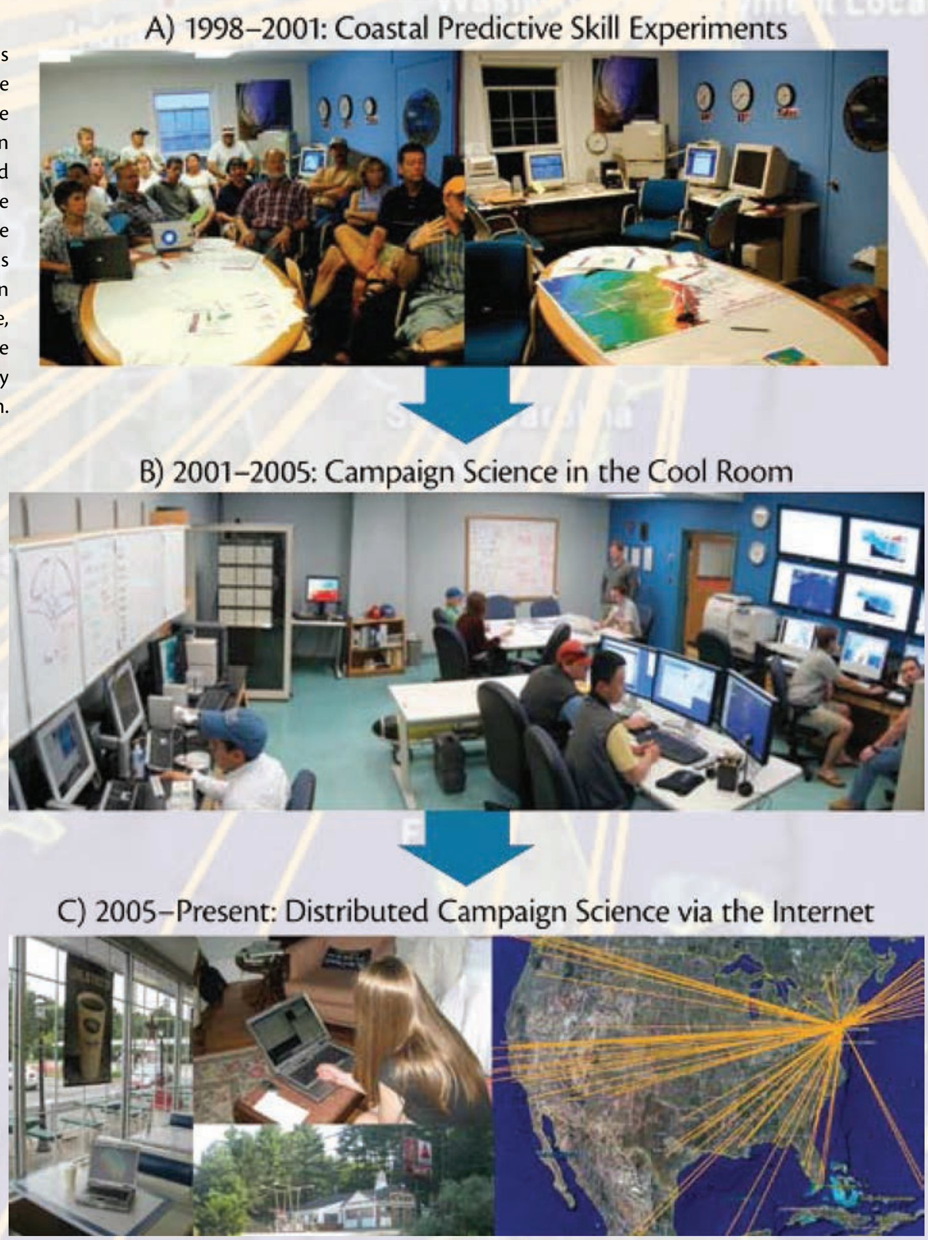

Figure 1. The evolution of the COOL operations center. (A) In the early years, science campaigns were conducted at remote field sites, such as the marine labs in Tuckerton, New Jersey. The remote location limited the duration of the experiments that could be conducted. (B) Improvements in the World Wide Web, combined with wireless technologies, allowed the operations center to be moved to the main campus of Rutgers University. (C) The most recent evolution allows experiments to be sustained remotely anywhere, anytime. Many large field deployments can now be supported from restaurants, from home, or from any location with a decent wireless connection.

ABSTRACT. The Rutgers University (RU) Coastal Ocean Observation Lab (COOL) is an enduring product of the National Oceanographic Partnership Program (NOPP). The key to its longevity is the academic, industry, and government partnerships that were formed through the NOPP process. These partnerships were galvanized by time at sea and then sustained through peer-reviewed proposals. The lab operates an advanced ocean observatory that has maintained a continuous presence on the New Jersey continental shelf since 1992. Key technologies for sustained spatial observations include locally acquired satellite infrared and ocean color imagery, a multistatic high-frequency radar array, and a fleet of autonomous underwater gliders. COOL provides a regional perspective that supports interdisciplinary process studies; provides a test bed, allowing rapid spiral development of sensors and platforms; and has anchored new "campaign" science programs where hundreds of scientists come together for intensive multi-institutional experiments. RU COOL is now a core component of the National Oceanic and Atmospheric Administration Mid-Atlantic Regional Ocean Observing System that, in 2007, began providing data for the full shelf from Cape Cod to Cape Hatteras. Looking to the future, in collaboration with partners from around the globe, the International Consortium of Ocean Observing Labs was formed to focus on improving global ocean observing. The NOPP approach was new and unique when introduced. Its philosophy of partnership among diverse groups was fundamental to the success of COOL and, we believe, will sustain international collaborations into the future.

INTRODUCTION

The Rutgers University Coastal Ocean Observation Lab (COOL) has sustained a continuous observational presence in New Jersey's coastal ocean for 16 years. Over this time, technology improvements have expanded its spatial observing capabilities. The system now provides: (a) a well-sampled region for process studies that range in size from the purview of individual principal investigators to multi-institutional science campaigns, (b) real-time and historical data sets and numerical forecasts supporting a wide variety of scientific and applied users, (c) a local test bed for new technologies, and (d) a focal point for a range of educational activities spanning K–12, undergraduate, graduate, and informal audiences, as well as in-service training. A broad portfolio of competitive grants awarded by US federal and state agencies, industry partners, private foundations, and foreign countries supports these varied activities. The diversified funding portfolio grows directly from our participation in the National Oceanographic Partnership Program (NOPP), which transformed our predominantly academic endeavors of the early 1990s into sustained academic-industry-government partnerships. NOPP provided the seed money to initiate and demonstrate the effectiveness of these approaches, and it continues to attract new partners from different disciplines.

In *Oceanography* and other publications, we have reviewed the evolution of our coastal ocean observatory and the international ocean observatory movement (Glenn et al., 2000a,b, 2004; Schofield et al., 2002, 2003, 2007; Glenn and Schofield, 2003; Schofield and Glenn, 2004). Here, we trace our progress, emphasizing developments since 2003 when our observatory operations center moved from a remote coastal location to the main campus of our research university, which is located two hours from shore (Figure 1A). The transition made the observatory an integral part of everyday campus life year round. This change also increased student involvement, most significantly at the undergraduate level. Since then, improvements in wireless technologies now allow the observatory to be controlled from any global location that has access to the World Wide Web.

THE NOPP DECADE

COOL has participated in six NOPP projects to date (Table 1). Beginning with the first round of NOPP awards, Rutgers-led projects focused on demonstrating the capabilities of an integrated ocean observing and forecast system to maintain a well-sampled 30 km x 30 km portion of the coastal ocean. The need for personnel to be moved to the coastal site to conduct these experiments, and the broad spatial coverage of these experiments, meant that they could only be sustained for about one month (Figure 1A). New sampling technologies and communications systems were required to expand the footprint in space and time. More importantly, initial partnerships formed through the NOPP process grew into a self-sustaining technology development and scientific study team. The team conducted process studies supported by the Office of Naval Research (ONR) and the National Science Foundation (NSF), and enabled

technology-development projects supported by ONR, the Department of Homeland Security (DHS), and the National Aeronautics and Space Administration (NASA).

NOPP also invested funds to develop key technologies and grow a diverse observatory community. Some NOPP efforts focused on improving communication networks for coastal observatories by enabling virtual collocation, ultimately freeing scientists from the constraints of having to move all operations to the shore lab for one-month time periods (Figure 1B, C). NOPP also supported the development of new sensors that were rapidly transitioned into the observatory for prototyping and feedback to developers. Additionally, NOPP focused on building linkages to K–12 and the education research community. We explored the concepts of using real-time ocean data in the classroom, a highly successful effort leading to the establishment of two NSF Centers for Ocean Science Education Excellence (COSEE) at Rutgers. The key lessons of our NOPP experiences are that equal partnership, rapid spiral development[1], and leveraging of resources lead to successful programs.

Scott Glenn *(glenn@marine.rutgers.edu) is Professor of Physical Oceanography, Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, USA.* **Oscar Schofield** *(oscar@marine.rutgers.edu) is Professor of Biological Oceanography, Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, USA.*

[1] Spiral development was introduced in the mid 1980s by Barry Boehm of TRW Inc. as a way to reduce risk on large software projects after finding that these programs were too often designed and built with little input from end users, resulting in failure to meet objectives. Boehm's cyclical approach included early customer evaluation and identification of potential trouble spots by in-house engineers at an early stage. This approach has since been applied more generally to large projects.

Partnerships

NOPP proposals required partnerships among academic, industry, and government laboratories. Our strategy was to assemble a distributed collaborative team regardless of each partner's academic status, proximity, or congressional district. The net result was a virtual institution fueled by a shared vision. The diversity of the partners contributed new perspectives, which were assessed through the peer-review process. The participants, whether they were data providers or data users, were always considered equal partners in the project's execution. This goal-driven mode of construction was in contrast to early efforts by others who built systems based on input from external users.

Spiral Development

The NOPP process recognized that many of the sampling, communication, and modeling technologies required to provide a self-sustaining ocean observatory had not yet been developed. The fixed duration of the NOPP funding promoted a rapid spiral development cycle, which encouraged engineers to work alongside scientists in the field. Early NOPP projects focused on developing novel sampling technologies such as high-frequency [HF] radar and autonomous underwater gliders; later projects were devoted to sensor development. With no guarantee of sustained support, survival of the partnerships was contingent on producing results that would support the next round of peer review or survive the commercial marketplace. This process accelerated the pace of development.

Leveraging of Resources

NOPP was founded, in part, to allow all relevant federal agencies to address ocean observation, modeling, and data management needs jointly. As NOPP challenged scientists and engineers to cross departmental and academic-industry-government lines, the research community was challenging the federal agencies to fund efforts that often overlapped the different agencies' missions. This arrangement resulted in the development of ocean test beds that could simultaneously serve multiple needs. The cyclical support from individual agencies was merged to provide a more continuous funding stream. As the technologies matured, the test beds became more cost efficient, so that keeping an ocean observatory running 24/7/365 was not much more expensive then the cost of repeated mobilization and demobilization cycles. Addressing the scientific research problems of multiple agencies resulted in diverse scientific programs that constantly pushed the limits of available technology and improved the observatory over time.

DEVELOPMENT OF THE COOL ROOM

Our initial NOPP efforts focused on the three-dimensional topographic steering of coastal upwelling and its role in driving bottom water hypoxia/anoxia along the New Jersey coast (Glenn and Schofield, 2003; Glenn et al., 2004b; Schofield et al., 2004; Figure 2A). To study the dynamics of upwelling events, we deployed a month-long coastal observatory during July 1998–2001. The network consisted of real-time remote-sensing data from multiple satellites, aircraft, and shore-based HF radars; a cross-shelf mooring array; and numerous research vessels, autonomous underwater vehicles (AUVs), and numerical forecast models. Nearly 200 researchers from over 30 institutions participated (Schofield et al., 2002, 2004; Glenn and Schofield, 2003) as part of NOPP-supported efforts and ONR programs. Overall, the scientific results: (1) provided a physical understanding of recurrent upwelling zones, (2) defined the biological dynamics within the upwelling eddies, (3) indicated significant loading of anthropogenic materials by small, nearshore, coastal jets not resolved using traditional sampling strategies, (4) quantified the annual importance of the summer upwelling events, and (5) linked biological dynamics to bottom-water hypoxia. While successful, the need for all operations and personnel to be moved to the shore-based center was a fundamental factor limiting the experiment's duration. Thus, future efforts focused on developing an operational command location on the main Rutgers campus.

The new COOL room was established on the Rutgers campus in 2001 (Figure 1B). It was designed to operate throughout the year and integrate students into the field efforts during the academic year. The first major effort to use the campus COOL room was the NSF 2003–2005 Lagrangian Transport and Transformation Experiment (LaTTE; Figure 2B). LaTTE focused on understanding how mixing and transport in the Hudson River plume regulates biological and chemical transformations within the coastal zone. The observatory guided the multi-ship field effort to track the buoyant plume, which was highly sensitive to local wind

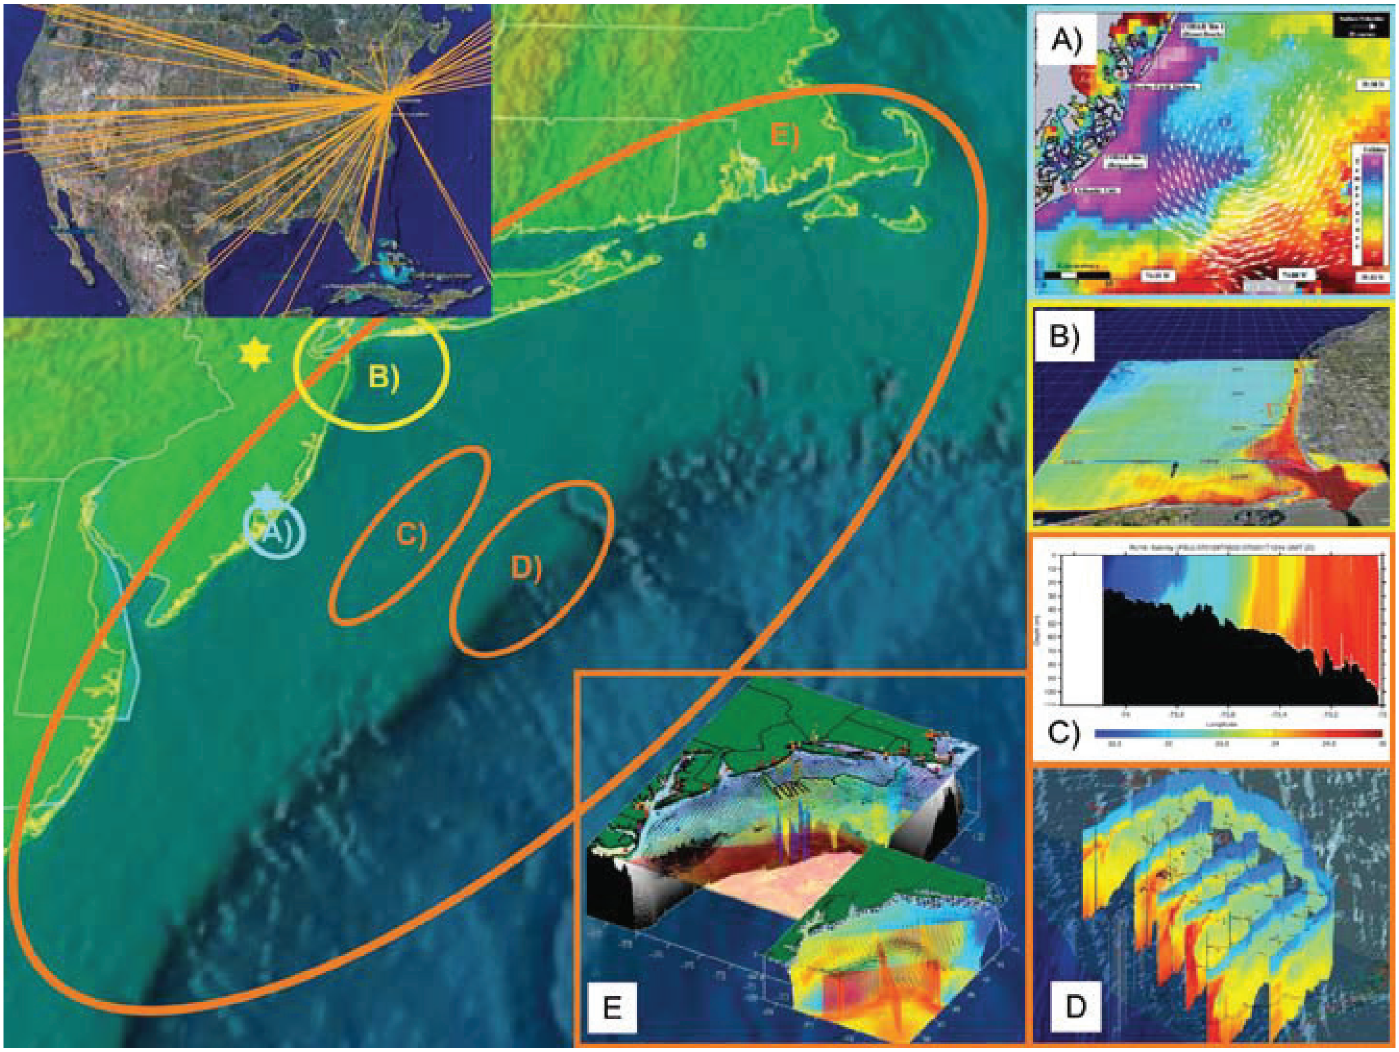

Figure 2. The experimental domains of the major COOL experiments supported by the observatory on the Mid-Atlantic Bight. Circles indicate the spatial range of the different experiments. (A) The first focus was on recurrent upwelling along the New Jersey coast and its role in driving local hypoxia/anoxia. (B) LaTTE focused on the transport and transformation of chemical and biological constituents present in the Hudson River buoyant plume. (C) Glider surveys were a critical component in efforts to resolve the physics driving front formation in Mid-Atlantic Bight waters. (D) The ONR Shallow Water 2006 joint experiment used fleets of gliders to support large mooring deployments focused on understanding the role of internal waves and the corresponding impact on acoustic uncertainty. (E) Recent work involves developing large, regional-scale observing networks to support data assimilative forecast models.

forcing. Scientists, graduate students, and undergraduates maintained the observatory with 24-hour shift rotations. Data from the Coastal Ocean Dynamics Applications Radar (CODAR) and satellites were combined with numerical forecast models to direct ship and glider operations using the wireless network available in this location (Schofield et al., 2007). The observatory-driven sampling effort provided data showing that the Hudson River recirculated in a near-shore eddy before being dispersed in an unexpected cross-shelf pathway, which represented two-thirds of the buoyant plume water being delivered to the shelf (Castelao et al., 2008; Chant et al., 2008). This unexpected cross-shore transport pathway provided a direct conduit between the urbanized watershed and the continental slope. Within the buoyant plume, phytoplankton assimilated nutrients, resulting in high rates of productivity associated with large chain-forming diatoms. The size structure of the phytoplankton mediated the accumulation of anthropogenic nutrients and contaminants in the higher trophic levels of the food web (Moline et al., 2008).

The success of the campus-based

efforts resulted in year-round offshore operations for sustained time periods (Schofield et al., 2008). For example, since late 2003, the lab's glider efforts have supported over 2300 glider days at sea spanning over 50,000 km under water (Figure 2C). Global glider efforts resulted in optimization of Iridium satellite communications, allowing a global footprint to be supported locally. The ONR Shallow Water 2006 joint experiment conducted on the outer shelf of the Mid-Atlantic Bight drove the next stage of observatory evolution (Figure 2D; Tang et al., 2007). The multi-ship and 60-mooring deployment was complemented with a fleet of Webb gliders. The efforts were supported with a daily environmental report that was delivered to the ships offshore via High Seas Net. This daily report summarized all the data for all the distributed parties. Additionally, the report provided the semblance of a social network for the large science campaign involving several hundred scientists. The daily report was coordinated through the COOL room over the three-month experiment duration; however, the lead Rutgers investigator was required to travel during the experiment for other obligations. This absence required the development of a suite of mission planning tools and Web-based products that would allow the daily report to be produced in any location with access to the Internet.

Scientific results from the glider fleet revealed four types of slope water salinity intrusions—surface, pycnocline, subpycnocline, and bottom—each appearing to be forced by different mechanisms. The extensive pycnocline intrusions were affected by stronger than usual shelf stratification due to remnants of low-density Hudson River water associated with a heavy rainfall. The new transport pathway discovered during LaTTE was observed in the CODAR surface current fields and verified with Coast Guard drifters (Castelao et al., 2008). Tropical Storm Ernesto went through an extratropical transition (the process by which a hurricane can change from a tropical cyclone to a mid-latitude depression) while transiting the region, with the transition and path well matched by an ensemble of high-resolution atmospheric forecast models that included the latest boundary-layer physics. Ernesto was observed by the gliders to resuspend significant amounts of sediment below the thermocline, which could not mix across it, motivating additional research on storms (Glenn et al., 2008).

With the success of distributed control for remote assets coordinated through COOL, the "footprint" of the observing efforts has increased significantly. Currently, ONR and NOAA are combining ocean observations and modeling dynamics to extend the limits of biological predictability using a technique called "data assimilation" (Figure 2E). Using this method requires observations at ecologically relevant scales spanning large marine ecosystems. The multiplatform observing networks provide the needed three-dimensional snapshots of water mass properties in near real time. These data are then assimilated into different models. Model uncertainties are estimated by comparing the different three-dimensional models with actual measurements. Ultimately, these models will be used to characterize regional three-dimensional water mass patterns to enable adaptive sampling.

SCIENTIFICALLY MOTIVATED TECHNOLOGY DEVELOPMENT

The expanding set of scientific problems that could be tackled by continuous data collection by our observatory resulted in an atmosphere conducive to technology development, which focused on enabling scientists to collect spatial time series. The major relevant technologies have included satellites, HF radars, gliders, and communications.

Satellites

A number of improvements have been made to observatory satellite data collection over the last five years (Figure 3). First, we set out to minimize the temporal gaps between satellite images by incorporating data from the international constellation of satellites, including Chinese and Indian ocean-color systems (Figure 3B, E). The international satellites' multiple passes per day at varying spatial and spectral resolutions provide numerous scientific and applied users with desired real-time imagery (Figure 3G). We developed customized views with input from thousands of satellite-imagery users. For example, a user could request enhanced imagery for a specific location at a specific time, allowing retrieval of the information needed without downloading a large file; this method is particularly useful for people who are working at sea with limited communication bandwidth. These real-time satellite images are complemented with a range of products developed in collaboration with the Naval Research Laboratory at Stennis Space Center, the University of Delaware, and Saint Andrews University. These collaborative efforts focused on deriving inherent optical properties from

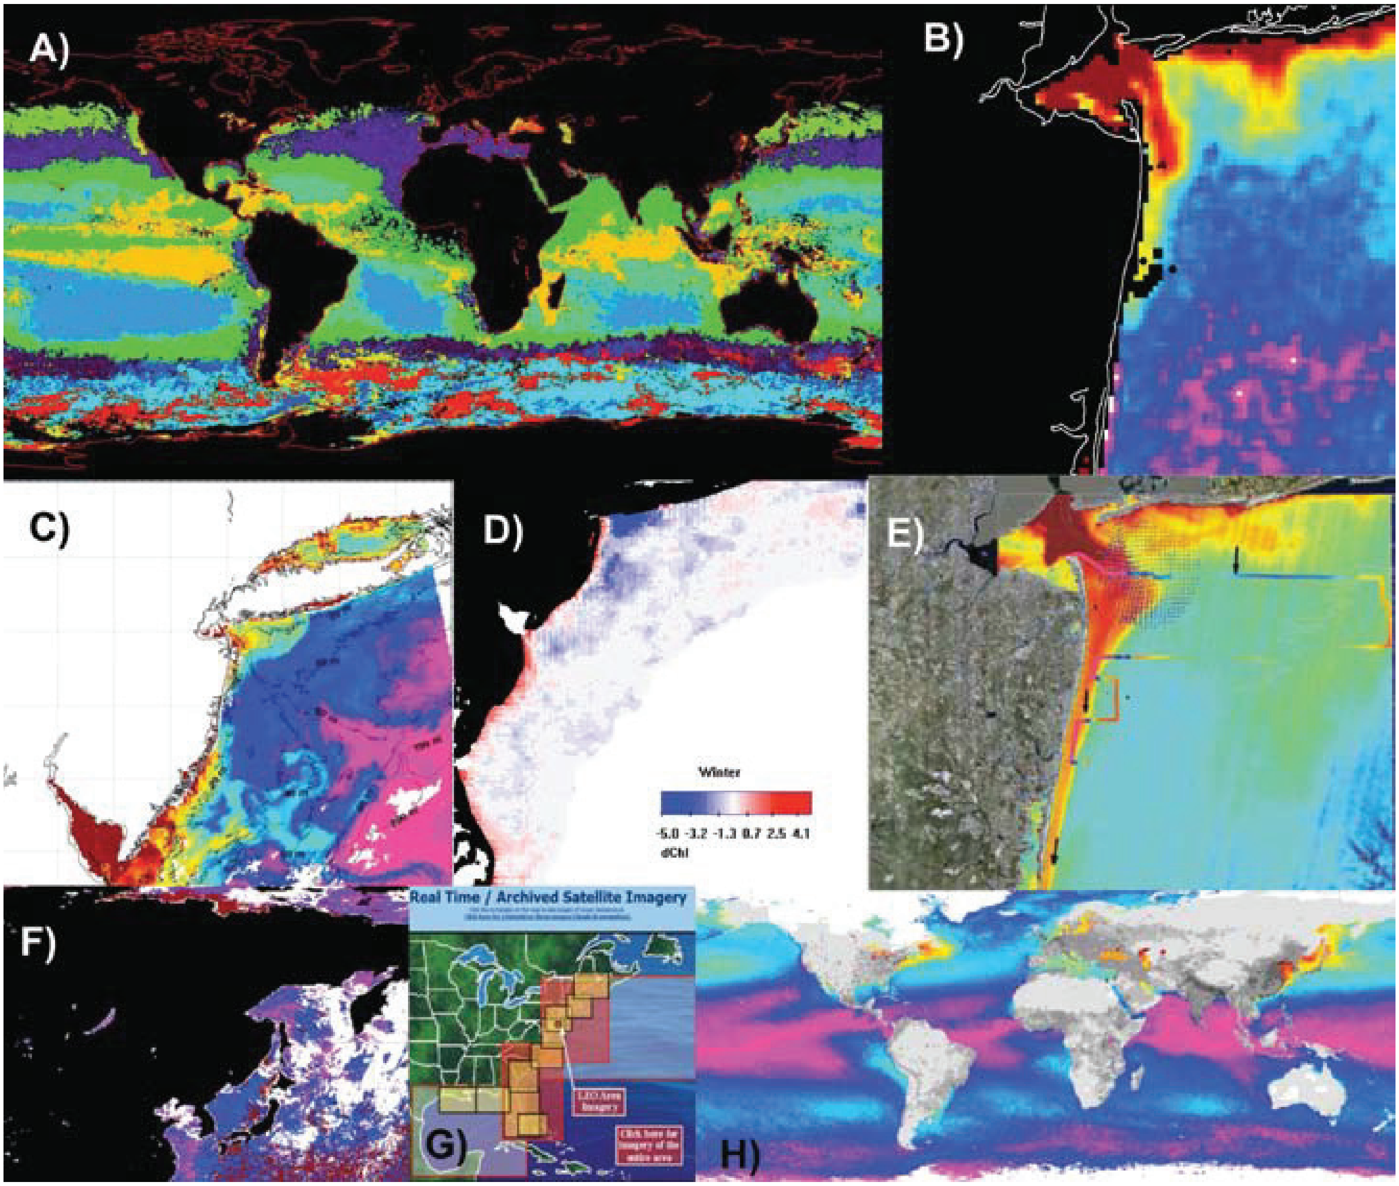

Figure 3. The major efforts in developing the capabilities of ocean remote sensing over the last decade. (A) A map of the major water masses delineated using objective bio-informatic approaches applied to satellite imagery. (B) The Hudson River plume visualized with the Chinese Fung Yen-1D polar-orbiting ocean color satellite. (C) A satellite image of the inherent optical properties (here, phytoplankton absorption) measured using ocean color satellite imagery. (D) The decadal change in the winter-season chlorophyll estimated by comparing imagery measured with the Coastal Zone Color Scanner and the SeaWIFs systems. (E) An ocean color image of the Hudson River plume visualized using the Ocean Colour Monitor on the Indian Remote Sensing Satellite. (F) Water mass classification approaches for delineating the presence of river plumes. (G) Customized satellite maps developed at the request of users who constantly access the COOL Web site. (H) The maximum annual temperature change in sea surface temperature.

space and validating the satellite estimates in the coastal ocean.

Another goal was to develop water mass classification procedures using satellite imagery. Computer algorithms were developed to identify on the satellite images the spatial extent of waters containing highly colored, dissolved organic matter associated with river inputs (Figure 3F). Because these initial algorithms were locally tuned, our recent efforts focused on developing methods that might have wider utility to the community. Instead of using subjective expert decisions (Longhurst, 1998; Devred, 2007), we used objective classification techniques that combine multiple satellite data sources to generate regional maps (Oliver et al., 2004). These objective mapping tools have been validated over a range of spatial and temporal scales and permit quick identification of water masses with particular characteristics. We also explored decadal changes in winter-season chlorophyll by comparing imagery from the Coastal Zone Color Scanner (operational from the late 1970s to the mid 1980s) with current SeaWIFs imagery. (Schofield et al., 2008; Figure 3D). Finally, there has been improvement in estimates of inherent optical properties (IOPs) from ocean color imagery (Figure 3C). IOPs are optical parameters that provide information on all materials that have color (phytoplankton, detritus, colored dissolved organic matter) and scattered light (organic and inorganic particles), and that are easier to interpret than traditional radiometry measurements. This attribute makes these optical parameters ideal for enhancing biological models. For example, photosynthetic rates are a function of total light absorption of the phytoplankton and the efficiency with which the absorbed radiation is converted into organic carbon.

HF Radar

The Rutgers CODAR HF radar network was reconfigured for LaTTE into a nested, multifrequency current mapping system that covered the New Jersey continental shelf and then focused in at higher resolution on New York Harbor and the Hudson River plume (Figure 4A). A 5-MHz network (Figure 4B) covers the shelf at 6-km resolution, a 13-MHz system covers the approaches to New York Harbor at 3-km resolution, and a 25-MHz inner nest covers the harbor entrance and the inside of the harbor at 1.5-km resolution (Figure 4 C,D). Similar nested networks were set up by other universities to cover the major bays to our south and the sounds to our east. NOAA-owned transportable HF radars designed for quick deployments from trailers were used temporarily to locally enhance coverage and for rapid response tests of simulated oil spills in remote locations (Figure 4E). Radial current data from each group participating in what came to be known as the Mid-Atlantic HF Radar Consortium (MAHFRC) was aggregated as part of the NOAA-sponsored HF radar national network server demonstration. The resulting regional array (Figure 4A) runs along ~ 1000 km of coastline, extending from Cape Hatteras to Cape Cod, though coverage at any given time remained subject to the research grant support available to each radar's host institution. The Coast Guard has conducted field tests using surface drifters to quantify improvements to search and rescue planning enabled by real-time CODAR surface currents. Similarly, NOAA was interested in validating the CODAR HF radar nearshore wave and current parameters to support rip current forecasting for lifeguards. These results were used to develop a three-phase plan to transition the current mapping network to sustained operations.

Beyond the development and demonstration of a regional current mapping capability, research on new CODAR hardware, processing algorithms, and products continued. The most significant hardware improvement was CODAR's addition of GPS timing to each radar. GPS timing enables multiple radars in close proximity to share the same frequency without interference, thus minimizing the network's footprint on the broadcast frequency spectrum. GPS timing also enables coordinated, multistatic operation of radars that are within range of one another. Standard monostatic radars, whose transmitters and receivers are collocated, operate in backscatter mode only. In multistatic operations, each receiver can acquire scattered signals from any radar transmitter within range. The result is that N monostatic radars are transformed into a multistatic network with N^2 look angles. Beyond construction of the land-based multistatic network, new bistatic transmitters were developed for stand-alone operation as either land-based systems (Figure 4B–D) or for offshore deployments on fixed platforms (Figure 4I) and buoys (Figure 4J). The network of fixed shore-based receivers acquires scattered signals from the bistatic transmitters.

Tests of the multistatic HF radar network capability were first funded by ONR for vessel-tracking experiments. The research question asked whether an HF radar network could detect and track surface ships. The positive outcome resulted in efforts to increase the range of over-the-horizon vessel detection without increasing the broadcast power of the radars. These efforts focused on improving the methodologies for enhancing signals acquired by land-based receivers, including test deployments of a super-directive multistatic receiver antenna (Figure 4F). Complementary strategies were undertaken to increase the offshore range by placing bistatic HF radar transmitters on offshore buoys, thus decreasing the distance from transmitter to target. The two approaches, both tested in the

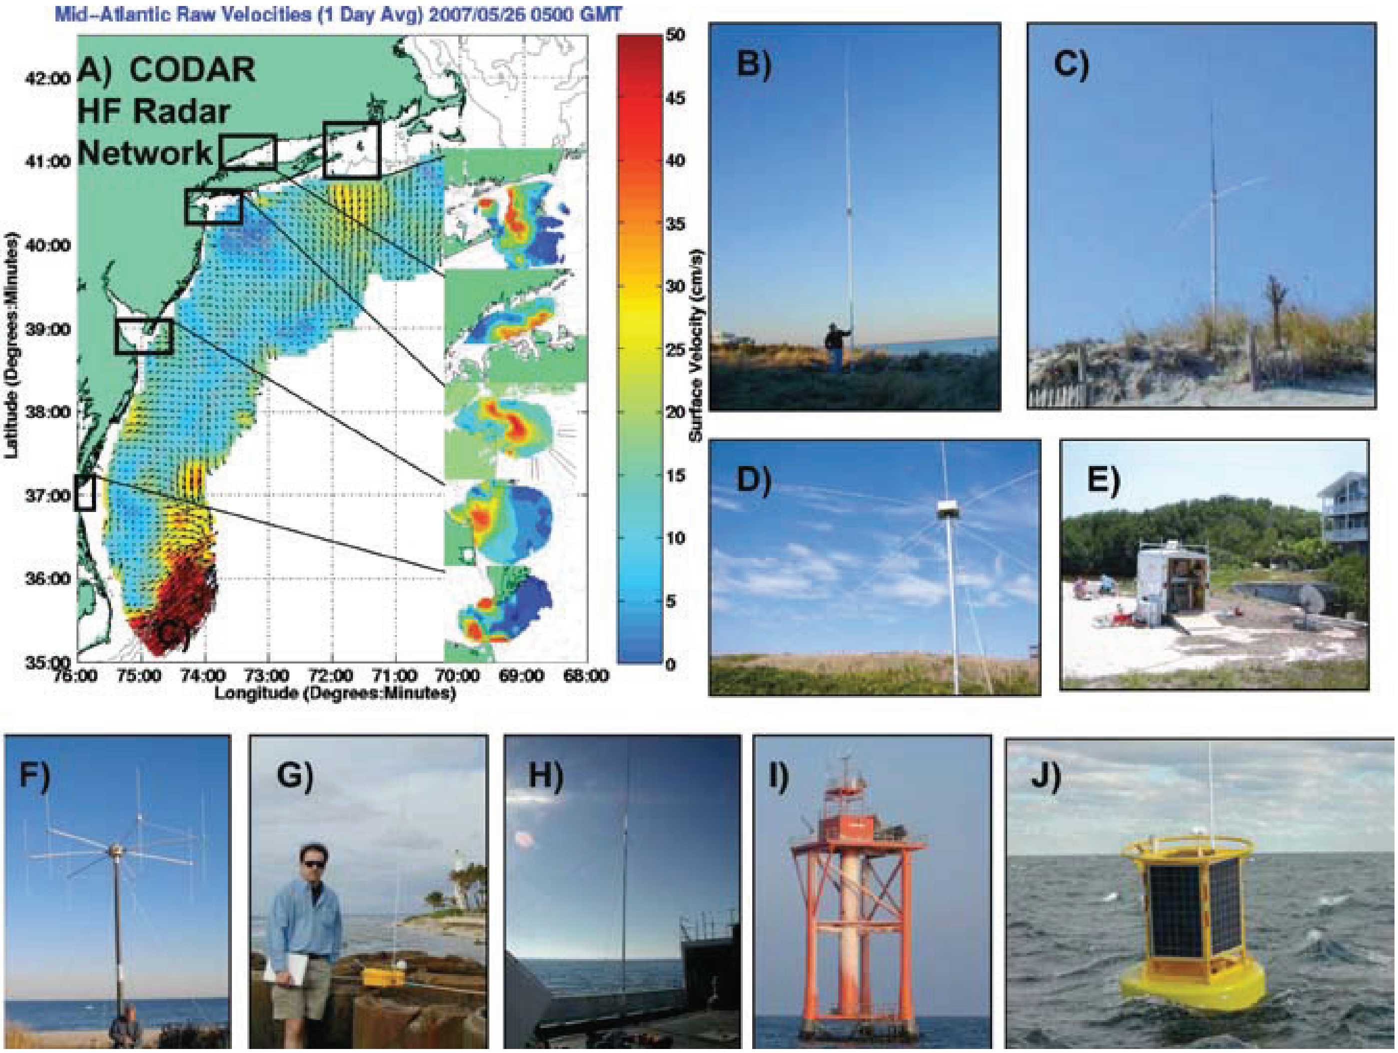

Figure 4. (A) The nested Mid-Atlantic HF radar network as currently supported by US IOOS through NOAA. Components include (B) transmitters for long-range systems (5 MHz), (C) transmitters for medium (13 MHz) and short (25 MHz) systems, (D) common receivers for all three, (E) NOAA mobile CODARs for temporary deployments and fast response, (F) superdirective receivers to increase the signal-to-noise ratio, and a series of bistatic transmitters that include (G) shore-based portable systems, (H) long-range systems deployed on ships, (I), short-range systems deployed on offshore platforms, and (J) medium-range systems deployed on buoys.

Mid-Atlantic HF radar test bed, led to improvements to the Coast Guard mapping capabilities.

Gliders

Mobile platforms are developing quickly and are transitioning into observational tools (Rudnick and Perry, 2003). One autonomous platform that is rapidly becoming indispensable is the underwater glider (Figure 5). Publicized in 1989 by Henry Stommel's view of a futuristic smart fleet of mobile, long-duration sensor platforms (Stommel, 1989), gliders are steadily earning their reputation for efficiency and endurance. A number of different gliders have been developed (Davis et al., 2003) but our group uses the Slocum glider developed by Webb Research Corporation (now Teledyne Webb Research). Gliders are a robust technology capable of anchoring large field campaigns and providing a sustained presence in the ocean (Schofield et al., 2007). Our efforts have focused on enhancing glider capabilities as part of a long-term NOPP-style partnership with Teledyne Webb Research by improving glider hardware, software, and increasing the sensors carried onboard these platforms (Figure 5).

Steady improvements in hardware and software over the last five years have

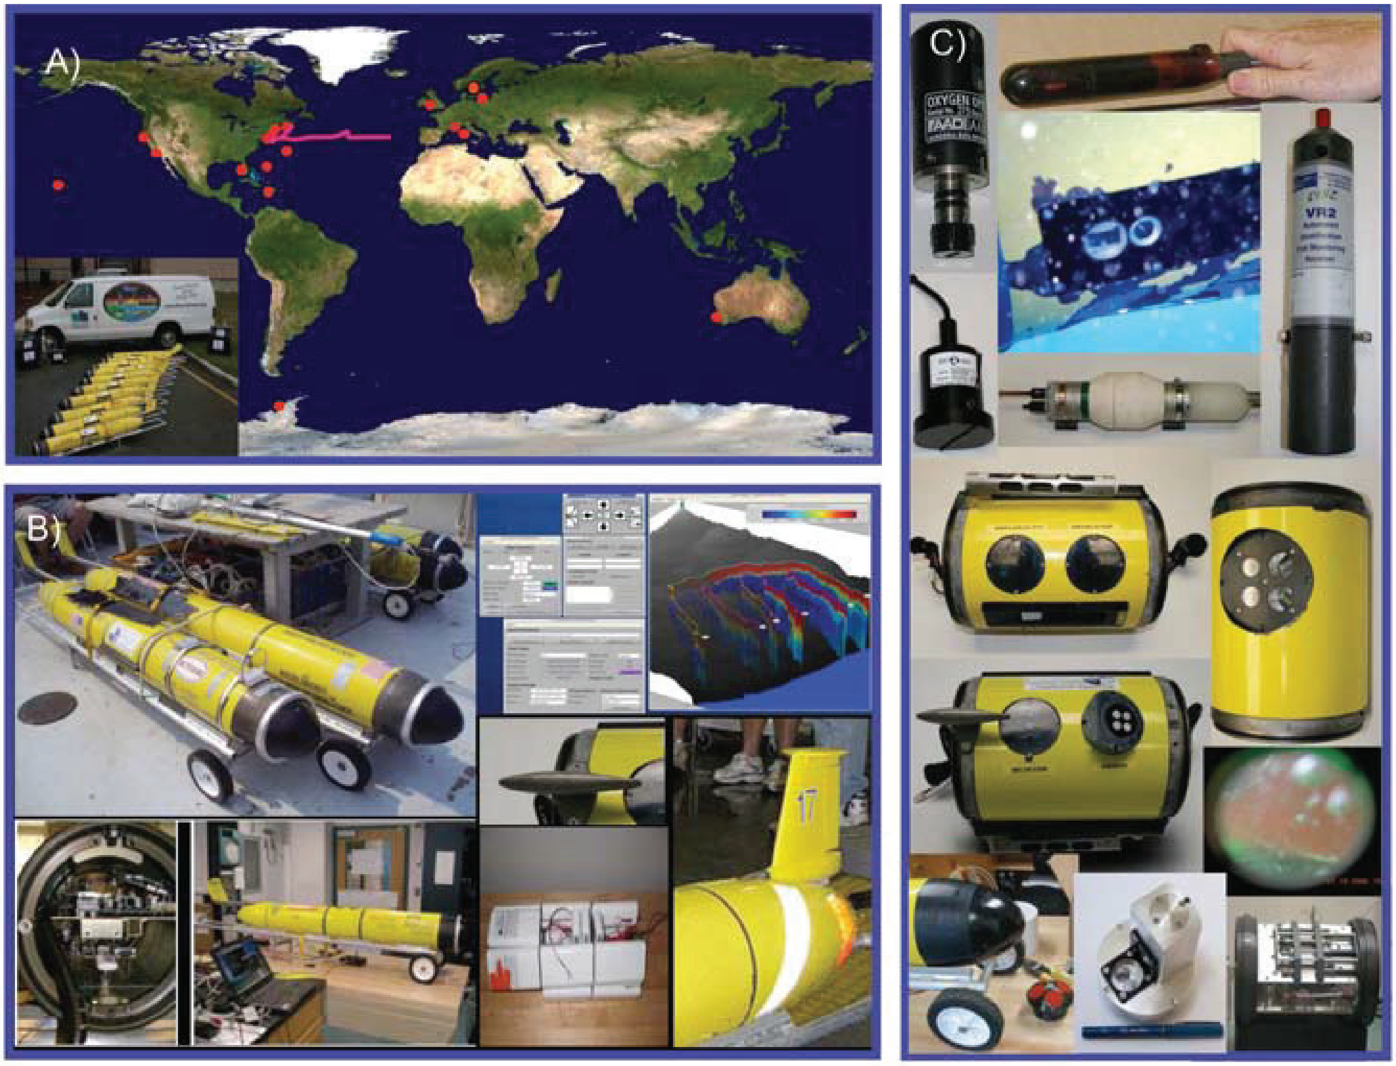

Figure 5. The success of Webb gliders deployed by Rutgers since late autumn 2003. (A) The global deployment map of the Rutgers Webb Glider fleet. (B) Hardware improvements developed under a Teledyne Webb Research/Rutgers partnership include extended glider payload bays, command/control and visualization software, pick points on the gliders, new more powerful computers inserted into the glider science bay, lithium battery packs to increase glider duration, and the new robust digi-fin. (C) Many instruments have been carried on Rutgers gliders over the last five years, including (starting at the top left panel) oxygen sensors, passive acoustic sensors, attenuation sensors, chlorophyll/colored dissolved organic flourometers, turbulence sensors, fish bioacoustic sensors, scattering and backscattering sensor packages, spectral backscatter sensors, radiometer sensors, video imaging components, acoustic Doppler current meters, fast-repetition-rate flourometers, and hyperspectral absorption sensors.

included simple features such as pick-up points to enable glider deployment/recovery from large ships, extended body forms for carrying larger sensors or extra battery packs, robust tail fins, command/control and visualization software, and improved onboard science computers (Figure 5B). The hardware improvements have extended glider duration and performance. Additionally, a wide range of new sensors has been incorporated into the gliders. Measurements presently being made by gliders include physical (temperature, salinity, turbulence), acoustic (active and passive), optical (spectral radiometry, backscatter, attenuation scattering, absorption, video imagery), fluorescence (chlorophyll *a*, colored dissolved organic fluorescence, fast repetition rate fluorometry), and dissolved gas (oxygen) (Figure 5C).

Communication Networks

During the 1998–2001 Coastal Predictive Skill Experiments, lack of communication capabilities necessitated removal of the entire shore-based team from the Rutgers main campus to a coastal site. The camaraderie stimulated by collocating personnel at one shore-based control center was similar to that of going to sea, but the multiple ships and shore crews involved in the experiment still required a means to communicate. During this time period, virtual collocation was enabled with radio modems that connected ships and aircraft to the shore-based science crew. This mode of communication was complemented by shore-based Web broadcasts of live video and radio chatter in an effort to involve the outside community. For these communication efforts, the physical range was limited to line of sight (~ 30 km). In 2003, the range changed with our participation in the Ocean.US Iridium Pioneers program. The ability to communicate globally using Iridium SIM cards was transformational.

During LaTTE programs from 2003–2005, we worked with a commercial vendor to expand communication regionally using higher-bandwidth cell phone modems. During the ONR Shallow Water 2006 experiments, which required coordination for three months and a virtual presence for COOL, all data sets were available via the World Wide Web. These changes in the mode by which the field teams communicated allowed science planning to be conducted from another research lab, from restaurants, or even from our living rooms via wireless Internet connections (Figure 1C). Global access to the observatory through WiFi hotspots remains in constant use today. Observatory assets can be accessed, systems checked, data visualized, and adaptive sampling plans adjusted on a sustained basis from any location in the world as part of normal life activities. Daily achievements are documented on public blog sites, enabling anyone—from collaborating scientists to the general public—to follow along on missions of discovery.

DEVELOPMENT OF A SUSTAINED REGIONAL TEST BED

The first long-range 5-MHz CODAR HF radar was deployed on the East Coast in the summer of 2000 during the third ONR/NOPP Coastal Predictive Skill Experiment. The 200+ km range of the radial current field covered the full cross-shelf distance to the shelf break. It solidified plans for developing a regional observatory spanning the Large Marine Ecosystem (#7) of the Northeast US Continental Shelf (see http://www.lme.noaa.gov/ for more information on the 64 Large Marine Ecosystems designated worldwide). The regional network would be anchored by a nested, multistatic HF radar network. Initial attempts focused on combining our existing subregional ocean-observing assets into a loose federation that we called the North East Observing System (NEOS). Building on the strength of the NOPP partnership approach, NEOS consisted of academic observatories, government backbone observatories, and industry networks collaborating with instrument developers. At that time, NEOS partners believed the observatory should be based on the best science available to improve coupled forecast models.

The NOAA regional network developed in the Mid-Atlantic Bight (MAB) is the foundation of the developing NEOS network (Figure 6). In 2007, NOAA funded the Mid Atlantic Regional Coastal Ocean Observing System (MARCOOS), which revolved around two regional themes. Theme 1, Maritime Safety, would provide maps of nowcasts and forecasts of regional surface currents to improve search and rescue and hazardous material spill response, as well as nearshore products to improve rip current forecasting. Theme 2, Ecosystem Decision Support, would provide regional three-dimensional temperature and circulation data, nowcasts, and forecasts of the ocean, extending from Cape Cod to Cape Hatteras, for the recreational, commercial, and fishery management communities. To generate the nowcasts and forecasts, an extensive array of existing observational data, data management, and modeling assets required coordination (Figure 6).

This NOAA investment will be augmented by other agencies. Currently, NSF proposes to build the Ocean Observatories Initiative (OOI), which calls for a robotic array to be placed on the MAB shelf south of Cape Cod near the shelf break. Research funded by ONR, while designed to support the Navy in forward deployed areas, often uses the same region as a test bed for instrument development and scientific process studies. Although there is no substitute for actually going to sea in specific regions of interest, the cost of foreign deployments exceeds the cost of local deployments by an order of magnitude. Local surrogate test beds for regions of interest are cost effective for development and training of operational Navy personnel. DHS is interested in the over-the-horizon capabilities of HF radar for maritime domain awareness. Leveraging the existing network was one cornerstone for a recently formed DHS Center of Excellence for

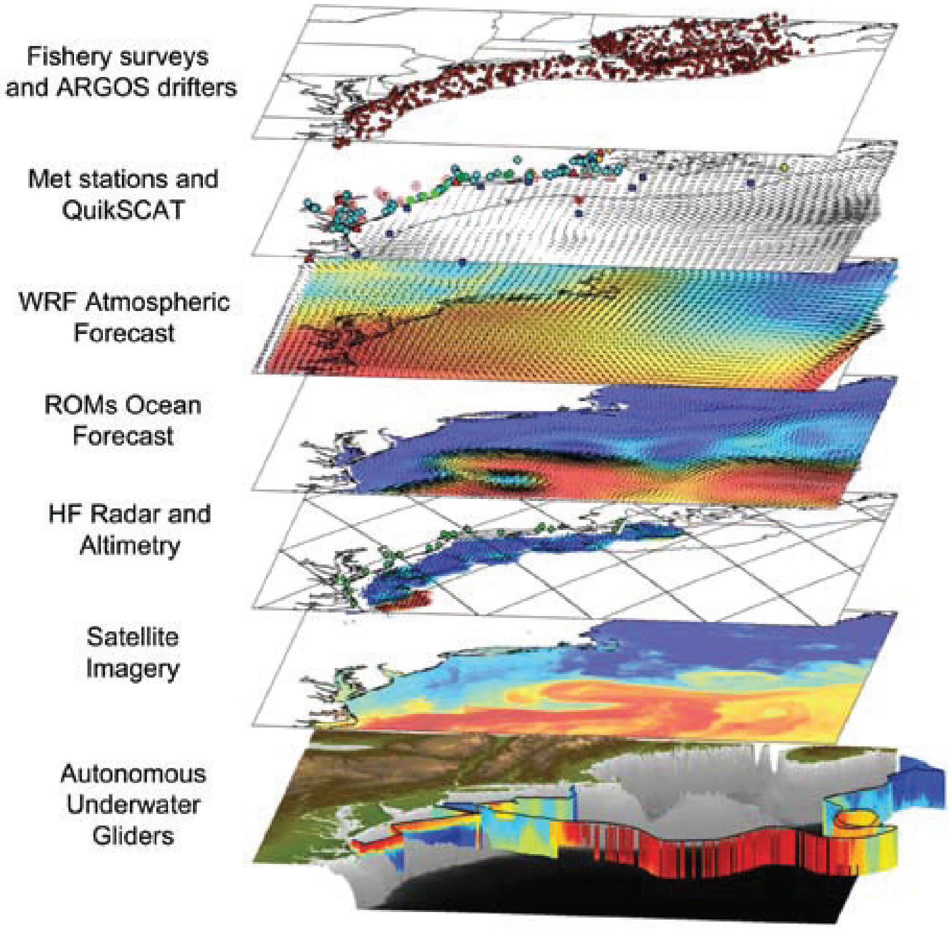

Figure 6. The current status of the North East Observing System (NEOS) showing the numerous data streams being compiled by the distributed academic-federal-commercial team.

Port Security. Additionally, there is rapidly expanding interest from the energy industry. Public Service Electric & Gas (PSE&G) funded high-resolution weather forecasts to pre-position service trucks during storms to reduce response time to power outages. Offshore wind energy companies provide support to enhance the observing network in the vicinity of proposed offshore wind farms. Offshore wave power companies are investing money to enhance offshore platforms in the region, using it as a test bed for energy harvesting systems.

Funding for the observatory emphasized commonalities. Development of new enabling technologies was central to all observatory users. All benefited from investments of others and all required access to real-time data and forecasts for operational decisions, ranging from adaptive scientific sampling with autonomous vehicles to adaptive response to storms by repair vehicles. All desired access to historical data to study specific events of interest in order to improve future responses. All required a sustained data stream to identify long-term trends that could affect their event-based responses. The result is a wide variety of observatory users that also happen to be observatory funders, spanning eight federal agencies and industry.

Collaboration and leveraging is evident throughout. Glider operations run by several universities in the region are supported by ONR, NOAA, and NSF. Satellite ground stations at Rutgers, University of Maine, and The Johns Hopkins University Applied Physics Laboratory each acquire the real-time direct broadcast data and provide a back-up data source in case one station goes down. Academic institutions mostly own the HF radars, with support now provided by NOAA for the US Integrated Ocean Observing System (IOOS). As with the gliders, ONR, NOAA, and NSF support the regional ocean models typically run by multiple academic institutions, while the Navy and NOAA operate the basin-scale models. Local NOAA Weather Service Offices, academics, and industrial partners run the ensemble of atmospheric models. NOAA operates the main regional fisheries cruises on agency vessels, while academics cover the supplemental surveys with fishing industry vessels.

DEVELOPMENT OF AN INTERNATIONAL COLLABORATORY

IOOS is the US contribution to the Global Ocean Observing System (GOOS), which, in turn, is the international oceanographic community's contribution to the Global Earth Observing System of Systems (GEOSS). The structure provides an international forum for governments to collaborate on the critical need for observing the world ocean in an era of human-induced climate change and population growth. Still, it is unclear how the practicing scientist contributes to the global expansion of the already difficult task of making observations in an often hostile ocean environment.

The 2005 Oceanography Society meeting in Paris was one turning point in the promotion of international collaborations in the spirit of NOPP. Discussion focused on how best to collaborate, share data, and begin to form a coherent network. This coalescing collaboration was reminiscent of the atmospheric observing community in the early 1900s when the telegraph first connected individual weather forecasters from different countries independent of official government organizations. It became clear there was much to be gained by sharing expertise and limited observational assets. Although enabling technologies continue to be demonstrated locally or even regionally in many places around the world, we remain capacity limited if we try to address the challenges of globalization.

Seeing the collaborative spirit at the Paris meeting as a way forward for the working scientist, at a Paris sidewalk café, John Cullen from Dalhousie University initiated the International Consortium of Ocean Observing Labs (I-COOL). Plans for the first collaborative I-COOL deployment followed the next morning with John Howarth from the Liverpool Bay Observatory proposing a glider mission coordinated with his ongoing shipboard cruises. Collaborations continue today, fueled by the need to sample the ocean with new satellite, HF radar, glider, and AUV-based technologies. Our objective is to distribute the technologies developed locally in the Northeast regional test bed to the global marketplace.

Currently, I-COOL has three main themes. One is to provide platforms and expertise that enable local scientists to demonstrate success and hence fuel local funding for programs that contribute to the larger I-COOL effort. There have already been many successful collaborations with European, Australian, and Caribbean scientists. For example, CODAR HF radars are being deployed in Norway, with gliders and AUVs to follow with support from the Norwegian government, which is interested in the environmental impacts of climate change.

The second I-COOL theme uses these novel technologies to explore extreme environments. Targeted environments include the poles, severe storms, urbanized ports, and developed coastlines, all of which are often avoided by scientists because of hazardous operating conditions. Now, gliders are being deployed along the West Antarctic Peninsula for climate change research as part of NSF's Palmer Station Long-term Ecological Research study in collaboration with British scientists. Because observing networks are robust, they are allowing scientists to safely study severe storm processes in real time without having to curtail operations, for example, glider operations on the New Jersey shelf that continued unperturbed and yielded to insights into shelf-water processes during a very stormy period in fall 2003 (Glenn et al., 2008). The natural and anthropogenic forcing at work in urbanized ports often result in extremely dynamic environments whose turbulence and spatial complexity are difficult to sample using traditional technologies; observing networks will help overcome the difficulties of conducting research in these heavily used environments.

The third I-COOL theme is to extend the limits of long-duration underwater glider flights by developing new power and control systems. The long-duration studies are powerful magnets that get undergraduates interested in science (see Box 1) and have the potential to increase the visibility of ocean exploration to the general public. Currently, efforts are underway to re-occupy the many legs of the 1872–1876 HMS *Challenger* voyage using a global fleet of long-duration gliders and to compare modern and historical physical and biological characteristics. This effort will require a global collaboration of scientists and students over the Internet. We hope to include developing nations in this project, but must overcome the lack of infrastructure in these countries, which have the fastest growing human coastal populations and thus a great need for ocean observing applications such as for fisheries management.

LESSONS LEARNED

Glenn and Schofield (2003) outlined concerns, lessons learned, and conclusions based on initial construction of the New Jersey shelf-wide observatory. Some of those lessons still apply, including the necessity of coalescing scientific and societal goals, the importance of iterative development supported by peer-reviewed grants, and the need to train a new workforce that currently does not exist. Other concerns have evolved, in particular those surrounding sustained funding. In 2003, entrance into the IOOS family of observatories was best obtained through congressional earmarking. The change to a scientific peer-review system in 2007 made it particularly painful for those systems that had not diversified their funding base through spiral development.

Observatories Inspire Young Scientists

In the 1990s, senior-level scientists warned us that our work on ocean observatories would negatively impact our scientific careers. We may have heeded that advice if not for the tenure system and the nine months of university salary support we received for teaching, research, and service activities. Thus, while NOPP enabled new partnerships, institutional support was critical in allowing those partnerships to mature. In 2003, we also warned young, untenured faculty that building and operating an ocean observatory was not a prudent choice at that early stage of their careers. This view was based on our experience with the excessive grant and management pressures required to sustain an observatory outside of the scientific mainstream. Our concern was that the required work would come at the expense of manuscript preparation, which is, and will remain, the central currency for earning tenure. We were not alone in sounding this alarm. In 2003, with the primary investment in observatories coming through congressional earmarks, faculty who did participate were required to focus on demonstrating accountability through political visibility rather than professional development. The end result was a missing generation of young, hard-working scientists supporting the ocean observatory movement.

In the last five years, we have seen dramatic changes. Observatories exist, they will continue to evolve, and in some form or another, they are here to stay. Young faculty members who access the observatories find they have a platform that provides them a competitive advantage. The existing infrastructure allows them to propose ambitious experiments that take advantage of the 24/7/365 spatial view of the ocean. Rather than having to raise all the money for expensive infrastructure themselves, young faculty can use existing observatory capabilities to meet many of their sampling needs, paying only for the incremental costs of pursuing their specific research problems. Two recent examples of multi-institutional research programs designed and led by untenured Rutgers COOL faculty are the NSF-supported LaTTE (Robert Chant) and Mid-Shelf Front Experiment (Josh Kohut) programs. Additionally, universities find that an environmental observation network serves the needs of multiple departments. The on-campus COOL control center provides an academic nexus that has enhanced collaborations spanning marine science, geological science, environmental science, microbiology, computer science, engineering, education, and economics. New joint faculty appointments among the Marine Science Department and the School of Engineering, the Graduate School of Education, and the Agricultural Experiment Station are growing the number of faculty interested in using or improving ocean observatories. These collaborations provide a means to unite diverse faculty interests while simultaneously accessing a wider range of sponsors. Our own Rutgers University Vice President for Research and Graduate and Professional Education, in a 2008 speech to incoming tenure-track faculty, warned that single-author papers are not enough anymore, and that collaborations, especially interdisciplinary, are highly valued by tenure reviewers. Observatories are an effective means for young faculty to conduct interdisciplinary research.

> "THE LESSONS LEARNED THROUGH THE NOPP EXPERIENCE DEMONSTRATED THE VALUE OF PARTNERSHIPS, THE ROLE OF RAPID SPIRAL DEVELOPMENT, AND THE VALUE OF LEVERAGING THE SUPPORT OF MULTIPLE FEDERAL AGENCIES."

Partnerships That Result in Diversification

In 2003, when congressional earmarks for ocean observatories were on the upswing, observatory management was being pushed away from the already successful NOPP model of equal partnerships. In the user-driven model that the earmarks encouraged, the scientist's role was undervalued. Data providers were made subservient to data users, and management did not understand the difficulties of operating in a hostile ocean environment. Narrow definitions of the users that were expected to drive this system, and the refusal of management to

Box 1. Transforming Undergraduate Education through Ocean Observatories

BY SCOTT GLENN, DAKOTA GOLDINGER, ETHAN HANDEL, SHANNON HARRISON, DANIELLE HOLDEN, JOSH KOHUT, ANTHONY LUND, JANICE MCDONNELL, EVAN RANDALL-GOODWIN, EMILY ROGALSKY, JUSTIN SHAPIRO, ERIC VOWINKLE, AND OSCAR SCHOFIELD

The Coastal Ocean Observation Lab is developing new initiatives as part of a university-wide effort to transform undergraduate education at Rutgers. Enabled by an ocean observatory operations center purposely located on the main campus of a major research university, the lab has established a program featuring hands-on, team-based research projects that complement course work and are specifically designed to engage undergraduates in science. The program encourages students to become involved as early as the freshman year, remaining in contact with many of the same students and professors for their full four years at Rutgers. A series of Introduction to Oceanography courses with significant freshman participation, and a variety of small seminars for first-semester freshmen, serve as the feeder courses. Interested students join faculty in the lab during their second semester, either through one-credit research courses or work-study programs. The students are organized into a NOPP-style research team, and given a task reflecting the core NOPP values —collaboration between scientists and engineers from multiple disciplines, rapid spiral development cycles that work toward achieving a long-term goal, and leveraging the support of multiple groups from around the world. The initial task supported by the undergraduate team—to be the first to fly an autonomous underwater glider from Tuckerton, New Jersey, to Halifax, Nova Scotia—was accomplished during spring 2008 with RU15. Their second task, still ongoing, is to fly the first glider across the Atlantic from New Jersey to Spain.

These long-duration underwater robotic flights are made possible through the convergence of research, engineering, and educational projects from multiple agencies. Slocum gliders are now being delivered with the new DigiFin, an improved design that requires testing by ONR to meet Navy needs. NOAA initiated testing of lithium primary batteries for the new higher-powered sensors proposed for a NOPP instrument development project. NSF required testing of an extended payload bay to enable additional batteries to be carried for flights between the United States and British bases in Antarctica. Still, the main purpose of the long-duration flights remains educational. Rutgers alumni donated a glider for use as the primary platform to engage undergraduates in projects related to ocean observatories. NSF provided a summer intern from its Research Internships in Ocean Sciences (RIOS) program, in this case, an aeronautical engineer from the University of Maryland. Qualitas, a Spanish company installing and operating the national HF radar network for Spain, contributed an internship for a student with a dual major in marine science and Spanish. Glider training courses, developed and delivered for NOAA-sponsored IOOS projects and used extensively by the operational Navy, NATO, and the European Glider Association, were used to spin students up in every aspect of glider operations over the winter break.

Each student on the team was responsible for a specific aspect of the long-duration flights. Two freshmen worked alongside the three glider technicians to help with construction and testing of the actual glider, RU17. At the end of their spring semester, they returned to their high school, giving talks to their science teacher's class and the high school robotics team at Marine Academy of Technology and Environmental Science, in Manahawkin, New Jersey, on what they accomplished at Rutgers in their freshman year. Two juniors worked on the flight characteristics of RU17, optimizing the flight controls and providing feedback to the manufacturer. Two freshmen worked on the NOAA-sponsored IOOS Mid-Atlantic HF radar network as the launch zone for these two flights, while a junior worked on HF radar in Spain to help prepare

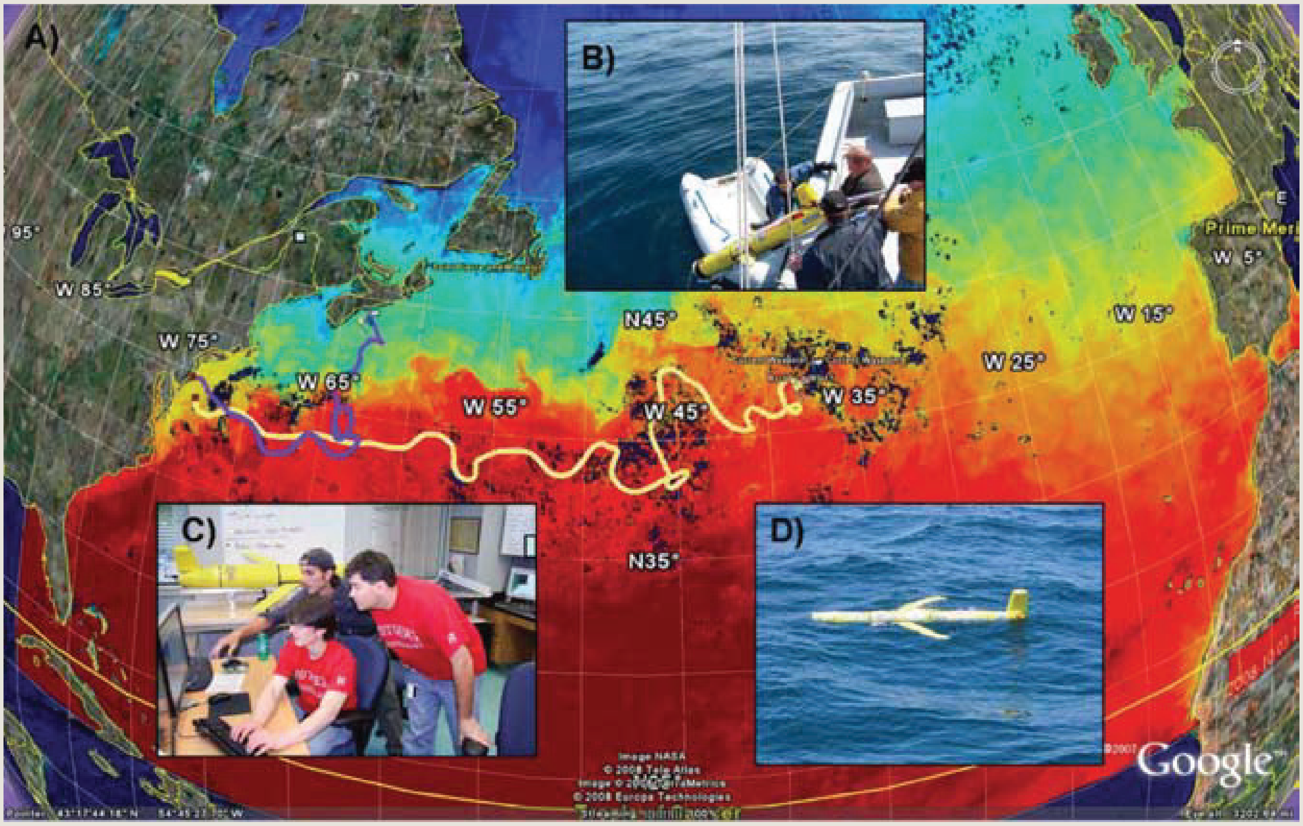

Figure B1. (A) Glider tracks overlain on a weekly composite satellite sea surface temperature image displayed in the Google Earth interface for the Halifax (RU15; blue) and Trans-Atlantic (RU17; yellow) missions. After setting the world record for distance traveled, communication with RU17 was lost just 220 miles shy of the Azores. Following our philosophy of rapid spiral development, lessons learned from the flight of RU17 are incorporated for the transatlantic mission of RU27, scheduled to begin its journey in April 2009. (B) Recovery of RU15 in Halifax, Nova Scotia, by NOPP partners at Satlantic Inc. (C) Undergraduates and a faculty member retasking RU17 to a new waypoint based on environmental data collected in the COOL room. (D) RU17 deployed off New Jersey prior to the start of its record-breaking journey.

the landing zone. Two seniors worked on path planning, Web site development, and the Google Earth interface that has been used in three Navy exercises, and is part of our Mid-Atlantic control center.

Our objective is to attract and retain students in lab activities for their full undergraduate careers. The on-campus operations center draws students from a variety of majors, and the excitement of the hands-on projects keeps them coming back semester after semester, and summer after summer. The students follow the cognitive apprenticeship learning model, which we reduce to the simple three-step teaching philosophy of "watch one, do one, teach one." They begin in freshman year with a lot of watching, often shadowing full-time research staff. By their sophomore and junior years, they know their way around the lab and are contributing key components to a variety of projects. By senior year, they are concluding their work, and passing their knowledge on to others by helping train the incoming freshmen. An NSF-sponsored education course, Communicating Ocean Sciences to Informal Audiences, is provided to the seniors so they can develop the teaching skills they will use in their last semester at Rutgers and beyond. The end result is a cluster of students that have demonstrated their ability to work together on a team for years, contributing to cutting-edge projects and building bonds they will remember as they pursue their careers.

upgrade technologies, limited the range of the data's applicability (Pettigrew et al., 2008). Ultimately, many of these observatories proved unsustainable due to overreliance on a single source of funding.

We have seen this increase in interest over the last five years as COOL continues to transition additional sampling and forecasting technologies from supporting discrete science experiments, government exercises, or industrial tests, to year-round operations. The transitions were coordinated with a growing number of academic, industry, and government partners that together sought federal, state, and foreign support as well as funding from industry and private foundations. We found that in many cases, the data users were also data providers regardless of their academic, industry, or government homes. We found that the NOPP concept of partnerships, focused on specific targeted and funded goals, moves observatories forward faster than general support for a wide range of observational parameters. Most users we ask will insist that they want the best science to support the decision-making process. In many cases, operational decisions are based on forecasts and their uncertainties rather than static historical data. Just as new technologies provide new data sets as a product of the observatory, new science that enables new forecast models is also a valued product.

Exploration and Discovery Enhances Education

The ocean is still a great unknown, far from being fully explored and understood. It is a difficult, exciting, and sometimes dangerous environment in which to work. These concepts are generally not taught in school. A common misconception is that everything is already understood. Daily difficulties that must be overcome to make progress typically go unshared, and dead ends encountered along the way go unreported. The public view is that science is conducted behind closed doors and that results are only shared when the scientist has already developed a complete story. This view contributes to a science culture that is risk adverse, where failure is viewed as a negative as opposed to a regular and common feature of scientific exploration and discovery. Additionally, the public does not see the ongoing process of science, and thus often has an incomplete perspective of how science is conducted and, therefore, how exhilarating the scientific process can be.

The committee appointed by the National Research Council identified the need to entrain the wider society to increase science and technical literacy of the United States by inspiring the next generation of scientists (National Academies, 2007). In oceanography, past discovery often involved unexpected events on the deck of a ship, far away and disconnected from the public we are trying to engage. Yet, the challenges of working in an extreme environment provide a great vehicle for capturing the public imagination. Observatories have developed the initial means to broadcast these adventures widely. Our experience indicates the audience that is excited to follow these adventures is much larger than our community might expect. Developing the means to broadcast our stories and thus entrain the wider community in our science requires effort prior to an experiment; the scientist must be prepared to be in public view through the full discovery process, including failures. Oceanography is fun, exciting, and suspenseful. It requires passion, blood, and sweat. Sometimes experiments don't work, but when they do, the excitement of discovery is indescribable. Therefore, we believe it is time to include wider society in the scientific "thrill of victory and the agony of defeat."

CONCLUSIONS

The lessons learned through the NOPP experience demonstrated the value of partnerships, the role of rapid spiral development, and the value of leveraging the support of multiple federal agencies. We have learned that partnerships are made by the hard work and dedication of the people involved based on the strengths of individuals and their belief in the synergies achievable through teamwork. New technologies born of the partnership model have enabled the evolution of our observatory with a diverse funding base in the Northeast United States at the scale of the Large Marine Ecosystem. Based on the same partnership model, we have expanded internationally, first with scientific partners around the world, followed by the exploration of extreme environments, and now the challenges of long-duration underwater flight. We have seen young faculty become involved and succeed through new science and new applications, and we have seen enabling technologies produce new data sets, and the science produce new forecast models. Public exploration of the ocean is attracting the next generation of scientists by involving undergraduates in the daily operation of an ocean observatory.

This is a unique time in the maturing of our field of oceanography. The world ocean is vastly under-sampled and presents a challenging work environment. Our generation of ocean scientists, originally trained only within our own core disciplines, is growing more collaborative as we tackle interdisciplinary problems. And federal funding agencies are growing more collaborative in their search for dual-use technologies, new science, local development test beds, and leveraging opportunities. People from academia, industry, and government are forming virtual communities for collaboration independent of their home institutions. The definition of an oceanographer continues to expand as we attract new people to the field and make it easier to spend time at sea. It is a great time to be an oceanographer.

ACKNOWLEDGEMENTS

The Rutgers University Coastal Ocean Observation Lab acknowledges the broad support of the oceanographic community. We are especially grateful for the friendships established with our long-term industry partners, including SeaSpace, CODAR Ocean Sensors, Teledyne Webb Research, Teledyne RD Instruments, Satlantic, WET Labs, Ocean Power Technologies, Deepwater Wind, and Public Service Electric & Gas. Our growing list of international colleagues, representing over ten different countries, is too long to list here. Finally, we acknowledge the daily support of COOL faculty, research staff, and students who work alongside us. The combined efforts of this diverse group are transforming ocean observing capabilities globally at a critical time for the unselfish benefit of generations to come. Thank you all for providing the inspiration that keeps us moving forward.

ABSTRACT

Autonomous underwater gliders have proven to be a cost-effective technology for measuring the 3-D ocean and now represent a critical component during the design and implementation of the Mid-Atlantic Regional Ocean Observing System (MARCOOS), a Region of the U.S. Integrated Ocean Observing System. The gliders have been conducting regional surveys of the Mid-Atlantic (MA) Bight, and during the 3 years of MARCOOS, the glider fleet has conducted 22 missions spanning 10,867 km and collecting 62,824 vertical profiles of data. In addition to collecting regional data, the gliders have facilitated collaboration for partners outside of MARCOOS. The existence of the MA glider observatory provided a unique test bed for cyber-infrastructure tools being developed as part of the National Science Foundation's Ocean Observatory Initiative. This effort allowed the Ocean Observatory Initiative software to integrate the MARCOOS assets and provided a successful demonstration of an ocean sensor net. The hands-on experience of the MA glider technicians supported training and provided assistance of collaborators within the Caribbean Regional Association, also a region of the U.S. Integrated Ocean Observing System, to assess the efficacy of gliders to resolve internal waves. Finally, the glider fleet has enabled sensor development and testing in a cost-effective manner. Generally, new sensors were tested within the MARCOOS domain before they were deployed in more extreme locations throughout the world's oceans. On the basis of this experience, the goal of the MARCOOS glider team will be to expand the MA network in coming years. The potential of how an expanded network of gliders might serve national needs was illustrated during the 2010 Macondo Gulf of Mexico oil spill, where gliders from many institutions collected subsurface mesoscale data to support regional models and oil response planning. The experience gained over the last 5 years suggests that it is time to develop a national glider network.

Keywords: Webb gliders, IOOS, Ocean observatories

Introduction

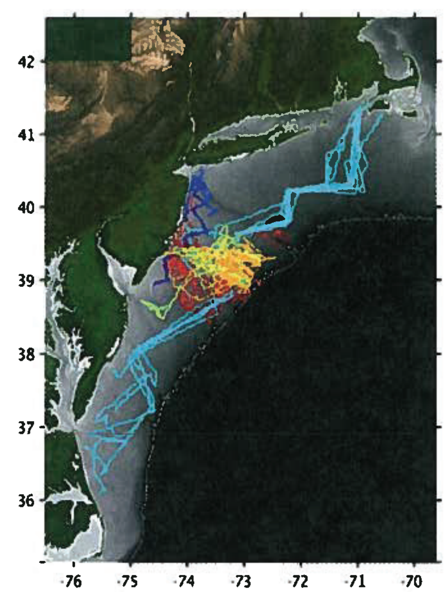
The Mid-Atlantic (MA) region, spanning from Massachusetts to Cape Hatteras, contains an extremely productive continental shelf supporting diverse and abundant fin and shellfish populations (Gates, 2009). The MA is characterized by a broad continental shelf that extends out for several hundred kilometers. The MA exhibits considerable seasonal and interannual variability in temperature and salinity (Mountain, 2003), which has a great influence on the abundance and distribution of its living resources. Seasonal hydrographic dynamics of the MA underlie many of the evolved life strategies of resident species that are evidenced by regional migrations and breeding dynamics. For example, the breeding success of many fish and shellfish are tied closely to overall hydrography off the MA (Weissberger and Grassle, 2003; Ma, 2004; Ma & Grassle, 2004; Lazzari & Able, 2006; Manderson, 2008). Therefore, understanding the dynamics of the MA ecosystem requires at minimum an understanding of the seasonal evolution of hydrographic features and preferably enough temporal/spatial information over the year to resolve the quantitative importance of episodic effects. Increasing our understanding of these processes is critical for the development of any ecosystem-based management strategy, which is extremely important as the MA hydrography (Mountain, 2003) and ecosystem (Schofield et al., 2008) appears to have changed over the last few decades.

Efforts to understand the seasonal dynamics of the MA has been a major research focus for decades (Walsh et al., 1988a,b; Biscaye et al., 1994). These research efforts have relied on ships (Walsh et al., 1988a,b; Mountain, 2003), moorings (Biscaye et al., 1994), satellites (Yoder et al., 2001, 2002; Ryan et al., 1999, 2001; Moline et al., 2004), and high-frequency (HF) radar (Gong et al., 2010). Satellites and HF radar provide a regional perspective and collect data continuously throughout the year; however, they only provide data on surface waters, which is problematic as the MA is characterized by a great deal of subsurface variability. In late spring and early summer, a strong thermocline develops across the entire continental shelf, isolating from the surface a continuous mid-shelf "cold pool" of water that extends from Nantucket to Cape Hatteras (Houghton et al., 1982). This stratification forms one of the most extreme coastal thermoclines on Earth with temperatures ranging from 30° at the surface to 8°C below the thermocline. The thermal gradient is very sharp with the majority of the change occurring within 5 m (Biscaye et al., 1994). Many of the biological features of interest reside at or below the thermocline, which is below the detection limits of satellites and HF radar. Ships can provide detailed 3-D data (through profiling and undulating instrument platforms); however, the expense of the ship operations limits the temporal coverage. Moorings can collect HF temporal data, although the maintenance and operations costs prohibit a sufficient number to be deployed that could resolve the spatial variability. Therefore, there is a critical need to deploy new technologies that can routinely provide a regional sustained presence at sea. Autonomous underwater gliders have proven to be a robust technology (Davis et al., 2003; Schofield et al., 2007; see Figure 1), which is why they were specifically chosen as a critical component during the design and implementation of the Mid-Atlantic Regional Ocean Observing System (MARCOOS), a region within the U.S. Integrated Ocean Observing System (IOOS®).

This manuscript will describe the glider efforts within MARCOOS. We will highlight the science motivations of the glider network and the current metrics (number of missions, costs) of the glider network. We will also provide three examples of how the gliders provide a unique capacity that has allowed MARCOOS to collaborate with science communities outside the MA. Finally, we look to future glider efforts as MARCOOS matures and argue that this and other regional glider programs will provide the foundation for a national glider network for United States.

FIGURE 1

The Webb glider tracks for deployments in the MA Bight since October 2003. Each color represents a different funding source. The turquoise lines represent joint deployments between ONR's ESPreSSO program and NOAA's MARCOOS program. The red lines represent the deployments associated with the Rutgers Endurance Line. The orange lines represent the glider deployments associated with the ONR's Shallow Water 2006 experiment. The green lines are associated with NSF's OOI Observing simulation experiment in November 2009. The light blue lines near New York Harbor represent deployments associated with the NSF Langragian Transport and Transformation Experiment. The dark blue lines are deployment funded by the State of New Jersey focused on conducting water quality surveys. (Color versions of figures available online at: http://www.ingentaconnect.com/content/mts/mtsj/2010/00000044/00000006.)



History and Motivations for the MARCOOS Glider Network

The regional glider efforts grew out of the Rutgers Endurance time series transect, which began in Fall 2003 (Glenn & Schofield, 2009). The endurance transect is a cross-shore survey from offshore Tuckerton, New Jersey, to the edge of the continental shelf and has been conducted as many times as possible as funds allowed over the last 7 years. To date, there have been 55 glider missions flown along the Endurance line since October 2003, collecting surveys more than 18,000 km from 826 glider-days at sea (Table 1). It has provided data allowing a full characterization of the seasonal dynamics offshore New Jersey (Castelao et al., 2008a,b, 2010a,b). It should be noted that this effort has been conducted with no formal funding award to maintain the time series. When MARCOOS was funded, the goal was to expand Endurance glider surveys to span the waters from Massachusetts to Cape Hatteras.

One scientific motivation for this effort was to provide a foundation to support ecosystem decision support. In the MARCOOS region, direct, indirect, and induced economic impacts of commercial and recreational fisheries are substantial, with the dockside value of commercial marine fish landings averaging approximately $1 billion/year and annual spending on recreational coastal and ocean fishing being estimated at $7.4 billion. The long-term economic value of fisheries would be increased if managers could prevent overfishing; however, uncertainty about the status of fish stocks and about how ocean conditions influence fish population dynamics and fishing success limit current management practices. Efforts are underway to develop "ecosystem-based fishery management" and "spatial marine planning." Both approaches rely on near synoptic ocean observations collected over ecologically relevant scales (spatial scales of meters to hundreds of kilometers, temporal scales of days to years) to better characterize the fishery dynamics. Defining habitat indicators for fishery resources is challenging because of the complex interactions between marine ecosystems and physical forcing; however, preliminary research efforts suggest that MARCOOS data can increase the explanatory power of habitat models (Palimera, personal communication). One of the most important subsurface physical features that structures fisheries on the MA is the cold pool water (CPW), which is spatially and temporally variable (Bignami & Hopkins, 2003). The CPW is the lowest temperature water and seasonally contains significant chlorophyll (Wood et al., 1996), and its location can affect the migration and spawning behavior of many fish (Sullivan et al., 2005).

Gliders provide a useful tool for collecting data on the CPW, which is not detectable by remote sensing techniques. They also provide data that can support numerical modeling via data assimilation. Past coastal predictive skill experiments have emphasized the importance of resolving the source waters (i.e., the upstream condition) to the model domain (Wilkin et al., 2005). This required that surveys span the entire MARCOOS domain, which require two separate glider missions to be conducted, because the standard glider batteries (alkaline) do not have sufficient energy to survey the entire MA; however, recently lithium batteries have been used and have sufficient

TABLE 1

The data collected by Webb Slocum gliders on the MA Bight. There were three major classes of missions. The first was the Rutgers Endurance line. The second was the surveys of the MA conducted by the IOOS and the Office of Naval Research's ESPreSSO program. The final class of MA glider missions was individual research projects. Some of the glider numbers collected by those individual research programs is also listed.

Mission	No. Missions	Glider-Days at Sea	Vertical Casts	Kilometers
Endurance line	55	826	159,011	18,028
MA surveys[a]	22	493	62,824	10,867
Research Projects	29	500	90,413	9,543

energy to survey the entire region. The drawback of the lithium batteries is the increased cost. For the alkaline surveys, one of the missions begins in southern Massachusetts and conducts a series of cross and along shore transects to central New Jersey. A second survey is typically conducted from central New Jersey to the mouth of Chesapeake Bay. Funding leveraged between the IOOS Program in the National Oceanic and Atmospheric Administration (NOAA) and the Office of Naval Research (ONR) Experimental Shelf Predictive Shelf-Slope Optics (ESPreSSO) program, allowed us to begin conducting MA surveys. To date, these programs have supported us to conduct 22 missions spanning 10,867 km while collecting 62,824 vertical profiles of data. The surveys were timed to coincide with the northeast National Marine Fishery Survey cruises.

The extensive glider experience in MA provides a basis for assessing the cost-effectiveness of these technologies. Cost estimates for glider missions are based on a full-time dedicated glider technician ($411 per day[1]), the coastal vessels for glider deployment and recovery,[2] and the expenses for batteries/Iridium/insurance/nominal maintenance and repair.[3] The estimated costs for MA operations assumes for each mission a dedicated technician for each day the glider is deployed as well as the deployment/recovery and ancillary expenses. Note, however, that a single technician can monitor many gliders when deployed, and the gliders represent cost-effective scalable technology. During past experiments, a single technician has monitored up to eight gliders. These estimates do not include support for the development of new hardware or software. On the basis of the MA deployment of gliders for 1,819 days, the costs are $1,815,534. This simplifies to $6 per vertical profile, $47 per kilometer traversed, and $998 per day. These costs compare favorably with research class vessels (nominal cost ~$25,000 per day) and a smaller coastal vessel ($1,500 per day) in which daily glider costs are 4% and 66% of comparable ship rates, respectively. Gliders cannot replace ships, which remain the most modular and flexible ocean sampling platform available to oceanography that far exceeds the current capabilities of existing sensors for gliders. Therefore, we recommended that gliders in near future take over the coastal monitoring needs, which would free up ships to conduct more sophisticated adaptive sampling without needing to dedicate time to ocean mapping.

[1]The costs include salary, fringe, and university indirect cost return.

[2]We have taken a high-end estimate of $4,000 per day for ships for deployment and recovery.

[3]We place the total upper end of costs for coastal waters at $10,000 per mission.

Collaboration Beyond the MARCOOS Domain

A major advantage of having a robust glider effort in the MA is that it has provided a means to galvanize collaborations from outside the MARCOOS community. MARCOOS (1) provides an existing open access observatory for users, (2) has a large pool of technical experience that can assist other groups in building observatories, and (3) provides a cost-effective test bed for new technologies. The benefits to MARCOOS are that this helps ensure that new technologies from external groups are integrated into the existing network and help develop a larger cohesive distributed ocean observatory community that provides a national resource (see below in future directions).

MARCOOS Provides an Existing Observatory

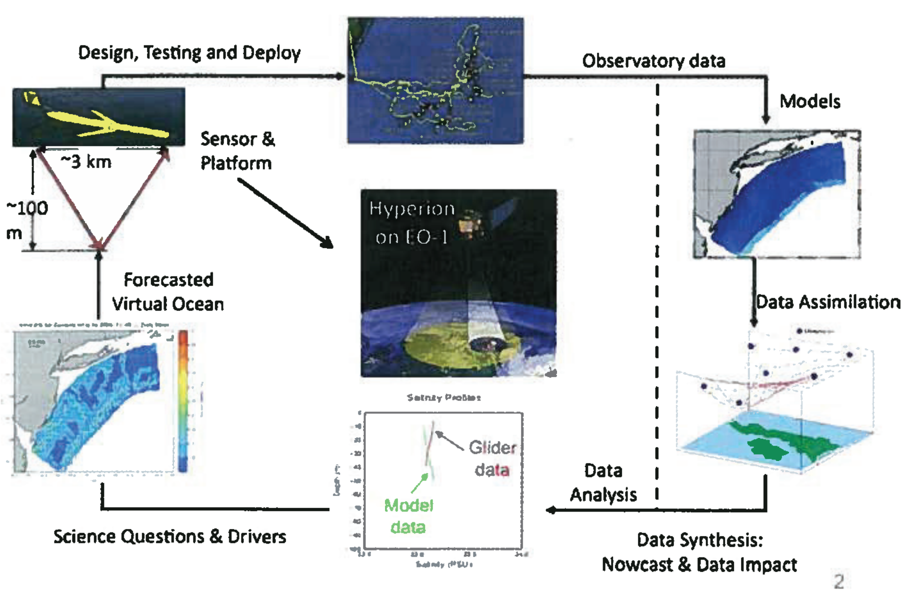
The MARCOOS glider network provides a test bed for partners external to the MA. One good example of this was demonstrated in November 2009 when the MARCOOS supported the U.S. National Science Foundation's (NSF) Ocean Observatory Initiative (OOI). A significant focus of the OOI is on developing a sophisticated cyber-infrastructure (CI) that links physical ocean observatories, computation, modeling, storage, and network infrastructure into a coherent system of systems. The software also provides a Web-based social network enabled by real-time visualization and access to model outputs allowing for adaptive sampling science. To ensure the development of a useful CI, a "spiral design strategy" is being used encouraging the oceanographic community to provide input during the construction phase. MARCOOS provided an existing test bed with a wide range of streaming data and an existing glider fleet that could be used to test the planning and prosecution software (Schofield et al., 2010).

The goal of the November experiment was to assess how well the CI software can aggregate data from ships, autonomous underwater vehicles, shore-based radars, and satellites and to make it available to ocean forecast models. Scientists used the model forecasts to guide future (next 24 h) glider missions, which then were used to coordinate satellite observing to demonstrate the feasibility of two-way interactivity between the sensor Web and predictive models. A distributed community of MARCOOS scientists provided the OOI CI team with daily adaptive guidance for a task-able satellite, using information from a fleet of four MARCOOS gliders.

The OOI software was being developed to enable operators to monitor and control individual components within an ocean observing network. The CI software coordinates and prioritizes the shared resources, allows for the semi-automated (Thompson et al., 2009, 2010) reconfiguration of asset tasking, and thus enables an autonomous execution of observation plans for the fixed and mobile observation platforms (Figure 2). For this effort, numerical model ocean forecasts allowed the simulation of future *in situ* robot trajectories, which could be used by a distributed group to optimize sampling on the basis of the science needs (Figure 3) and the practicability of moving gliders efficiently in the resolved current field (e.g., were targets actually "reachable"?) (Thompson et al., 2009, 2010). Thus, the CI software could deliver the community science needs back to the *in situ* observation network in a timely manner. The CI software coordinated sampling between underwater gliders and the space-based Hyperion imager flying on the Earth Observing One (EO-1) (http://eo1.gsfc.nasa.gov) spacecraft leveraging the Earth Observing Sensorweb (Chien et al., 2005, 2008) capability. The Hyperion images are typically 7.5 km (across track) by more than 100 km (along track) and resolve 220 spectral bands from 0.4 to 2.5 microns with a spatial resolution of 30 m. This small spatial footprint makes it difficult to ensure *in situ* assets are present for calibration. The Hyperion is a task-able platform and therefore an alternative approach would mobilize *in situ* assets and simultaneously adjust the satellite swath to be coincident. During the field experiment, observational data and multimodel forecasts were analyzed to determine the tasking location for the satellite. These coordinates were used by the EO-1 Web capability (http://sensorweb.jpl.nasa.gov) to retask the spacecraft. The 48-h model forecast was then used by the CI software to plan the optimal path to colocate any gliders within the tasked EO-1 Hyperion swath. Two MARCOOS gliders were successfully moved within the narrow Hyperion swath, which is only 7.5 km wide, whereas other gliders were diverted outside the swath to accomplish other science missions (Figure 4). This represents a major technology breakthrough in simultaneously coordinating satellite and underwater assets guided by multimodel forecasts. It provided a machine-to-machine interactive loop driven by a geographically distributed group of scientists.

FIGURE 2

The machine-to-machine data flow during the OOI's Observation Simulation Experiment. A fleet of gliders was informed by model-driven forecasts to optimize science sampling being conducted by a geographically distributed team of scientists. The observatory data were assimilated by an ensemble of numerical forecast models that were used to optimize the glider sampling. Optimized glider data were also used to adjust the data collected by the Hyperion EO-1 satellite.



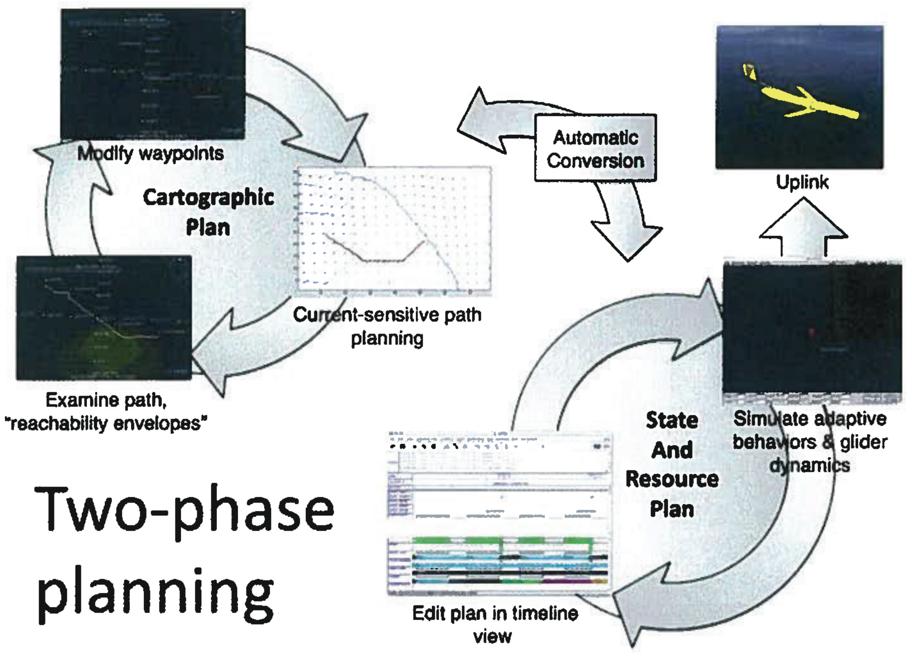
Partnership with Other IOOS Partners

The extensive pool of expertise within MARCOOS provides a resource to the wider IOOS community. This has been particularly true for glider operations where the community is small but rapidly growing. Through funding from the ONR Environmental Optics program, formal glider training sessions have been developed and have provided training to researchers from within the MARCOOS, international universities, NATO, and the Naval Research Laboratories. Here we highlight the partnership between MARCOOS and the IOOS CAribbean Regional Association (CARA). MARCOOS and CARA have partnered in sharing expertise in both the installation of HF radar and the deployment of Webb gliders.

The focus of the glider efforts in the Caribbean (Figure 5A) was on studying mixing processes in the coastal waters

FIGURE 3

The automated planning prosecution tools used by glider operators during the OOI CI test. The automated software involves a two-phase planning strategy. One component is a cartographic planner that allows glider operators to examine the "reachability envelopes" of a glider on the basis of the currents forecasted for the future ocean. This provides a tool for scientists to modify glider waypoints to assess if they can reach proposed goals in a specified amount of time. This is coupled to an automated state and resource planner. The state and resource planner allows the user to simulate different mission strategies to make wise strategic decisions, which are then uploaded to the glider as a series of waypoints. The state and resource planner not only keeps track of the physical state of the glider (remaining battery power) but also other features that need to be considered by the operator (commercial shipping lanes). The net result is that the scientist can optimize the science missions to collect the highest possible quality data.



offshore Puerto Rico (Figure 5B). Internal tides, vertical oscillations of the pycnocline, can promote ocean mixing (St. Laurent & Garrett, 2002), modulate phytoplankton productivity (Evans et al., 2008), induce biological aggregations (Lennert-Cody & Franks, 1999; Moore & Lien, 2007), cause shelf break "scouring," modulate deep coral reef biology, and induce coastal seiching. Prior studies of internal tides in the Mona Passage between Puerto Rico and Hispaniola, initially driven by interest in billfish aggregations at the site, have shown that the Mona Passage and the shelf break along the SW coast of Puerto Rico are sites of internal wave generation. These phenomena have been partially characterized through the work of Bejarano (1997), who documented large-amplitude internal tides in the Mona Passage, by Teixeira (1999), who looked deeply into associated seiches and their excitation, and to Alfonso-Sosa (2001), who explored the local generation of internal tides through the action of tides impinging stratified waters on topographic slopes. In summary, these interfacial tides are approximately in phase with the astronomical tide, are of semidiurnal frequency, and exhibit amplitudes of up to 50 m (Teixeira & Capella, 2000).

Glider-based observations in the Mona Passage were used to characterize internal waves revealing the periodic generation of a wave train spanning the entire passage. Wave generation occurs in the region of "El Pichincho," a submerged ridge across the passage where tidal action induces hydraulic forcing of the wave (Figure 5B). Here, semidiurnal isopycnal displacement centered at depths around 100 m spans a vertical range of up to 50 m. Density sections along the glider transects to the south of the suspected generation site reveal a gradient of decreasing wave amplitude suggesting damping of the wave along its southward propagation axis toward the open Caribbean Sea (Figure 5C).

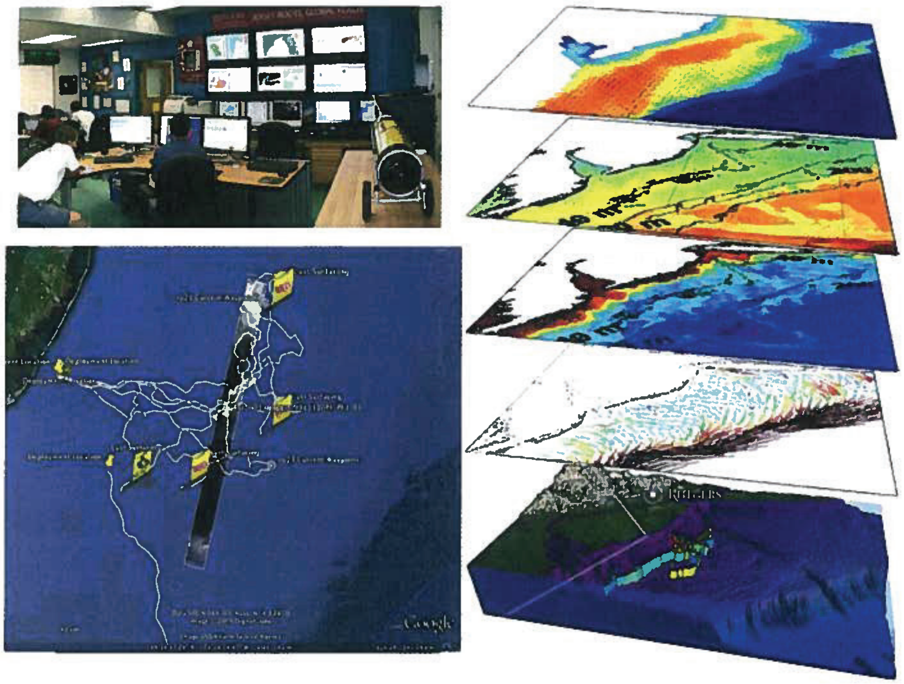
Chlorophyll sections for two transects (Figure 5D) show significant modulation of phytoplankton biomass within the subsurface chlorophyll maximum (SCM). We propose that this modulation is brought about by the spatial and temporal variation of the irradiance field, resulting from the vertical displacements of the SCM and the diurnal cycle. This hypothesis is supported by the correspondence between chlorophyll *a* concentration at the SCM and the depth of the pycnocline. These joint IOOS glider observations prompt us to propose that Caribbean passages may be the main source of internal tide energy prevalent throughout the Western North Atlantic.

MARCOOS Provides a Sensor Test Bed

The MA Webb gliders allow MARCOOS to act as a test bed for new sensors. The MA provides a location where the community has extensive experience as well as existing facilities that allow for field calibration of new sensors with ongoing operations. Sensors developed by funding from the ONR, the National Ocean Partnership

FIGURE 4

The IOOS observatory backbone that supported the OOI effort. The right-hand column shows the regional data provided by IOOS. The data included subsurface data from gliders, regional CODAR surface currents, ocean color and sea surface temperature remote sensing, and an ensemble of five numerical models. The data were coordinated and distributed over the world wide web via the Rutgers Coastal Ocean Observation (upper panel on left column) to the science/engineering teams distributed throughout the country. The bottom-left panel shows the Hyperion data swath that was collected after the ocean observatory directed the tilt of the satellite.



Program, the Environmental Protection Agency (EPA), the NSF, and the Gordon and Betty Moore Foundation have provided new sensor packages that were then first tested in the MA. These sensors are typically tested and refined in the MA before being deployed in more extreme locations that cannot provide the logistical support available within the MA. Initial testing and deployment of sensors aboard the gliders in the MA that have occurred over the last 5 years include development of physical sensors (acoustic Doppler current profilers, turbulence shear probes), optical instruments (backscatter sensors, multispectral radiometers, light attenuation sensors, light scattering sensors, hyperspectral spectrometers, cameras), fluorometers (chlorophyll, colored dissolved organic matter, fast repetition rate chlorophyll), oxygen sensors, and passive acoustic sensors (Glenn & Schofield, 2009). In addition, the glider test bed has supported the development of customized lithium batteries (Glenn et al., 2010), improved onboard computing (Woithe et al., 2010), new glider tail technologies (Glenn & Schofield, 2009), anti-fouling skin (Lobe et al., 2010), and extended payloads (Glenn & Schofield, 2009). Sensors that have been initially tested have then anchored missions along many of the North American coastlines (Chao et al., 2008; Glenn et al., 2008; Schofield et al., 2008), North Atlantic (Glenn et al., 2009), Pacific Northwest, Caribbean, Antarctica (Kahl et al., 2010), Baltic, Norwegian fjords, Sargasso Sea, and Alaska.

Future Directions

On the basis of the experience gained during the last 3 years of IOOS, the MARCOOS team has identified several key goals for the next 5-year effort. Within the MARCOOS domain, future strategies call for expanding the glider presence beyond a single seasonal survey each year. This need is based on one of the original goals of the MARCOOS gliders to assist in ecosystem-based management, which determined that defining the CPW was a critical need. Although the initial regional glider surveys could resolve the CPW, they could not resolve the formation, dynamics, and dissipation of the CPW; this calls for an aggressive expansion of the existing time series glider lines. This effort will require an expanded fleet of MARCOOS gliders (note MARCOOS currently owns one Webb glider) and increasing the surveys from a seasonal effort to a monthly time series. The high-resolution time series will enable numerical modeling of the CPW, which can resolve the dynamics in the MA.

IOOS represents the framework within which to establish a national backbone of ocean observation capabilities. This backbone is critical for overcoming the chronic undersampling of the coastal waters of the United States. The cost-effectiveness of gliders offers the potential to establish a cost-effective national backbone for subsurface spatial observations while HF radar and satellites complete the surface picture. The importance of developing a national capacity was clearly illustrated during the Deepwater Oil

FIGURE 5

The collaborative glider efforts between MARCOOS and CARA were crowned with joint deployments of the MARCOOS glider in Puerto Rican waters. (A) The CARA and the MARCOOS team members congratulating each other after the glider is deployed offshore (which can be seen in the white circle). (B) The glider transect into the Mona passage offshore Puerto Rico. (C) The glider measured density showing large internal waves. (D) The glider measured chlorophyll showing the phytoplankton concentrations being enhanced in the region of high internal wave activity.

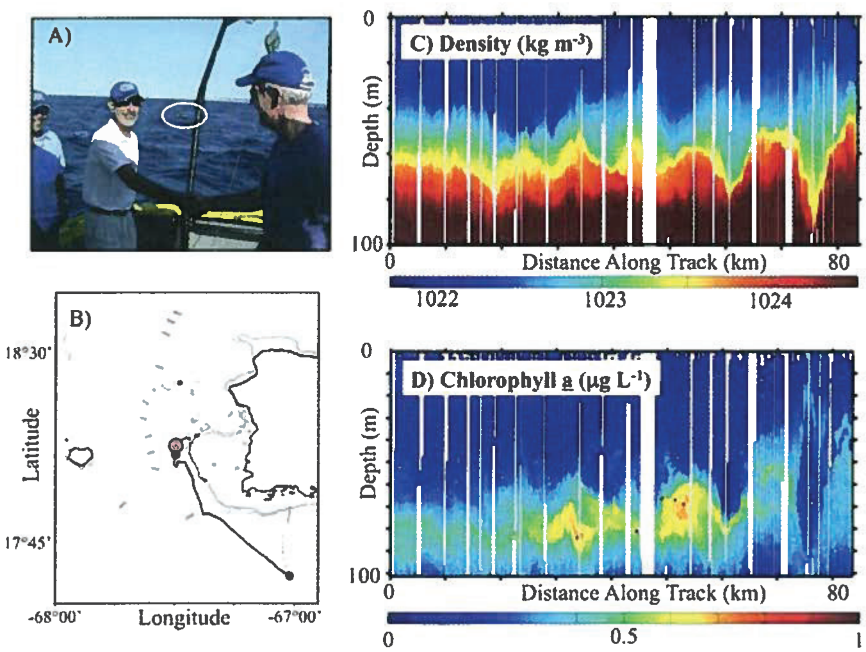


FIGURE 6

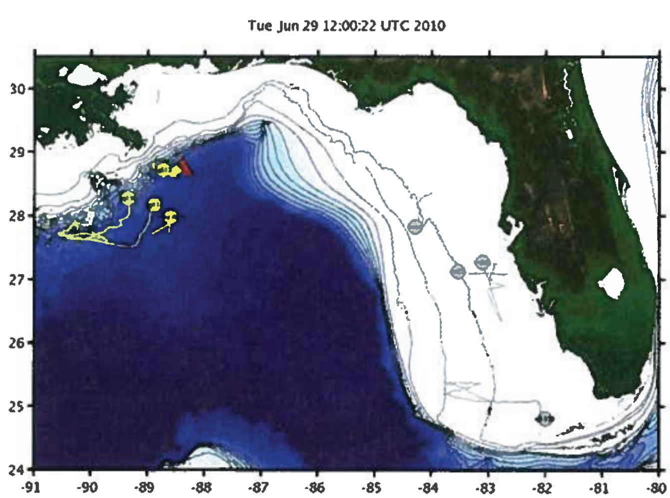
The positions of a community of gliders (yellow and gray circles) in the Gulf of Mexico on June 29, 2010. The glider fleet was assembled by community in response to the Deepwater oil spill. The community of partners included the U.S. Navy (sg135 and sg137), the Scripps/WHOI (spray-00-48), the iRobot/Applied Physics Lab (sg515), the University of South Florida (bass), the Rutgers University (ru23), the Mote Marine Laboratory (Waldo), and the University of Delaware (ud-134).



spill disaster (http://rucool.marine.rutgers.edu/deepwater/), when the paucity of subsurface measurements hindered response planning to the oil spill. This gap was addressed when a wide range of federal (U.S. Navy), commercial (iRobot, Teledyne Webb Research), and academic partners (Applied Physics Lab, Mote Marine Laboratory, Rutgers, Scripps Institution of Oceanography (under the IOOS Region–Southern California Coastal Ocean Observing System), University of Delaware, University of South Florida (under the IOOS Regions South Eastern Coastal Ocean Observing Regional Association and Gulf of Mexico Coastal Ocean Observing System), and Woods Hole Oceanographic Institution) joined forces and provided a fleet of gliders to make subsurface maps of the Gulf of Mexico (Figure 6). The gliders provided months of subsurface data, which would have been prohibitively expensive to collect using ships. Although the partners provided gliders, they came at the expense of their individual research efforts within their local waters; therefore, there is a critical need to develop the national capacity so the regional time series can be collected, the ocean modeled, and the assets tasked. There is a great need to develop a capacity to efficiently deal with events of national importance in the future. Additionally, strong partnerships with technology development initiatives, such as the OOI, are critical to ensure that despite the operational focus of IOOS, it is continuously infused with maturing technology that will provide expanded functionality to the growing network. Using these new technologies will make deploying a national glider fleet achievable and represents a cost-effective investment for IOOS.

Acknowledgments

The authors gratefully acknowledge support from the IOOS Program Office in NOAA, the Office of Naval Research, the NSF's OOI, the NASA New Investigator Program, and Delaware Sea Grant. This research was carried out, in part, by the Jet Propulsion Laboratory (JPL), California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA).

SYMPOSIUM

Autonomous Gliders Reveal Features of the Water Column Associated with Foraging by Adélie Penguins

L. Alex Kahl,*[,1] Oscar Schofield* and William R. Fraser[†]

From the symposium "Advances in Antarctic Marine Biology" presented at the annual meeting of the Society for Integrative and Comparative Biology, January 3–7, 2010, at Seattle, Washington.

[1]E-mail: alex@marine.rutgers.edu

Synopsis Despite their strong dependence on the pelagic environment, seabirds and other top predators in polar marine ecosystems are generally studied during their reproductive phases in terrestrial environments. As a result, a significant portion of their life history is understudied which in turn has led to limited understanding. Recent advances in autonomous underwater vehicle (AUV) technologies have allowed satellite-tagged Adélie penguins to guide AUV surveys of the marine environment at the Palmer Long-Term Ecological Research (LTER) site on the western Antarctic Peninsula. Near real-time data sent via Iridium satellites from the AUVs to a centralized control center thousands of miles away allowed scientists to adapt AUV sampling strategies to meet the changing conditions of the subsurface. Such AUV data revealed the water masses and fine-scale features associated with Adélie penguin foraging trips. During this study, the maximum concentration of chlorophyll was between 30 and 50 m deep. Encompassing this peak in the chlorophyll concentration, within the water-column, was a mixture of nutrient-laden Upper Circumpolar Deep (UCDW) and western Antarctic Peninsula winter water (WW). Together, data from the AUV survey and penguin dives reveal that 54% of foraging by Adélie penguins occurs immediately below the chlorophyll maximum. These data demonstrate how bringing together emerging technologies, such as AUVs, with established methods such as the radio-tagging of penguins can provide powerful tools for monitoring and hypothesis testing of previously inaccessible ecological processes. Ocean and atmosphere temperatures are expected to continue increasing along the western Antarctic Peninsula, which will undoubtedly affect regional marine ecosystems. New and emerging technologies such as unmanned underwater vehicles and individually mounted satellite tracking devices will provide the tools critical to documenting and understanding the widespread ecological change expected in polar regions.

Introduction

Climatic change is, and will continue, altering marine ecosystems. However, the complexity of marine food webs, combined with chronic under-sampling of the ocean, constrains efforts to predict the effects of future change. Furthermore, these limitations also restrict our capacity to suitably manage and protect marine resources. All of these problems are magnified in polar oceans because these environments are extremely difficult to observe and to study (Anisimov et al. 2007). The harsh conditions associated with low temperatures, restricted sunlight for much of the year, high wind, sea ice, and limited logistic support often curb the widespread application of new technologies that are increasingly being deployed in temperate and tropical oceans. Fortunately, these technologies are maturing and are ready to be deployed in polar oceans. This is vital as many polar seas are experiencing changes in atmospheric/oceanic circulation (Turner et al. 2006), ocean properties (Meredith and King 2005), sea ice cover (Stammerjohn et al. 2008), and ice sheets (Steig et al. 2009). These rapid climatic changes are triggering pronounced shifts and reorganizations in regional ecosystems and in biogeochemical cycles (Grebmeier et al. 2006). However, it remains difficult to link these changes in the ecosystem to shifts in the physical ocean–atmosphere system. Overcoming this missing link, to decipher the mechanisms of climate-driven variability in an ecosystem, is a critical step in establishing predictive skills capable of contributing to adaptation and risk reduction strategies related to climatic change.

Because of the planetary scale and localized effects of climatic change in polar regions (Kwok and Comiso 2002), sampling strategies linking the changing dynamics of ecosystems with underlying physical processes must span a wide range of temporal and spatial scales. To this end, the oceanographic community has been developing technologies and strategies intended to bridge these vast gaps in observational capacity. For example, multi-platform observatories have been able to deconstruct mechanisms of different scales to elucidate shifts in temperate coastal ecosystems (Schofield et al. 2008). Given that such interdisciplinary and multi-platform approaches have proven themselves in expedient locations, they are ready for application in remote and harsh environments. Essential to the successful application of this approach to high latitude marine ecology will be the integration of technologies that have already succeeded on their own in polar regions. To ensure efficient observing and sampling strategies of dynamic processes, key ecological indicators should be identified and utilized to adjust data collection in real-time.

Top predators, such as marine mammals and seabirds, are key components of Antarctic marine ecosystems. Life-history strategies and population dynamics of these generally long-lived predators can reflect variability occurring over large spatial and temporal scales in both the physical, and biological environment (Fraser et al. 1992). As beacons integrating the dynamics of their ecological niche over decadal time scales, these marine predators are often regarded as sensitive indicators of ecological change (Ainley 2002; Costa et al. 2010) and as important units for the conservation and management of marine resources (Turner et al. 2009). Unfortunately, much of our understanding of the ecology of Antarctic marine predators is derived from animals at terrestrial breeding areas during only a small portion of the annual cycle. Traditionally, researchers studying the ecology of Antarctic marine predators have tried to overcome this constraint by using ARGOS satellite-based tracking technologies. Yet, the scope of these satellite-based tracking technologies is limited by their size, duration of deployment, the breeding phase of the predator, and by the predator's strategies for acquisition of prey. For example, most satellite-based tags are applied to animals at their terrestrial breeding sites during their annual breeding phase. As such, the resultant data document behavior and strategies. associated only with the breeding phase of the tagged predators. Increasingly, technological advances are allowing these satellite-linked tracking tags to include meters capable of detecting environmental variables such as depth, temperature, and salinity (Charrassin et al. 2008). Despite ever more sophisticated instrumentation, the aforementioned limitations still confound researchers' ability to independently characterize the subsurface marine environment shaping the ecology of Antarctic marine top predators.

Background

Adélie penguins as integrators of Antarctic marine ecosystems

Of the world's 18 extant species of penguin (Spenisciformes: Spheniscidae) (Baker et al. 2006), the Adélie penguin (*Pygoscelis adeliae*) is one of only two (the other is the Emperor penguin, *Aptenodytes forsteri*) true Antarctic species (Williams 1995). Circumpolar and geographically distributed at high southern latitudes, the Adélie penguin is characterized by a life-history that has evolved in close association with sea-ice in the Southern Ocean (Ainley 2002). For example, the species generally winters at the edge of the pack ice where nutrient stores are maintained during the winter months. Along the ice's edge during the early spring, Adélie penguins accumulate critical nutrient reserves required to sustain several aspects of the early-summer breeding effort. These nutrient reserves are fueled by the presence of a reliable food source that itself depends on sea-ice as a critical habitat. The Adélie penguin's primary prey are krill (*Euphausia superba* and *E. crystallorophias*) and the Antarctic silverfish (*Pleuragramma antarcticum*). Specifically, the survival and cohort recruitment of juvenile krill depends on their ability to consistently forage upon sea-ice dependent algae (Daly 1990) while Antarctic silverfish forage on krill (Hubold 1985). Furthermore, by hauling out on the sea-ice, Adélie penguins reduce the demands of their maintenance metabolism. Diminished maintenance metabolism, in turn, allows individual Adélies to store more energy. By increasing their energy stores, individual penguins are better able to cope with demands such as the spring migration to terrestrial breeding colonies, egg production by females, and defense of nesting territories by males.

As oviparous marine vertebrates, the Adélie penguin is entirely dependent on the terrestrial habitat for incubating eggs and rearing chicks. Due to the energetic demands of reproduction, predictable and reliable foraging areas must be located in close proximity to so-called ‘‘biological hotspots’’. It has long been appreciated that marine ‘‘biological hotspots’’ are regions of high ecological significance (Steele 1976). In terrestrial and corral reef systems, the hotspots have often been defined in terms of biodiversity (Meyers 1997; Hughes et al. 2002) while in marine systems the hotspots have often been defined in terms of increased biomass in either phytoplankton (Valavanis et al. 2004) or higher organisms. Such hotspots of biological activity are driven by pelagic bio-physical interactions resulting in elevated new primary production (i.e., phytoplankton blooms driven by newly introduced rather than regenerated nutrients). These photosynthetically driven blooms result in a trophic cascade of new energy. As the physics and chemistry of the oceans varies rapidly in space and time (at the scale of minutes to days), plankton biology (and the subsequent introduction of energy into the marine food web) is extremely patchy and highly ephemeral (ranging from hours to days). In contrast, higher trophic levels (nekton, sea birds, and marine mammals) by virtue of their long life-times (years to decades) integrate over larger space and longer time scales. Consequently, mapping top-predators often identifies ‘‘biological hotspots’’—or regions where such energy flows readily through the ecosystem.

The subsequent transfer of this energy, from lower trophic levels upward, is essential to the nutritional condition and reproductive performance of top predators such as Adélie penguins. Inevitably, perturbations in climatic parameters of the ocean (e.g., extent and timing of occurrence of sea ice) and in climatic anomalies have a strong affect on the propagation of this energy, ultimately modifying the availability of food for top predators. In particular, such anomalies of oceanic climate have a significant influence on seabird life history such as the timing of nest initiation and egg size (Gaston et al. 2005). Due to the energetic demands of reproduction, predictable and reliable Adélie foraging areas must be located in close proximity to biological hotspots, which represent regions with consistently high and predictable food resources. These hotspots appear to related deep sea canyons. The Adélie penguins breed in locations where deep ocean canyons exist near the land margin; these canyons provide a possible conduit for the warm Upper Circumpolar Deep Water (UCDW) to extend to near the land margin (Klinck et al. 2004), keeping winter ice low and supporting high primary productivity rates (Prezelin et al. 2000). As a result, the life history of these seabirds, driven by sea-ice dynamics and associated food web dynamics, can spatially and temporally integrate variability in oceanic climate along the WAP. For these reasons, populations of the Adélie penguin are regarded as sensitive indicators of global climatic change (Ainley 2002).

Climatically, the WAP is among our planet’s fastest warming regions with an increase in average air temperature of 6°C during the winter months over the last half century (Ducklow et al. 2007). This rapid warming has resulted in a reduction in the extent and duration of annual sea-ice formation (Vaughan et al. 2003). Proximate causes of regional warming and sea-ice decline involve the impact of climatic phases such as El Niño-Southern Oscillation, and the Southern Annular Mode on the atmosphere–ocean systems (Kwok and Comiso 2002). The interactions within these atmosphere–ocean systems can result in an increase of the cross-shelf transport of relatively warm water derived from the Antarctic Circumpolar Current (ACC). Such cross-continental-shelf intrusions of the ACC are possible because the WAP is the only place where the ACC encounters the Antarctic continent. Furthermore, submarine canyons present on the WAP funnel the warmer ACC deep water across the continental shelf to the near-shore sea surface. In addition to being warmer than the locally formed Antarctic water masses, the ACC’s deepwater is nutrient-laden, and when brought to the sea surface may drive persistent upwelling that is localized at the head of each cross-shelf canyon (Ducklow et al. 2007).

As a result, the WAP is susceptible to the increase in oceanic heat transport across the continental shelf that appears to have intensified over the last 30 years (Martinson et al. 2008). In response, along the Palmer Archipelago near Anvers Island (64°46′S, 64°03′W, Fig. 1), *Pygoscelis* community composition has shifted over the last 30 years (see Forcada and Trathan 2009 for review). Most dramatically, the population of breeding adults has declined from ~15,000 in the mid-1970s to presently < 4000 (Ducklow et al. 2007). Concurrent community shifts are evident in rising populations and the expanding of the sea-ice intolerant chinstrap (*P. antarctica*) and gentoo (*P. papua*) penguins. Population growth and range expansion are occurring at chinstrap and gentoo nesting colonies, respectively established in 1976 and 1994, on islands in close proximity to the declining

Adélie colonies near Palmer Station (Ducklow et al. 2007, Fig. 2). Understanding why one species is declining while others are increasing remains an open question. The differences likely reflect distinct foraging strategies among the penguin species and the dependence of such strategies on the variability of sea ice along the WAP.

These broad shifts in top predator community structure point to significant and fundamental changes at the base of the WAP marine ecosystem (Schofield et al. 2010). Indeed, such shifts in the basic composition of the pelagic marine environment are manifest in variability in foraging strategies by top predators at the decadal-scale (Ainley et al. 2005). However, sampling of the pelagic marine environment at spatial and temporal scales contemporaneous to top predator foraging behavior will be required to develop an understanding of the mechanisms and processes underlying variability in the WAP marine ecosystem.

Diet sampling of seabirds, traditionally conducted from the terrestrial environment, provides an

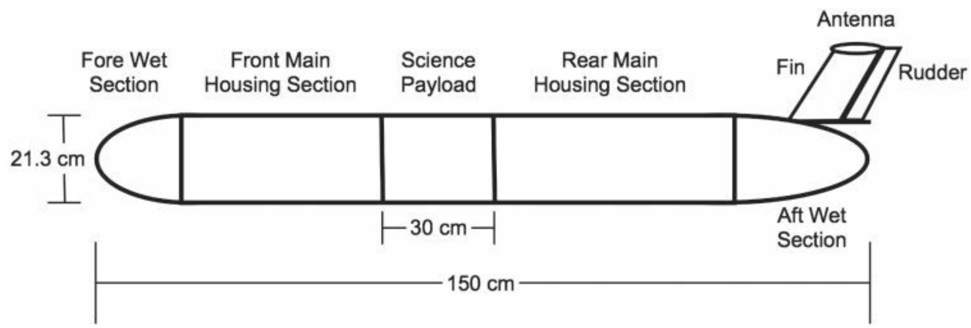

Fig. 1 Diagram of Teledyne-Webb Corporation's Slocum Glider (coastal model). The Front Main Housing Section glider's ballast, and consequently it's flight, is controlled by moving water into or out of the Fore Wet Section. The Front Main Section contains battery packs supplying power to both the ballast regulator and the Science Payload. The Science Payload can be modified to contain a wide variety of instrumentation including an externally mounted (port side) SBE CTD. The Rear Main Housing Section holds more battery packs and all of the glider's electronic hardware. While at the sea surface, a bladder is inflated in the Aft Wet Section to increase the fin-mounted antenna's clearance above the water. The rudder is controlled by the onboard computer (in the Rear Main Housing Section). Depending on the year of manufacture, the wings may be mounted on either the Science Payload or the Rear Main Housing Section.

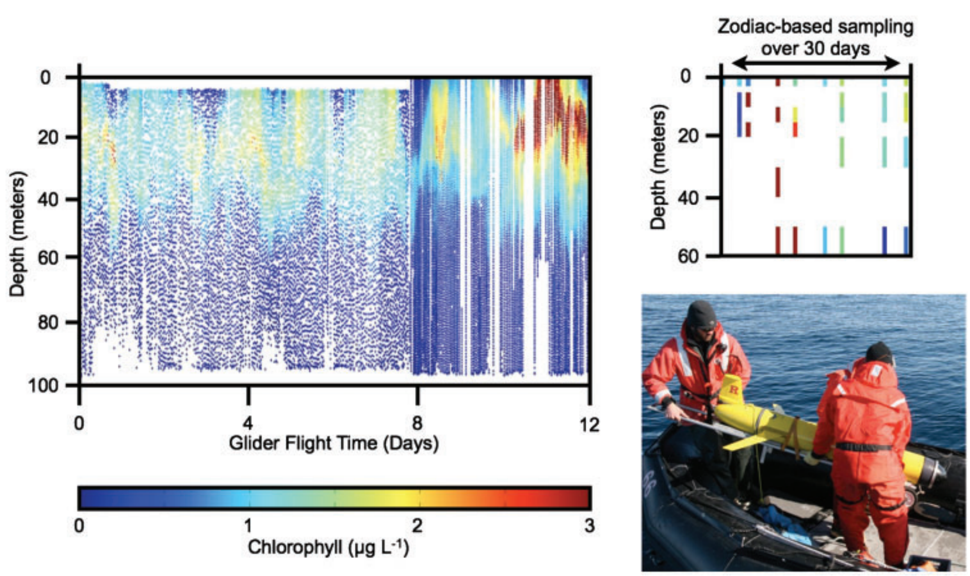

Fig. 2 Comparison of chlorophyll concentration at the Palmer LTER collected by the Slocum glider (12 days) and by hand via zodiac (30 days). The glider chlorophyll data also show the ability to change the sampling rate of the fluorometer (increased beginning on Day 8) without disrupting the glider flight. The image in the lower right depicts the deployment of the Slocum glider by hand over the side of a zodiac at the Palmer LTER.

integrated signal of the ecology of the foraging region. However, traditional diet sampling techniques do not provide insight into *in situ* foraging strategies and their constraining bio-physical factors. Indeed, some polar pelagic marine environments have been sampled (e.g., salinity and temperature with depth) with satellite-tracking tags on marine mammals (Boehme et al. 2008). However, the data derived from these tags are biased by the behavior of the tagged animal. Consequently, it has been difficult to illustrate a broad-scale picture of the hydrography driving the lower trophic levels in Antarctic marine ecosystems. Additionally, tagged marine animals only provide snapshots of the pelagic marine environment when conditions are ideal for the predator (e.g., during feeding or transit). Ideally, satellite-tagged animal data should be complimented by both contemporaneous and temporally extraneous high-resolution regional sampling of the oceanographic factors shaping these marine environments. For a robust definition of the factors, data focusing on both the biology and physics of these polar pelagic marine environments should be collected for sustained periods of time.

Integrating autonomous underwater vehicles into a long-term ecological study

Due to its remote location and harsh conditions, it is exceedingly difficult and expensive to observe polar marine ecosystems at the appropriate time and space scales. By necessity, observing and sampling of such systems must be highly efficient both in terms of logistics and costs. Inevitably highly efficient methods of observation in polar regions must be "scalable" to the process of interest (Rudnick and Perry 2003). Mobile platforms are undergoing exponential development and are transitioning into observational tools (Rudnick and Perry 2003). One autonomous platform that is rapidly becoming indispensable in temperate marine research is the buoyancy-driven underwater glider. Buoyancy-driven gliders, as currently configured, were first detailed in Doug Webb's lab book in February 1986 as a novel instrument approach. Gliders were widely publicized in 1989 by Henry Stommel's view of a futuristic smart fleet of instruments (Stommel 1989). During the time it has taken to bring these concepts to reality, gliders have earned their reputation as a high-endurance sensor platform. More importantly, this class of long-range and relatively low-cost autonomous underwater vehicle (AUV) is making affordable adaptive sampling networks a reality (Rudnick et al. 2004).

Slocum gliders

All of Rutgers University's Slocum gliders are controlled and monitored from a centralized control center located on Rutgers Campus in New Jersey (USA). The control center is called the Coastal Ocean Observation Lab (RU COOL) at the University's Institute of Marine and Coastal Sciences. For almost two decades RU COOL has posted freely available real-time data to the world-wide-web. RU COOL maintains control of a fleet of more than 24 gliders that are routinely deployed around the world. Taking advantage of rapidly expanding telecommunications technologies has allowed the centralized function of the COOL room to also be accessed remotely, continually increasing the flexibility of glider operations. However, glider operations in the Antarctic are unique from deployments and recoveries elsewhere because of the remoteness, unique hazards such as sea ice, and lack of reliable access to ships should a malfunction occur. High winds, heavy seas, or thick ice conditions also frequently hamper these deployments and recoveries.

The glider used for this study is the Webb Slocum Coastal Glider (Figs. 1 and 2). Coastal gliders such as the one deployed in this study have a hull diameter of 21.3 cm and an overall length of 1.5 m (Fig. 1). The 56 kg glider is rated to dive depths of 100 m and has a horizontal average speed of 0.4 m/s. The glider propels itself through the water column by changing its buoyancy. Consequently the glider's path of travel resembles a continuously advancing saw-tooth pattern between the surface and 100 m depth.

While at the surface, an internal air bladder thrusts the glider's tail above water allowing satellite communications. The glider can receive commands and send data via line-of-sight radio frequency modem, or satellite telephone link (i.e., Iridium Satellite phone). Each glider in our fleet uses its Iridium connection to call into the COOL room to upload scientific and engineering flight (each underwater Glider deployment is termed as an underwater flight) data. These data are generally archived for subsequent analysis and are also posted to the web in "real-time" to allow sampling strategies to be adapted in real-time based on the most recent information ("adaptive sampling"). Conversely, data transfer between the glider and the COOL room is bi-directional such that the Glider may also download new navigation or sampling command files from the COOL room. A glider can only transmit data or receive commands while at the surface of the ocean as all communications are transmitted via antennas located in the tail fin. Also contained within the tail is an ARGOS emergency beacon and a GPS. The glider uses the GPS to navigate between waypoints uploaded in a "mission" text file. Because the glider dead reckons between waypoints while underwater, upon surfacing any deviation from the intended path of travel is compensated for on the next dive by virtue of a rudder in the tail fin. During these "surfacings", flight parameters such as; duration until next surfacing, the list of upcoming GPS waypoints, and instrument sampling rate can be modified by the operator.

All Slocum gliders come with an external CTD and a modular science payload. The science payload module can be adapted to hold a wide variety of instruments. In this deployment, the glider had a fluorometer and two backscatter meters. Other scientific payloads include a photosynthetically available radiation sensor and a variable fluorescence detector. The factors limiting the type of scientific instrument onboard the glider are the size of the payload section (length = 30 cm, diameter = 21.3 cm, maximum weight = 4 kg) and power consumption of the scientific instrument. Depending on the science payload the duration of a glider deployment on one pack of batteries may last as long as one month. However, the duration of the deployment is subject to a wide variety of variables such as environmental temperature, scientific payload power requirements, and dive depth (i.e., shallower water requires more cycles of ballasting and unballasting seawater thus requiring more use of the pumps).

Glider personnel monitor the polar ocean deployments carefully because of the high risk of encountering objective hazards such as icebergs, sea ice, and uncharted seamounts. Conducting most glider flights during the peak of Austral summer has minimized risks associated with sea ice. Additionally, because objective ice hazards exist year-round but are primarily at or near the surface, keeping the glider away from the surface as much as possible further minimizes the risk of such encounters occurring. We also reduce the risk of colliding with various forms of ice in the marine environment by receiving annotated images from the National Oceanographic and Atmospheric Administration's National/Naval Ice Center. The combination of flying the gliders during the three months of annual ice minimum and using satellite ice images to avoid flying in ice-dense waters have both helped to increase the viability of operating gliders in polar regions.

Expanding the Palmer long-term ecological research

Spatial and scientific expansion at the Palmer long-term ecological research site

Since it's inception in the early 1990s, the bulk of the work at the Palmer long-term ecological research (LTER) site has been focused on collecting and maintaining time series data to study systemic shifts in polar environments due to climatic change. Historically, oceanographic measurements at the Palmer LTER have consisted of zodiac-based collection of *in situ* physical and optical parameters and acquisition of water samples for subsequent analysis. Such labor-intensive *in situ* measurements have been complimented by satellite remote sensing which opened the doors to quantifying ice-dependent ecosystem shifts along the WAP (Stammerjohn and Smith 1996). This sampling regime of combining *in situ* investigations with remotely sensed observations has been highly effective at capturing the seasonal variations and the decadal trends in primary production. However, the data required to resolve the dynamics linking primary production to top-predators have not been acquired because of spatial and temporal constraints associated with traditional Zodiac sampling techniques. Principally, the glider is able to survey the head of the adjacent submarine canyon, an area that has been outside the scope of operations of the traditional LTER sampling regime. This is especially crucial as the head of this canyon is increasingly being recognized as an area of elevated primary production responsible for supporting the large populations of breeding penguins (i.e., a "biological hotspot") nearby Palmer Station. In addition to expanding the spatial reach of the Palmer LTER scientists, underwater gliders are also increasing the temporal resolution of the data. While traditional sampling techniques may yield several hundred water column profiles of temperature, salinity, and other properties over the course of a summer season, the glider provides several hundred water column profiles in a matter of days (Fig. 2). By merging data from satellite-tagged penguins with data from an underwater glider, the monitoring and hypothesis testing capacity of the Palmer LTER site has been expanded.

As part of the Palmer LTER study, pelagic top-predators such as Adélie penguins have been used to integrate ecological shifts in the ecosystem. However it has been difficult to acquire environmental constraints that reside in the pelagic environment in which the Adélies forage. Indeed, relevant water-column characteristics such as salinity, temperature, chlorophyll-a, and mixed layer depth can now be measured using gliders. Adélie penguin diving behavior, which spans much of the euphotic zone, can be tracked using satellite-tagging techniques. Data from satellite-tagged penguins have shown that 90% of foraging by Adélies occurs over the region of deep water adjacent to the Palmer LTER site (Fraser WR, unpublished). Prior to incorporating gliders into the Palmer LTER, the water-column (i.e., vertical) characteristics of this "biological hotspot", have not been studied at relevant ecological time and spatial scales because this area is outside the safe boating limits of scientists working at the Palmer LTER site.

Results from penguin-driven adaptive sampling by gliders

Penguin tracking data from 2006 to 2008 were analyzed to determine the extent of the foraging region for the Adélie populations near Palmer Station. These historical data were then used to develop the flight plan for the Slocum underwater glider. The glider, RU05, was deployed and recovered from the Palmer LTER site in December 2008 and continuously surveyed the Palmer Basin "biological hotspot" during a 12 day deployment (Fig. 3). The glider was tasked with flying a box-like pattern around the penguin foraging zone and then conducting a series of cross-canyon transects within the same box. The data collected during the survey include; salinity, temperature, pressure, depth-averaged current, optical backscatter (470 nm, 532 nm, 660 nm), colored dissolved organic matter fluorescence, and chlorophyll fluorescence. RU05's flight path was adapted to cope with the currents and winds present during the mission by scientists in the COOL room at Rutgers University in New Jersey. This was enabled by the real-time data, which also allowed for adaptive sampling of changing conditions at the Palmer Basin "biological hotspot".

The Slocum glider transects of the Palmer Basin "biological hotspot" revealed a phytoplankton bloom, indicated by an elevated chlorophyll fluorescence signal, that lessened yet persisted over a six-day period (Fig. 4). The chlorophyll fluorescence signal of the phytoplankton bloom was more than an order of magnitude greater than the signal in the adjacent non-bloom waters. During the glider's survey of the "biological hotspot" the phytoplankton bloom predominated between 10 and 30 m below the sea surface. Accordingly, the temperature data show an intensification of nearly half a degree in the water being upwelled from below 100 m over the same period (Fig. 4). The intensification of the bloom likely comes from increased mixing of warmer, nutrient rich upper-circumpolar deep water (UCDW) and western Antarctic WW which are characterized by temperature and salinity (Martinson, Stammerjohn et al. 2008) relative to Antarctic Surface Water (AASW) (Fig. 5). While UCDW is nutrient-rich its relatively warm temperature often prevents mixing with significantly colder AASWs. However, if UCDW is mixed during

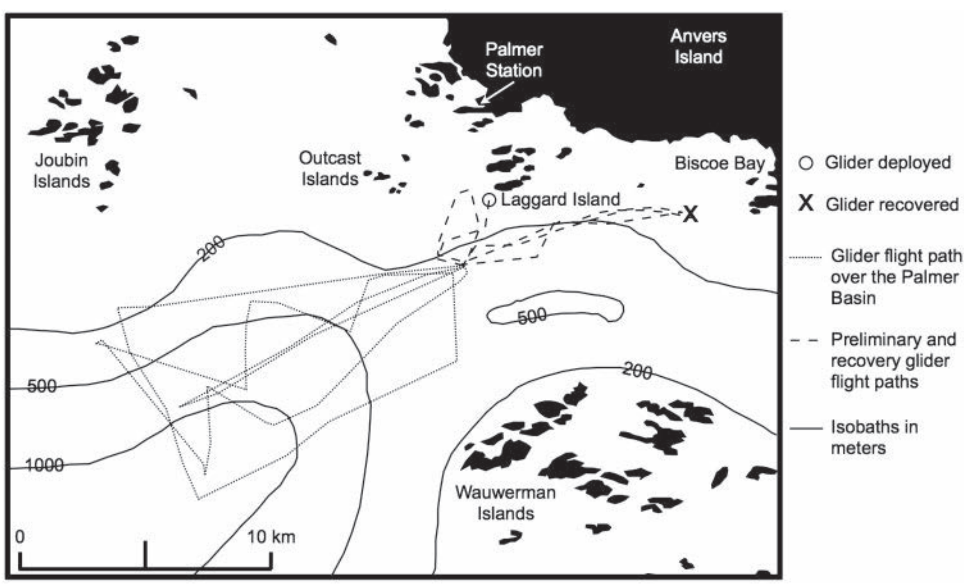

Fig. 3 Map of the Palmer Basin adjacent to Anvers Island on the western Antarctic Peninsula. Palmer Station is located at 64°46′S, 64°03′W. The Slocum glider was deployed for twelve days, six of which were spent over the Basin surveying the Adélie penguin foraging area.

cross-shelf transport and upwelling with WW, then the combined UCDW/WW water mass can more readily mix nutrients into locally formed AASW. The mixture of the nutrient-laden UCDW and WW with AASW provides an ideal environment for a phytoplankton bloom. Frequently, such phytoplankton blooms occur along the slope of the Palmer Basin closest to Anvers Island where the radio-tagged Adélie penguins preferentially forage.

The radio-tag information provides data on the location in the water column where the penguins forage. The radio-tagged data suggest that more than half (54%) of penguin foraging occurred at depths ranging from 30–50 m. Within the 90% foraging

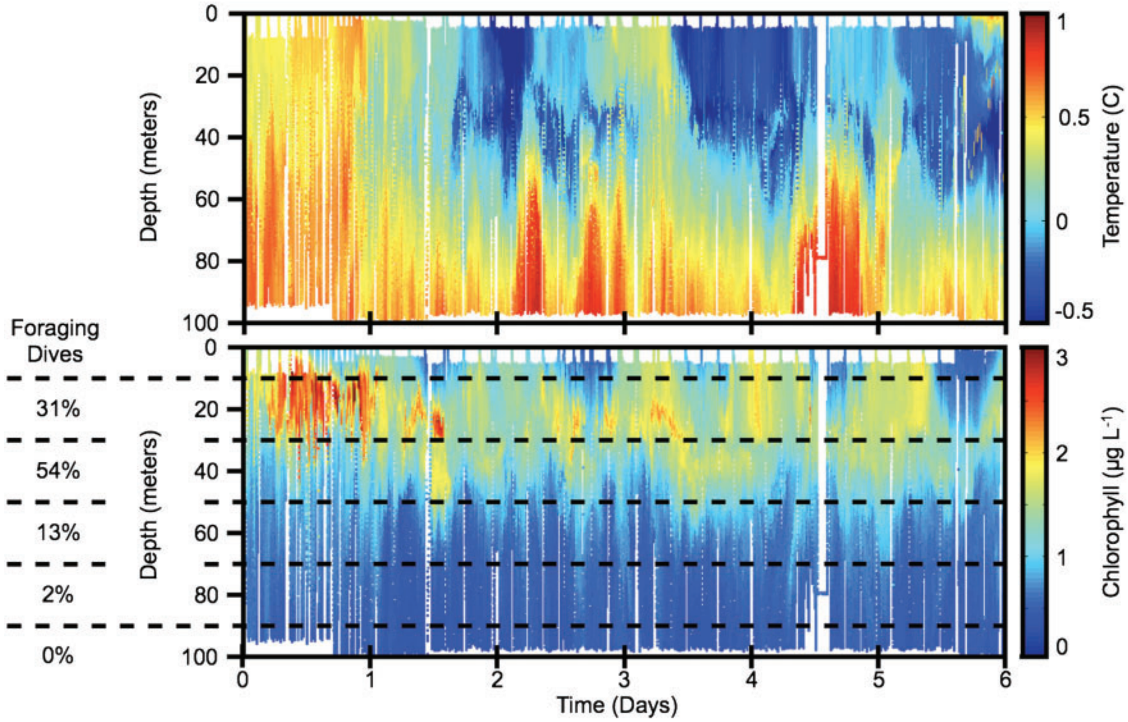

Fig. 4 Temperature (top) and chlorophyll concentration (bottom) measured by the Slocum glider within the Adélie penguin 90% foraging kernel over the Palmer Basin. Within the 90% foraging kernel, the percent of Adélie penguin foraging dives to five depth bins is aligned with the chlorophyll data.

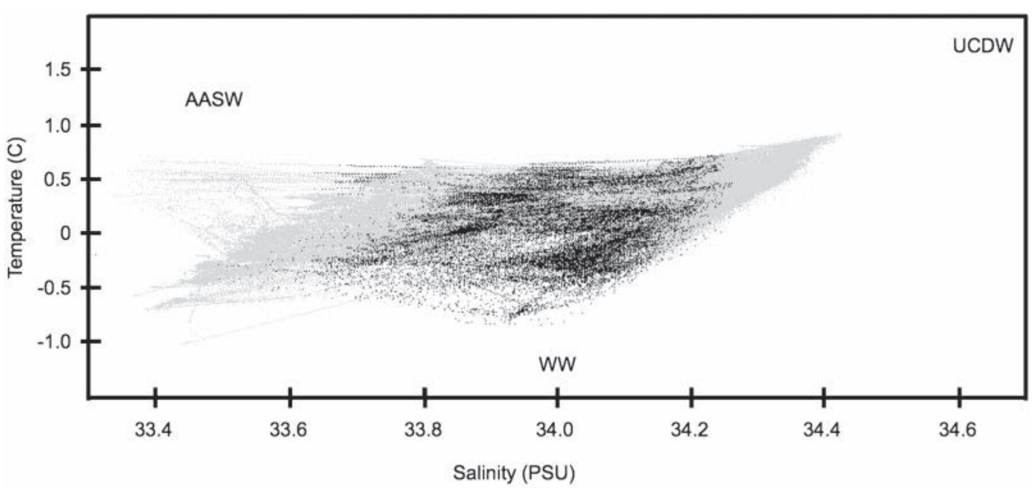

Fig. 5 Temperature versus salinity plot of water sampled by the Slocum glider. Black dots are samples collected from the primary foraging depth bin (30–50 m depth) of Adélie penguins in the Palmer Basin. The primary oceanic water masses, as defined by their temperature and salinity, in the region are; UCDW from the core of the Antarctic Circumpolar Current, western Antarctic Peninsula WW formed during the winter, and AASW formed during the summer along the coast of the western Antarctic Peninsula.

kernel, the maximum chlorophyll concentration was immediately above the 30–50 m penguin foraging dive depths. Comparatively, only 31% of foraging dives occurred at depths shallower than the depth of the chlorophyll concentration maximum. Because foraging dives originate at the surface, random feeding behavior would result in the highest number of dives occurring near the surface. However, in the Palmer Basin ‘‘biological hotspot’’, Adélie penguins appear to be targeting specific regions within the euphotic zone. In this study, the region being foraged was immediately below the most productive part of the water column. This foraging behavior suggests that the Adelies are preying on krill who are grazing on the phytoplankton cells at the base of the chlorophyll maximum. Krill undergo vertical migration (Morris et al. 1984; Godlewska and Klusek 1987) to graze in the high phytoplankton biomass regions in the surface waters at night, and have then been observed to migrate below the chlorophyll maximum during daylight hours (Morris et al. 1984) when Adelie penguin forage. Future studies will focus on this by deploying gliders outfitted with acoustic sensors to provide maps of the zooplankton biomass. These future efforts will combine swarms of gliders that measure the physical properties (temperature and salinity), phytoplankton biomass (chlorophyll fluorescence), and zooplankton (acoustic measurements). Further study is necessary to link krill at the bottom of the chlorophyll maximum to targeted Adélie foraging. Furthermore, because the depth of the mixed layer drives the location of the chlorophyll maximum in the water-column, variability of the mixed layer depth may have direct effects on the energetic balance for a foraging seabird. Bringing together satellite tagged birds and gliders to highlight linkages such as these will be critical towards expanding our knowledge of the role of environmental variability in Antarctic ‘‘biological hotspots’’.

Conclusion

While the traditional LTER needs to be maintained, modern ocean time series and ecosystem monitoring programs will increase the scientific questions that might be addressed (Ducklow et al. 2009). To this end, the subsurface-sustained- and high-resolution glider data will provide a critical tool. Not only do these low-cost emerging technologies expand scientific capabilities, they also have the potential to expand scientific collaboration. Indeed, these new technologies may provide a gateway for emerging earth science programs to enter polar research. For example, through collaborative purchasing of batteries or renting flight time on a glider, scientists working at institutions without a traditional capacity for polar research may be able to contribute to research that has traditionally been the province of well-established research entities. By focusing on innovative means of collaborating, low-cost, emerging technologies can lower the barrier of entry for many potential polar researchers. Increasing the capacity of scientists from around the world to help understand the climatically linked mechanisms already occurring in polar marine environments may have the added benefit of helping to prepare these same scientists to address similar responses to climatic change in marine ecosystems closer to home.

Using Webb gliders to maintain a sustained ocean presence

O. Schofield, J. Kohut, S. Glenn
COOL, Institute of Marine and Coastal Sciences,
School of Environmental and Biological Sciences, Rutgers University
New Brunswick, NJ 08901 USA

Abstract- **Buoyancy driven Slocum gliders were a vision of Douglas Webb, which Henry Stommel championed in a vision published in 1989. Slocum gliders have transitioned from a concept to a technology serving research and environmental stewardship. The long duration and low costs of gliders allow them to anchor spatial time series. Large distances, over 600 km, can be covered using a set of alkaline batteries. Lithium batteries can anchor missions that are thousands of kilometers in length. Since the initial tests, a wide range of physical and optical sensors have been integrated into the glider allowing measurements of temperature, salinity, depth averaged currents, surface currents, fluorescence, apparent/inherent optical properties active and passive acoustics. A command/control center, entitled Dockserver, has been developed that allows users to fly fleets of gliders simultaneously in multiple places around the world via the Internet. Since October 2003, Rutgers gliders have conducted 157 missions, traversed >55,000 kilometers, logged >2600 days at sea, and logged ~350,000 vertical profiles. The capabilities of the glider make them an indispensable tool for the growing global effort to build integrated ocean observatories. For example, gliders are now a central tool within the National Science Foundation Ocean Observatory Initiative (OOI) and the National Oceanic and Atmospheric Administration's Integrated Ocean Observing System (IOOS). Gliders provide a new magnet in which to attract young people into the ocean science and engineering. For example Rutgers undergraduates now anchor long duration flights of gliders world-wide beginning their freshmen year. This is critical to training the next generation.**

I. INTRODUCTION

For centuries, oceanographers have relied on observations gathered from ships during cruises of limited duration. This expeditionary research approach has resulted in major advances in understanding the global ocean. These and many other successes have expanded our view of Earth and ocean processes, and have demonstrated a need for sampling strategies spanning temporal and spatial scales that are not effectively carried out using ships. To address this observational gap, the scientific community has consistently called for the development of the capability to maintain a continuous sampling and monitoring presence in the ocean [1].

Mobile platforms are undergoing exponential development and are transitioning into observational tools. One such autonomous platform that is rapidly becoming indispensable are gliders. Gliders, as currently configured, were first detailed in Doug Webb's lab book on 2/8/86 as a novel instrument approach and was subsequently publicized in 1989 by Henry Stommel's view of a futuristic smart fleet of instruments [3]. It has taken some time to bring these concepts to reality, yet gliders are steadily earning their reputation as a high-endurance sensor platform. More importantly, this class of long-range and relatively low-cost autonomous underwater vehicle (AUV) is making affordable adaptive sampling networks a reality.

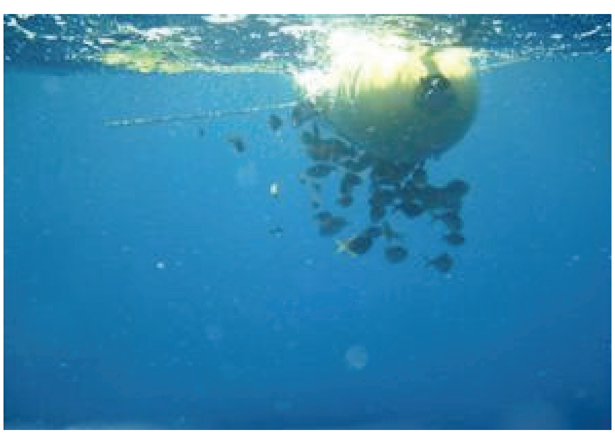

Fig. 1. A Webb glider at the surface offshore Hawaii attracting fish.

We will review our experience with Slocum gliders (Figure 1) and will demonstrate how they offer the potential improvement in our capability to observe the oceans. A number of different gliders have been developed and are being used by many organizations; however, for this paper we will only discuss the field efforts conducted by Rutgers University (RU) and Webb Research Corporation (WRC). We emphasize that the successes of this group are matched by other groups at other institutions. Our "take home" message is that Gliders are a robust technology capable of anchoring large field campaigns. Additionally, we will also highlight how Gliders will benefit many different users and serve as a magnet for the next generation of scientist and engineer.

II. OUR GLIDER EXPERIENCE AS OF WINTER 2009

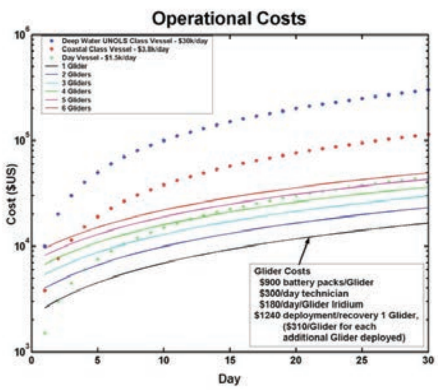

Figure 2. The costs in United States dollars for maintaining ships and gliders at sea. Ship costs represent the average daily charge that varies with ship class based on averages in the year 2005. The glider costs include the expenses of deploying, maintaining, and recovering a glider.

The Slocum glider is a 1.8 m long torpedo-shaped, winged AUV. It maneuvers through the ocean at a forward speed of 20–30 cm/s in a sawtooth-shaped gliding trajectory, deriving its forward propulsion by means of a buoyancy change and steering by means of a tail fin rudder. The altimeter and depth sensor enable preprogrammed sampling of the full water column. The primary vehicle navigation system uses an on-board GPS receiver coupled with an attitude sensor, depth sensor, and altimeter to provide dead-reckoned navigation, with backup positioning and communications provided by an Argos transmitter. Two-way communication with the vehicle is maintained by RF modem or the global satellite phone service Iridium. All antennas are carried within the tail fin that is raised out of the water when the vehicle is commanded to surface at some predetermined interval. Operational endurance, utilizing alkaline batteries, is 25 to 60 days, depending on sensor payload and sampling regimes. Horizontal distance traveled averages 24 km per day. The vehicle is operational in 5 to 200 m of water depth and can be optimized for 30, 100, 200 and 1000 m operation with select gearboxes.

The mission duration of a glider is largely a function of the number of sensors and the water depth. The largest power drain in the glider involves the operation of the pump and, therefore, the battery life is shortest in shallow seas. Despite the shortened battery life, deployments last over three weeks, providing the scientist usually several thousand vertical casts. The increase in data quickly justifies the costs of maintaining Gliders for sustained observations (Figure 2). The operational costs for Gliders include technician time, costs for deployment/recovery, batteries, and Iridium phone charges. Based on standard daily costs for a range of research vessels (deep water, medium, small coastal vessel), the operational costs of Gliders are economical (Figure 2). The typical costs of operating the deep-ocean and coastal class research vessels exceed the cost of operating single glider deployed for a full multi-week mission. The costs of smaller research vessels exceed a glider after three days. One technician can operate several gliders so the increased costs associated with operating multiple gliders reflect increased deployment/recovery costs, batteries, and Iridium charges. Given this the costs of medium research vessel will exceed operating a fleet of six gliders in about four days. Gliders will never replace ships, but populating the oceans with Gliders will allow ships to use their time wisely as they will

Figure 3. RU gliders ready for deployment.

know when and where to sample the ocean. This will allow the ship time to be used to spend its time at sea testing/deploying new instruments and conducting experiments.

Rutgers currently maintains a fleet of over 20 gliders (Figure 3). The glider built through competitive grants have to date conducted 157 missions, traversed >55,000 kilometers, logged >2600 days at sea, and logged ~350,000 vertical profiles. These gliders missions have been conducted world-wide and are coordinated at Rutgers main campus (Figure 4). The missions have spanned efforts from the polar to temperate and tropical seas. The data has been highly valuable and has been central to 13 peer reviewed manuscripts in 6 years with 9 more papers in press or in review. The manuscripts have a mean number of 7 authors and thus the gliders are central to interdisciplinary ocean science.

Operating a fleet of gliders necessitates an automated command and control (C2) system in order to optimize glider missions to resolve the temporal and spatial patterns of the process of interest. This requires the C2 to be flexible and adaptable as the environment is constantly evolving. We have been constructing a C2 system for a fleet of Webb Gliders; however, the system is scalable to allow the incorporation of a number of data inputs, allowing the fleet to make intelligent goal oriented decisions that feeds back into dynamic adaptive resource allocation. The software package allows information from a scientist, the glider itself, other sensing systems such as high frequency radar, satellites, or additional gliders, to optimize a particular glider's flight characteristics or waypoints. New mission directives are automatically uploaded to the glider during surfacing and the glider begins its new sampling regime or waypoint bearing. Optimization can be done for features like, but not limited to, currents, tides, thermoclines, and haloclines.

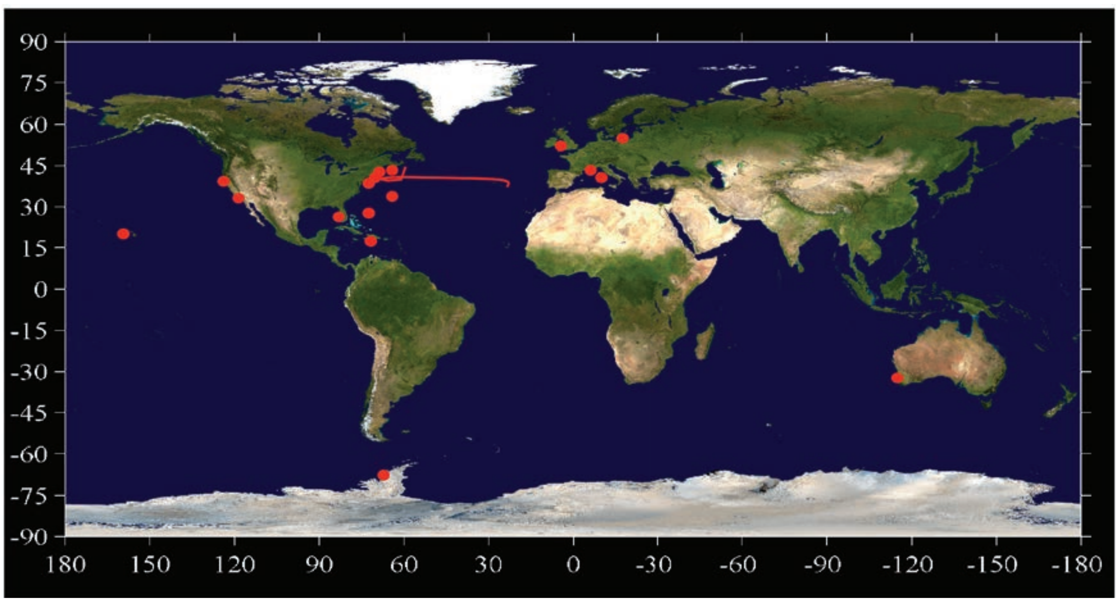

Figure 4. The global deployments for the RU gliders. The coming months in summer 2009 has missions planned for a second attempt to cross the Atlantic, along with science missions offshore Norway, Alaska, and Northeast seaboard of the United States.

Deployments can also allow ground-truthing of satellite imagery. Data are automatically pulled from the vehicle and made available for web based presentation.

III. GLIDER SENSORS

The value of the Glider surveys will increase as the sensors available for Webb Gliders expands (Figure 5). The main bottleneck for integrating sensors is minimizing their size and power consumption. In experience this has been a three-step process. The first is the efforts by the manufacturers to minimize the sensors for the gliders. Most often, the second phase involves mounting a self-recording sensor on a glider to collect data, which is often needed to secure funding from federal agencies for full sensor integration. The full integration and field demonstration is the final and third phase. Based on history working with WetLabs, Mote Marine Laboratory, Satlantic, and Webb Research this end-to-end process takes close to two to three years depending on the sensor complexity. This process has successfully integrated many diverse sensors into a Webb glider. Measurements presently being made by gliders include physical (temperature, salinity, turbulence), acoustic (active and passive), optical (spectral radiometry, backscatter, attenuation scattering, absorption, digital imagery), fluorescence (chlorophyll a, colored dissolved organic fluorescence, fast repetition rate fluorometry), and dissolved gas (oxygen)

Figure 5. The sensors that have been carried on Webb gliders. They include (starting at the top left panel) oxygen, passive acoustic, attenuation, chlorophyll/colored dissolved organic flourometers, turbulence, fish finders, scattering and backscattering packages, spectral backscatter, radiometer, digital cameras, acoustic doppler measurements, fast repetition rate flourometry, and absorption.

With so many sensors now available, the power required often outstrips the capabilities of a standard glider configuration. To address three strategies have been pursued. The first strategy is to increase the number of batteries that the glider can carry. This has resulted in the development of the "stretch" glider. The stretch glider's longer body allows for more battery packs and/or larger sensors. The second strategy has been to develop lithium battery packs for the Webb gliders. Working with Electrochem, a fully outfitted lithium glider was operated for several months and Coulomb meter measurements suggest glider lifetimes of 300-360 days is now available. The final strategy is to fly the gliders as swarms. The swarms represent packs of gliders carrying distributed sensors, allowing a full complement of data to be collected. These swarms we have termed "Darwin clusters" as the adaptive capabilities of gliders are operated as evolving network that allows data to be merged between the platforms while also providing a mesoscale network to map features in the ocean.

IV. Near Term Challenges

Gliders are key technologies to exploring extreme environments and episodic events, which are disproportionately important to many ocean processes. Targeted extreme environments include the poles, severe storms, urbanized ports and developed coastlines, which are often avoided by scientists because of the hazardous operating conditions.

Gliders are now a central technology that will anchor climate change research being conducted in the Antarctic and Arctic. One effort will use gliders along the West Antarctic Peninsula as part of the NSF's Long term Ecosystem Research program in collaboration with British scientists. Here the efforts will be to provide a sustained regional presence when the research vessel is not available. This requires scientists to utilize the Antarctic field stations as a staging facility. This strategy was demonstrated successfully in 2007 and 2009 (Figure 6). Additionally, gliders will help scientists to understand why deep canyons are associated with large penguin breeding colonies. Radio-tagged penguins will be used to adjust the sampling areas of a Darwin cluster of gliders capable of mapping the physics, chemistry, phytoplankton, currents and higher trophic levels, in order to understand if canyons are associated with sustained upwelling that provide a predictable food resource near the breeding colonies. The second polar effort will be conducted in the Arctic in collaboration with Norwegian researchers. Here the goal will be to develop a time series site between the Svalbard and Norway to understand regional circulation impacting ice flows and regional warming trends.

Science efforts are usually curtailed during severe storms; however observing networks are robust and allow scientists to safely study these processes in real-time. One nice example was from a storm event encountered in October of 2003 [2]. The gliders are equipped with a conductivity–temperature–depth sensor, and an ECO-sensor pucks. October is the transition between summer and winter seasons, which starts with surface cooling that preconditions the shelf for rapid mixing during fall storms. The mixing storm of October 2003 was a classic northeaster. Early in the storm when waves were high, sediment resuspension was limited to below the pycnocline. After the pycnocline eroded through growth of the bottom boundary layer, particles immediately filled the full water column. The spectral ratio of backscatter indicated that the particles were likely similar materials both before and after the stratification was eroded. The backscatter profiles in the bottom boundary layer decay with distance from the bed at rates consistent with theory but with variable slopes. The reduced slope of the backscatter profiles increased after stratification was lost, which is consistent with an increase in vertical transport or turbulent mixing. Wave bottom orbital velocities during this time were decreasing, and the glider vertical velocities showed no enhancement consistent with Langmuir cells. Enhanced mixing was related to the interaction of the surface and bottom boundary layers while the stratification was eroded, and the observed variability in the resuspension during the event was also due to the tide.

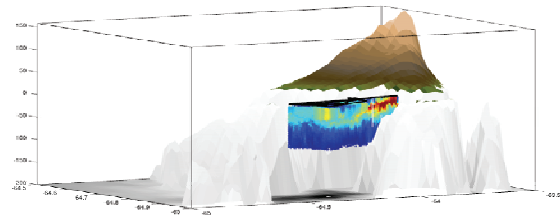

Figure 6. A 3-D section of chorophyll fluorescence measured offshore Palmer Station in December 2008. The high chlorophyll values are associated with upwelled water. The next phase of the research is to understand if this upwelled water is associated with the Antarctic Circumpolar Deep Water.

Urbanized ports are often process-rich environments with strong signals to study, but the difficulties of working in a heavily used environment often preclude scientific study. These areas are often regions of high current. Therefore it is critical to develop the new automated flight behaviors that allow the glider to sense its environment and make smart decisions to enact the best behavior to sample the local environment while avoiding contact with humans. This challenge is perhaps the most difficult to tackle.

A final theme is to extend the limits of long-duration underwater glider flights. These efforts have focused on developing new power and control systems. The long duration studies are powerful magnets to entrain undergraduate students. These flights have the potential to increase the visibility of ocean exploration to the general public. The Coastal Ocean Observation Lab is developing new undergraduate initiatives as part of a University-wide effort to transform undergraduate education at Rutgers. Enabled by an ocean observatory operations center purposely located on the main campus of a major research university, the lab has established a program featuring hands-on team-based research projects that compliment course-work and are specifically designed to entrain undergraduates. The program encourages students to become involved as early as their freshman year, remaining in contact with many of the same students and professors for their full 4 years at Rutgers. A series of Introduction to Oceanography courses with significant freshman participation, and a variety of small seminar courses given to first-semester freshman, serve as the feeder courses. Interested students join us in the lab in their second semester, either through 1-credit research courses or work-study programs.

These courses are focused on specific long duration glider missions to teach to students oceanography while simultaneously gaining hands-on experience. The initial task supported by the undergraduate student team - to be the first to fly an autonomous underwater glider from Tuckerton, New Jersey to Halifax, Nova Scotia - was accomplished in the spring of 2008. Their second task, still ongoing, is to be the first to fly a glider across the Atlantic from New Jersey to Spain. Rutgers alumni donated a glider for use as the primary platform to engage undergraduates in projects related to ocean observatories. The National Science Foundation provided a RIOS summer intern, in this case an aeronautical engineer from the University of Maryland. Qualitas, a Spanish company installing and operating the national HF Radar network for Spain, contributed an internship for a student with a dual major in Marine Science and Spanish. Glider training courses, developed and delivered for NOAA-sponsored IOOS projects, used extensively by the operational Navy, NATO and the European Glider Association were used to spin students up over the winter break in every aspect of glider operations. Each student on the team was responsible for a specific aspect of the long-duration flights. Two freshman worked alongside the three glider technicians to help with the construction and testing of the actual glider. At the end of their spring semester, they returned to their high school, giving talks to their science teacher's class and the high school robotics team on what they accomplished at Rutgers in their freshman year. Two juniors worked on the flight characteristics of RU17, optimizing the flight controls and providing feedback to the manufacturer. Two freshmen worked on the NOAA-sponsored IOOS Mid-Atlantic HF Radar network as the launch zone for these two flights, while a junior worked on HF Radar in Spain to help prepare the landing zone. Two seniors worked on path planning, website development, and the Google Earth interface that has been used in three Navy exercises, is part of our Middle Atlantic control center. The first attempt in 2008 failed, as the glider encountered problems close to 200 kilometers from the Azores. The students despite the set back set the world's record for distance covered by an AUV (Figure 7). A second attempt begins in Spring 2009.

V. SUMMARY

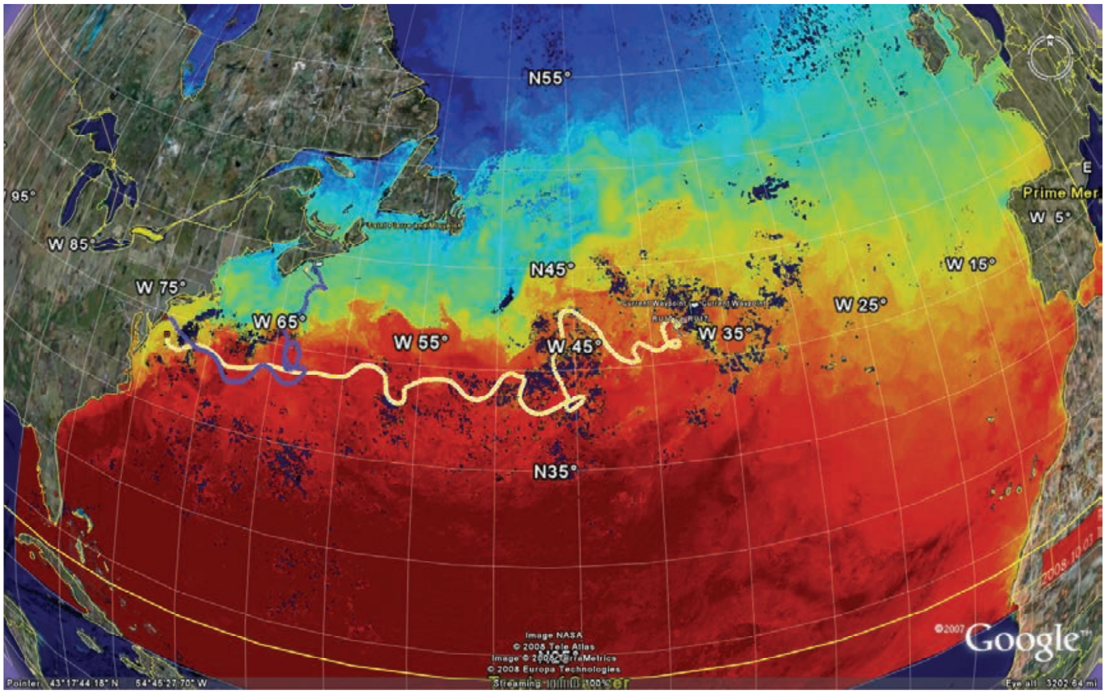

Figure 7. The path of undergraduate glider missions focused on long duration missions. The blue line shows the successful flight from New Jersey to Halifax. The yellow line shows the student's first attempt to cross the Atlantic.

Gliders are a robust technology that allows scientists to maintain a sustained presence in the ocean and this will enable oceanographic to tackle critical issues facing the community. The gliders will also provide a unique technology that will entrain the next generation ocean scientists and engineers. These two factors make it a very exciting time to be an oceanographer.

ClearSignal Coating Controls Biofouling On the Rutgers Glider Crossing

A Nonstick Coating Gives the Scarlet Knight Glider Permanent Biofouling Control on Trans-Atlantic Mission

One of the most exciting new tools in present day oceanography is the glider, which can perform sustained collection of oceanographic data. Gliders are unique in that they provide the ability to conduct long-term oceanographic data collection missions on a mobile and directionally controllable platform.

The glider's performance is derived from its highly efficient buoyancy-derived propulsion system, enabling the platform and associated sensors to be deployed for many days or even months of sustained oceanographic sensing over navigationally controlled long distances.

The attributes of the glider—extended mission deployments and high-efficiency, low-power propulsion—are not without operational vulnerabilities. By virtue of their extended immersion times, long-deployment glider missions have an increased susceptibility to the settlement of biofouling organisms on all of the glider's exposed surfaces. Even a low to moderate degree of biofouling can impart enough hydrodynamic drag to significantly inhibit or prevent both forward movement and directional control of the glider.

Biofouling on Gliders

A glider's susceptibility to biofouling attachment depends on a number of environmental and operational factors. The most important of these are geographic location, water temperature, mission duration, operational depths and the seasonal variabilities of biofouling organisms. In general, seasonally warmer waters and shallower depths are more conducive to biofouling settlement. The gooseneck barnacle is the most common biofouling organism that gliders and other open-water platforms encounter.

Glider prior to biofouling.

(Below) Recovery of the Scarlet Knight.

Scarlet Knight Atlantic Crossing

Rutgers hosts a glider team consisting of several professors/principle investigator scientists, an equal number of glider-dedicated engineers and technicians and a significant contribution from both undergraduate and graduate students. The overall goals of the team are to use and advance the capabilities of gliders for oceanographic data acquisition in support of advanced climate studies.

The team configures and operates several gliders manufactured by Teledyne Webb Research Corp. (East Falmouth, Massachusetts). The scientific data collected from glider missions is used to further develop and refine oceanographic prediction models that are a major component of climate and climate change studies.

One of these gliders, the Scarlet Knight, recently completed a trans-Atlantic crossing conceived so as to fulfill the following mission requirements: proving the ability of gliders to perform long-duration missions, collecting critical physical oceanographic data during the transit and providing a complex and science-based mission that could in large part be run by students.

The Scarlet Knight was launched on April 27, 2009, off the coast of New Jersey and recovered on December 4 off the coast of Northern Spain, having traveled a distance of just more than 4,600 miles.

Controlling Biofouling on Gliders

In the years leading up to the Scarlet Knight mission, as the Rutgers team worked on extending the mission durations of their glider fleet, it became increasingly evident that biofouling was becoming a major factor limiting shallow (less than 200 meters) glider mission durations and transit distances achieved.

In response to this concern, the Rutgers team initiated an investigation to determine if a suitable biofouling control technology existed for use on their Scarlet Knight glider. The first steps in the investigation were the development of a glider biofouling coating performance criteria and an analysis of available biofouling control solutions.

A somewhat unique requirement for gliders is that of a constant density anti-fouling coating. Gliders are ballasted and trimmed to within several grams of weight and must remain at this set condition for the entire mission. Durability, long-term effectiveness and safety in handling are obvious attributes that must be achieved by a biofouling control system. A final desired attribute is for the coating to be optically clear. This enables the glider as configured to retain its identity of color, logos and other identifying markings, including contact numbers and handling instructions for vessels it may encounter on its mission.

Traditional Biofouling Solutions

Historically, biofouling control has been achieved by exploiting the toxicity of metals, organometals and other similar marine invertebrate biocides and incorporating them in paint matrices to form anti-fouling coatings.

This class of coatings and associated methodology is unacceptable for gliders for a number of reasons.

The use of released organometals to achieve biofouling control is not acceptable for gliders because the density of the coating changes as the metal is released from the paint matrix. This is also true of most nonmetal biocides.

This problem is further exacerbated when using an ablative paint matrix, as is common in most traditional anti-fouling paints.

The traditional anti-fouling paints also often impose occupational hazards to those handling coated equipment. At Rutgers, many of the handlers are young students. Another consideration is that the long-term effectiveness of the paints is limited because the active biocide is eventually all released from the paint matrix over time. This would necessitate the annual removal and recoating of a paint system, which is time consuming and imposes additional occupational and hazardous material issues. Finally, the traditional anti-fouling paints are not transparent.

Other anti-fouling techniques that are sometimes used on oceanographic instrumentation, such as ablative greases containing various pepper extracts, were also evaluated, but they were judged to be unacceptable when evaluated against the performance requirements of long-term effectiveness, durability, occupational safety and constant density.

Biofouling Solutions for Gliders

A newer class of coating that is specifically formulated for undersea instruments (optical or acoustic, for example) and specialized platforms such as gliders has recently emerged and was identified by the Rutgers engineering group as a good candidate for the Scarlet Knight. This coating, ClearSignal™, is a clear, nontoxic, rubber-like coating that resists biofouling because of the nonstick properties of the material itself. The product is a permanent coating that is designed to last for the life of the platform or instrument it is protecting.

The ClearSignal biofouling control system is the product of a joint development effort by Severn Marine Technologies LLC (SMT) and Mercer Island, Washington-based Mid-Mountain Materials Inc. (MMM).

The companies originally developed ClearSignal to coat instruments used in the offshore seismic exploration industry. The product was recently reformulated to accommodate the larger oceanographic research community.

"ClearSignal is a clear, nontoxic, rubber-like coating that resists biofouling because of the nonstick properties of the material itself."

Coating Selection and Use

After a careful review and evaluation of a variety of biofouling solutions by the Rutgers marine lab, it was determined that the ClearSignal anti-fouling system was the best solution for meeting all of the performance requirements described. It was determined that for this initial implementation of ClearSignal, the yellow main body sections were to be coated. This comprised approximately 90 percent of the Scarlet Knight's surface area. The individual glider sections were sent by Teledyne Webb Research Corp. to the SMT-MMM coating facility in Arlington, Washington, for application of the coating. The coated sections were then sent to Rutgers so that the Scarlet Knight could be assembled and configured for the transatlantic crossing.

Coating Performance

The Rutgers research team documented the performance of the glider anti-fouling coating during its transit through diver inspection and photography in the Azores, as well as inspection upon recovery off the coast of Spain.

In early July, three months into the crossing, Rutgers observed that the glider was having trouble turning and holding its navigation course as instructed. This was the first indication that at least a moderate degree of biofouling was adversely affecting the glider. The control problems became more acute in mid-August, with the Scarlet Knight losing a significant portion of its steering and navigational ability as it headed toward the Azores.

With the journey three-quarters complete and the Scarlet Knight's forward propulsion and control now at a critical state, the Rutgers field service glider team intercepted the glider in late August at its location west of the Azores.

Observations and Actions Taken

An initial inspection of the Scarlet Knight revealed a significant settlement of gooseneck barnacles on specific areas of the glider. It was obvious from the outset that Scarlet Knight was being impeded by the observed barnacle settlement.

The ClearSignal-coated yellow main body sections of the Scarlet Knight were free of all but minor barnacle attachment. The biofouling that did occur was mostly sporadic and consisted of small individual barnacles. It was also noted that some of the sporadic biofouling that occurred on the ClearSignal-coated body were in areas where the biofouling had propagated from the heavily biofouled uncoated sections of the glider.

The glider sections that were not coated with ClearSignal, such as the front-nose-cone pump section aft of the nose cone, connecting seams and the conductivity, temperature, depth (CTD) sensor area had moderate to severe biofouling.

The areas that were most vulnerable and had the highest accumulation of barnacles were the seams between the glider sections, wing rails and the areas on and near the CTD sensor. It is important to note that these areas suffered from severe biofouling as a result of not being coated with ClearSignal and because of the turbulence generated by the glider surface discontinuities in these areas. It is a known phenomenon that barnacles accumulate in these types of low-pressure turbulent areas.

The biofouling noted was cleaned by the divers on site without removing the Scarlet Knight from the water. As reported by the divers, the small degree of biofouling removed from the ClearSignal-coated areas of the Scarlet Knight were removed with almost no effort. The significant barnacle accumulation removed from the areas not coated with ClearSignal required a moderate degree of effort.

After the Scarlet Knight was cleaned, it was given a check for operational soundness and sent back on its way to Spain.

Observations in Spain

The Scarlet Knight performed well on its final leg of the crossing, but did show impediments to its speed near the end of the journey in November and December. The recovery on December 4 provided a second opportunity to assess the glider's vulnerabilities to biofouling and the performance of the ClearSignal solution.

The biofouling settlement observed in Spain was the same species of gooseneck barnacle and was greater in degree and areas of settlement than observed in the Azores. Again, the most vulnerable areas were the body-connecting seam areas, wing rails and CTD areas, the portions of the glider unprotected by ClearSignal and subject to high turbulence. It was also observed that the wing sections were moderately biofouled. Overall, the ClearSignal-treated sections of the Scarlet Knight had little to no fouling settlement. There was, however, moderate biofouling on the ClearSignal-coated area where barnacle settlement had propagated from the vulnerable and uncoated highly biofouled areas of the glider.

"Overall, the ClearSignal-treated sections of the Scarlet Knight had little to no fouling settlement."

As with the cleaning in the Azores, the effort to remove the barnacles from the body-section seams, CTD areas and other nontreated areas of the glider was moderate. The effort required to clean the small degree of settlement on the ClearSignal-coated areas was minimal.

Conclusions

The implementation of the ClearSignal biofouling control coating was integral to the Scarlet Knight's successful and historic Atlantic crossing. The coating system achieved this performance while meeting the important criteria of providing an anti-fouling coating with constant density, constant efficacy over time, optical clarity and long-term durability.

"The coating system met the important criteria of providing an anti-fouling coating with constant density, constant efficacy over time, optical clarity and long-term durability."

The ClearSignal system worked extremely well, as there was little to no biofouling settlement on the majority of the surface area protected with ClearSignal. Where areas of moderate biofouling attachment to the ClearSignal were observed, it was due to the propagation of barnacle settlement from the most vulnerable areas noted.

Since the barnacle settlement occurring on the seams of the glider sections was due to the turbulence generated in these areas and the lack of a biofouling treatment, the prescribed approach for eliminating the biofouling associated with these areas is to tape off these seams to eliminate turbulence and then coat with ClearSignal.

The implementation of additional ClearSignal coating and the turbulence reduction methods noted will significantly reduce the settlement of biofouling in these areas and significantly reduce the propagation of barnacles.

This is especially important as oceanographers seek to extend the duration of glider missions focused on the upper ocean. ■

Rutgers University

***Abstract*— Autonomous underwater vehicles (AUVs) are indispensable tools for marine scientists to study the world's oceans. Depending on their missions, AUVs are equipped with advanced sensors (sonar, cameras, acoustic communication, bio-sensors), have on-board computers for data analysis (image analysis, data compression), and are capable of on-board decision making (resource planning, swarming). Since AUVs operate solely on battery power, power and energy management is a crucial issue. Mission-critical tradeoff decisions have to be made between energy consumption and sensing, data processing, and communication activities. Mission planning has to consider these tradeoffs when provisioning resources for expected future events, or when dealing with changing environmental conditions such weather, water currents, and seafloor profiles. Effective power and energy management requires knowledge about the actual energy consumption of each active component within the AUV. Effective planning requires simulators that can predict energy consumptions based on expected future events and environmental conditions.**

In this paper, we discuss the design and implementation of a power measurement infrastructure for the Teledyne Webb research Slocum glider. This infrastructure can be used for online power/energy management or to better understand the time-dependent energy consumption profile of the active glider components during a particular mission. We also discuss the design of a new simulation environment for the Slocum glider which uses the power/energy data obtained by our measurement infrastructure, in addition to seafloor and coastal radar information. We illustrate the effectiveness of the new tools in the context of planning a glider flight across the continental shelf off the coast of New Jersey.

I. Introduction

The mission endurance of today's Autonomous Underwater Vehicles (AUVs) depends highly on the capacity and usage of the vehicle's batteries. Typically, missions for the Slocum Electric Glider last about 30 days [8]. Longer missions, such as the 221 day mission to cross the Atlantic by RU27 from Rutgers University [10] are possible through an increase in the number of batteries and through the careful planning of the usage of the vehicle's devices. Such planning is also crucial for shorter missions when gliders are equipped with advanced sensors such as an Acoustic Doppler Current Profiler (ADCP) or acoustic underwater communication.

With the recent integration of the coulomb meter into the glider, measuring the discharge of the battery has become more accurate. Knowing the rate at which energy is used and how much remains is vital to mission planning. However, the glider's coulomb meter only measures whole vehicle current. To perform more precise mission planning, being conscious of the energy consumption of individual components is necessary. We have developed a measurement infrastructure which captures the currents drawn from distinct components of the Slocum Glider. The infrastructure has been deployed in test missions off of the coast of New Jersey, and the data collected have been integrated into a Slocum Glider simulator. Our measurement board and simulation framework can be used to assist in the planning and decision making of missions and shows possible tradeoffs, for instance, between mission duration, speed, and energy consumption.

II. Measurement Infrastructure

We have created a measurement infrastructure to measure and record the electric current drawn by individual devices of the Slocum glider. The infrastructure consists of a measurement board and a data logger. The design philosophy in creating the infrastructure was to not compromise the safety of the vehicle, even if quality of the resulting measurements are affected. The

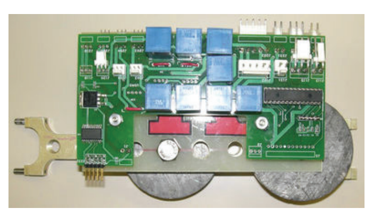

Fig. 1. Measurement board mounted on a weight bar used for ballasting the Slocum glider.

978-1-4244-5222-4/10/$26.00 ©2010 IEEE

glider components measured are: the main, external, and emergency power, the buoyancy pump and brake, and the pitch and fin servos.

The measurement board, shown in Fig 1, was intended to be housed above the glider's mainboard in the aft section of the vehicle. However, due to the different space constraints between different generations of gliders, the board was moved to the center payload bay. This allows the board to be quickly uninstalled and re-equipped onto another glider.

The board makes use of eight Hall Effect sensors which do not interfere with the vehicle's current flow. This ensures that in the event of sensor failure, the glider will continue to operate normally. Three 20A sensors are used for the main, external, and emergency power, while two 5A sensors are used for the buoyancy pump. Three 3A sensors are used for the buoyancy pump brake, pitch servo and fin servo. The sensors were over-provisioned for safety, but still allow the capture of large spikes in the current.

The microprocessor used in our design was the PIC16F767. The processor typically operates at less than 2mA at 8MHz. It contains eleven 10-bit analog-to-digital (A/D) channels of which eight are in use to measure the currents drawn by the glider using the Hall Effect sensors. The microprocessor has been programmed to use interrupts to generate constant samples at 32ms intervals. These samples are transmitted to the glider's science bay processor.

The measurement board communicates its samples via a 9,600 baud serial connection to the science bay processor. The stock 6.38 software version of the glider's science computer software has been retrofitted to record the samples produced and transmitted by our measurement board. The science processor, a CF1 from Persistor Instruments Inc. [6], is typically clocked to run at 3.68MHz using the stock software, but is usually run at higher clock speeds when collecting data as part of our infrastructure.

The power consumption of the science processor is shown in Table I. The CF1 as programmed during our previous deployments, was clocked at 14.72MHz which consumed approximately 520mW more power than the stock software release. We have since developed optimizations in the logging process to reduce energy consumption. These improvements allow the clock speed to be lowered down to 3.68MHz provided that the mission specifications allow for the trade off of four second, instead of two second, sampling from the conductivity, temperature and density (CTD) sensor. The CTD is a standard sensor on a Slocum glider.

The power consumption of the measurement board

TABLE I
CF1 POWER CONSUMPTION

Software	Clock Rate (kHz)	Power (Watts)
Stock 6.38	3680	0.19
Deployed 6.38	14720	0.71
Development 6.38	3680	0.35
Development 6.38	7360	0.49

TABLE II
MEASUREMENT BOARD POWER CONSUMPTION

Description	Channels	Power (Watts)
Deployed	8	0.76
Development	6	0.58

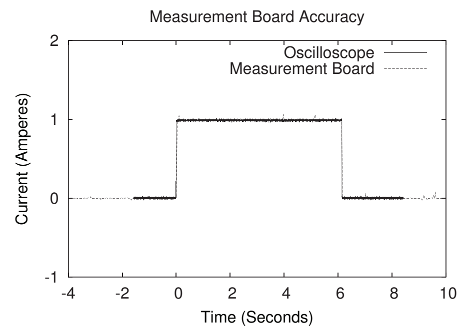

Fig. 2. Assessment of the measurement board's accuracy using a Tektronix MSO4034 oscilloscope.

itself is shown in Table II. After deploying gliders equipped with our infrastructure we have found little use in measuring the external and emergency current. The external power supply is only active on bench, so it is unnecessary for a board which will be deployed at sea. In the event of a emergency, the safe recovery of the vehicle is of higher priority than collecting good data. The presence of the emergency sensor could not be justified for the additional power it consumes. By removing the two Hall sensors, 180mW of power was saved. An additional benefit comes from the fact that the measurement board and the science processor now measure, transmit, and log less samples allowing for more data to be collected.

The measurement infrastructure has been extensively tested to ensure that recorded current samples are representative of the actual events. Fig 2 shows the results of a test where a current of 1A was applied to one of the sensors for approximately six seconds. The event was measured and logged by a Tektronix MS04034 oscilloscope as well as a PC connected to our measurement board. The results of these experiments indicate that the samples collected are within the expected error of the sampling rate, A/D conversion and the sensors

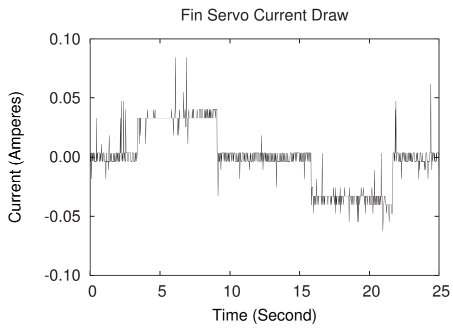

Fig. 3. Current draw of the fin servo during a "wiggle."

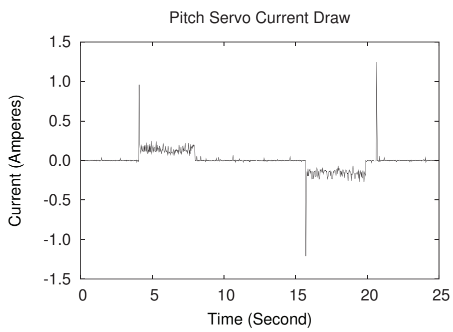

Fig. 4. Current draw of the pitch servo during a "wiggle."

themselves.

The infrastructure as installed on the gliders records all measured samples. Without compression, data can be recorded for mission lasting up to 26 days. However, multi-week missions using this revision of the board with alkaline batteries are not feasible due to the significant energy overhead. It may be possible if lithium batteries are used instead. In future work we hope to significantly reduce the power dissipation of the system so that full length deployments are possible.

III. Deployments And Measurements

The measurement infrastructure has been installed and deployed on two Slocum gliders. It has been used to collect current readings of the vehicles on the bench top as well as at sea. The sea trials took place off of the coast of New Jersey in September of 2009 and in February of 2010.

Before the measurement infrastructure was trusted to be deployed, it was installed in the glider and extensively tested on the bench top. To ensure the vehicle components still performed up to par in the presence of the measurement board, the vehicle's motors were subjected to "wiggle" tests. This entails moving its motors through their full range of motion. Sample results of such a wiggle of the fin and pitch servos are depicted in Fig. 3 and Fig. 4, respectively. The Hall Effect sensors used for these devices are bipolar so the reported currents show the current flow in both directions as the servos move the opposite direction. The fin is used to steer the vehicle, and the pitch motor is used to fine tune the vehicle to the commanded pitch by moving an internal battery pack. The power draw of these two motors is generally very low, and during a mission motor activities typically occur in brief bursts. Through wiggle, overnight, and weekend tests the system was deemed stable and reliable for sea tests.

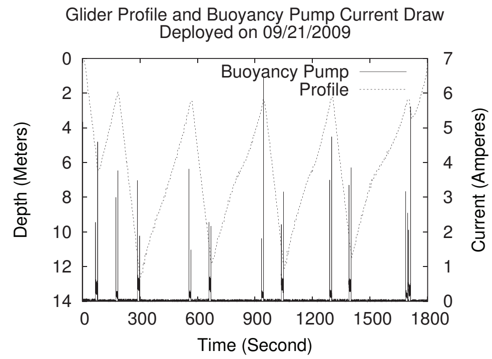

Fig. 5. Current drawn from the buoyancy engine during our deployment. The flight profile is shown together with the current draw of the buoyancy pump. It can clearly be seen that the buoyancy engine activities align with inflection points, and that the power consumption at depth is significantly higher than near the surface.

The first sea trial involved two short mission segments of approximately thirty minutes in length each. The glider was instructed to perform yos, sequences of dives and climbs, between 1 and 20 meters. The glider depth profile along with the current draw of the buoyancy pump of one mission segment are illustrated in Fig 5. The glider never reached a depth of 20 meters because the seafloor was not sufficiently deep enough at the deployment location. The experiences gained in the sea trial were used to prepare the infrastructure for a longer term mission.

The second deployment was a 6.5 day mission in early February of 2010. A map of the glider's path is shown in Fig 6. The mission's goal was to fly to the continental shelf to gather buoyancy engine readings at depths of up to 100 meters. The mission was cut short due the combination of inclement weather and the high power consumption of our measurement infrastructure. After heading east toward the shelf for two days, the vehicle was commanded to head north because a Nor'easter storm was expected to push the vehicle south. After being forced south for two days, it was again commanded to head east towards the shelf to gather readings at deeper

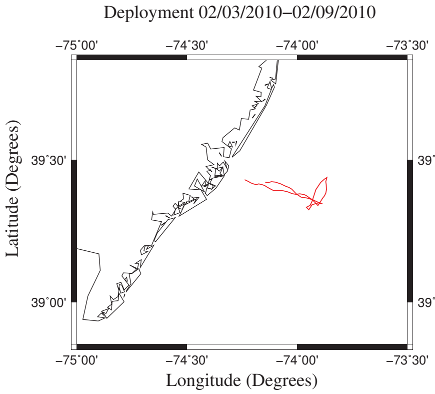

Fig. 6. Flight path of the mission deployed with the measurement infrastructure in February of 2010.

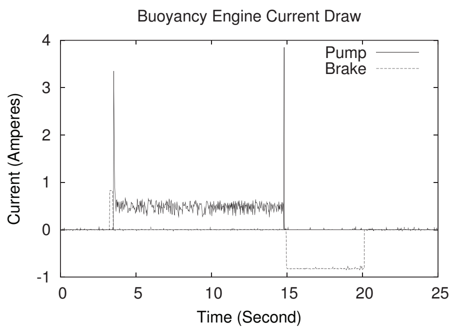

Fig. 7. Current draw of the buoyancy engine during an inflection at approximately 12 meters.

depths for a short time. Unfortunately, another Nor'easter was imminent so the mission was aborted and the glider spent the remaining time flying back to shore to be retrieved.

The buoyancy engine of the electric Slocum glider consists of a buoyancy pump and a brake mechanism. The pump moves a piston to change the vehicle's buoyancy by altering its displacement of water. The brake locks the pump's position in place which would otherwise be forced to retract due to water pressure. The current draw of the buoyancy engine is shown in Fig. 7. When commanded to inflect from a dive to a climb, or from a climb to a dive, the brake first unlocks the pump. The pump follows by moving the piston to the commanded position. When the position is reached, the brake again locks the pump's position in place.

The energy used by the buoyancy pump increases with depth because the pump must work harder to battle the additional pressure. This was confirmed by our first sea trials, Fig. 5, where inflections from a dive to a climb state used more energy when the inflections occurred at three, six and twelve meters. Fig. 8 depicts the measured

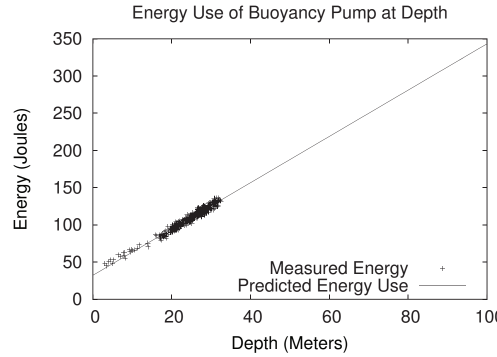

Fig. 8. Energy use of the buoyancy pump at depth.

energy used by the pump during the deployment in February of 2010. The energy used for similar depths in the two seal trials were comparable considering different gliders were used. In both missions, however, the energy necessary for the pump to perform inflections from a climb to a dive at shallow depths is at times less expensive than the cost associated with the brake. Having detailed knowledge of the cost of components is important when trying to optimize vehicle flights.

IV. Simulator

To assist in planning of future missions, we have created a simulator for the Slocum glider. The simulation environment incorporates energy, speed, seafloor and sea surface current models, and is used to predict the flight path, longevity and energy usage of a mission. The simulation environment has been validated against Teledyne Webb's Shoebox simulator and compared to a deployment to the continental shelf off of the coast of New Jersey.

A. Implementation

The longevity of missions performed by AUVs rely on the limited energy resources the vehicle carries on board in its batteries. This resource limit can effect the quality of missions. Missions which require the vehicle to maintain a constant presence at a location or require traveling to an area of interest are constrained in the amount of information they can collect. For the aforementioned reasons, we have developed and implemented new energy models in our simulation environment.

The energy models were formulated from the samples recorded by our infrastructure along with the voltages reported by the glider. Our simulator uses models for the buoyancy pump, brake and steady state load, where no motor and most devices are not in use. The average observed cost associated with the brake is applied at

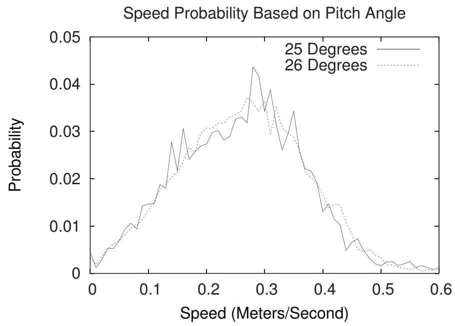

Fig. 9. Speed distribution derived from over four years of glider flights.

every inflection point. The expense of inflections near the surface where the vehicle state changes from a climb to a diving state is modeled as a constant. Inflection performed at depth from a diving to a climbing state use a linear cost function. The function has been fitted to the data points from the deployment in February 2010. The function is shown in Fig. 8 labeled "Predicted Energy Use." The energy used in simulated missions is dependent on the vehicle's pitch angle and speed. The pitch angle of the flight impacts the number of inflection points, and thus the use of the buoyancy engine. The speed determines the amount of time required to complete the mission.

The simulation environment makes use of two types of speed models. The first is a model similar to that of the Slocum glider's shoebox simulator. The Shoebox, named after its physical similarities to a shoe box, contains the essential glider electronics to perform simulations in real time. The software running in the Shoebox is the same software used during deployments but makes use of simulated device drivers. The speeds and missions generated by this model when used in our simulator should be similar to that of the commercial Shoebox. However, unlike the Shoebox, our framework is able to simulate missions significantly faster than real time.

The second speed model integrated into the simulator is based on speed distributions which were empirically derived from over four years worth of glider flight data. The flights took place off of the New Jersey coast between the years of 2003 and 2009. The resulting distributions are shown in Figure 9 and were constructed by measuring the distance covered in each dive segment and the time necessary to travel the segment. A dive segment starts when a glider submerges and ends when it resurfaces. The 25° distribution was comprised of 2,539 segments, covering 6,263km over 293 days, while the 26° distribution span 16,411 segments, 32,527km and 3.48 years. Sufficient data to build speed distributions were available only for 25° and 26°, which are the most common angles used by the Slocum Glider. These speeds are sampled by the simulation environment to produce realistic over-the-ground speeds. Although very similar, the 26° distribution is slightly faster than the 25° distribution. Along with the dive and climb pitch angles specified by the mission, the depth rate is calculated and used to position the glider in space. The depth rate and the seafloor determines the number of inflections that occur during flight.

The simulation environment also supports the use of a seafloor terrain. The seafloor model used may be artificial, come from prior deployments as measured by a glider, or can be interpolated from NOAA's National Geophysical Data Center's (NGDC) bathymetric data set [7]. The current data set (from the NGDC) used by the simulation environment is of the coast of New Jersey at a resolution of one arcminute. The addition of a seafloor model improves the quality of the vehicle's predicted energy usage especially in shallow waters. Simulated open ocean deployments, or deployments where it is known that the glider will never reach the seafloor will not benefit from a seafloor model, and could therefore be removed for such missions.

Time dependent sea currents can significantly impact the flight profile of a glider, and are therefore modeled within our simulation framework. The currents may be artificially and dynamically generated, or can be interpolated much like the seafloor. The use of Coastal Ocean Radar (CODAR) [5] data from Rutgers University has been integrated into the framework. This data describes the sea surface currents of the New Jersey area at a spatial resolution of six kilometers and a temporal resolution of one hour. The addition of sea currents add another degree of realism which should improve the prediction quality.

Our simulation framework can be used to analyze past glider flights, support active deployments, or help to plan future missions. CODAR information is valuable when simulating past flights and can be used in the decision making of active missions. For example, if recent sea surface current data is available, it can be used to predict the location of where the glider may resurface next. With the utilization of weather trend or prediction models, such as the Regional Oceanic Modeling System (ROMS) [9], the simulator could also forecast the general outlook of missions.

B. Validation

To validate our simulation infrastructure we have compared its predictions to that of Teledyne Webb's

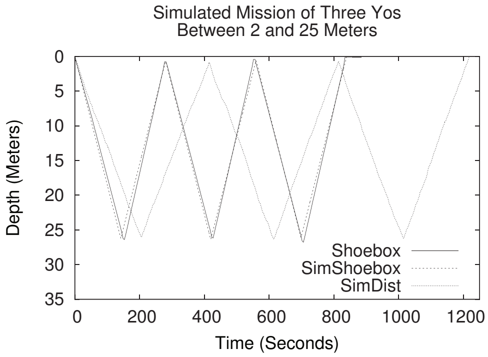

Fig. 10. Validation of the simulation environment with respect to the Shoebox simulator.

Shoebox simulator. The mission executed on both the Shoebox and our simulation framework entailed three yos (a sequence of climbs and dives) between 2 and 25 meters.

The depth profile of the simulations are shown in Fig. 10. The Shoebox profile describes the flight as performed by the Shoebox simulator. SimShoebox and SimDist are the flight profiles generated by our simulation environment. SimShoebox generates speeds similar to that of the Shoebox, while SimDist sampled speeds from the distribution in Fig. 9.

The time necessary to complete the missions for Shoebox and SimShoebox are very similar. Like the Shoebox, our simulated vehicle also slightly overshoots the commanded depth limits. On average, the SimShoebox is slightly slower, taking several seconds longer to complete the mission. The results produced are however a reasonable representation of what may be generated by the manufacturer's simulator. The advantage of our simulation framework lies in the runtime necessary to produce the simulated mission. The Shoebox took approximately 15 minutes to simulate the sample mission, while SimShoebox required only 0.35 seconds on a 2.2GHz dual core processor.

The flight simulation which applies the speed distribution model, SimDist, requires an additional 380 seconds longer in mission time than both the Shoebox and SimShoebox. The simulation took 0.5 seconds. This suggests that the vehicles speed is on average slower using this model than that of the Shoebox. We believe the speed model based on speed distributions is more accurate than the Shoebox model since it is derived from over fours years worth of vehicle flight time. The speed distribution model should then not be compared to that of the Shoebox simulator but against an actual deployment.

V. Deployment Simulations

To validate the simulator and its speed distribution model, a deployment from September 2009 is compared to similar flights in our simulation environment. The goal of the original mission was to fly to the continental shelf from the coast of New Jersey and back at 26°. The flight path of the mission is illustrated in Fig. 11(a). Due to strong currents for portions of the mission, the glider was pushed south preventing it from making steady forward progress towards the target waypoint. An operator interfered with the flight and changed the target waypoint due west back to shore before the vehicle reached the commanded waypoint near the continental shelf. Waypoints were changed further throughout the mission, causing the vehicle to reach none of the target waypoints except the last which was used to collect the vehicle. The total length of the deployment was 14.84 days. To validate the simulation framework a similar deployment length should be achieved.

A. Baseline

The baseline simulation assumes that no seafloor or currents exist in the environment. Consequently, the runtime needed to simulate the mission is small, but the predicted mission will also not be very accurate. The simulated mission flown in the remainder of this section will be that of Fig. 11(a) except that the vehicle will be commanded to keep flying until it has reached all its waypoints. It is difficult to reenact the intentions or reasoning behind the operator's actions so they are ignored.

The SimShoebox simulation of the mission predicts a mission length of 7.9 days, with the energy usage of 707kJ and a flight path as depicted in Fig. 11(b). A runtime of 20 seconds was needed to simulate the mission. SimShoebox, which has been shown in the previous section to be fairly representative of the Shoebox simulator, would suggest a real time simulation of 7.9 days. If the speed distribution is used instead in the simulation (SimDist), the mission length increases to 11.5 days, 785kJ and a runtime of 86 seconds. SimShoebox in this scenario has erroneously estimated the mission length by 6.94 days while SimDist by 3.34 days. Unlike the previous validation experiment, the speed distribution produces a better estimate when compared to a real deployment

B. Seafloor Model

To add a layer of realism, the simulation environment can use a seafloor as previously described. Instead of flying to the full commanded depth, the vehicle must inflect several meters above the seafloor to avoid impact.

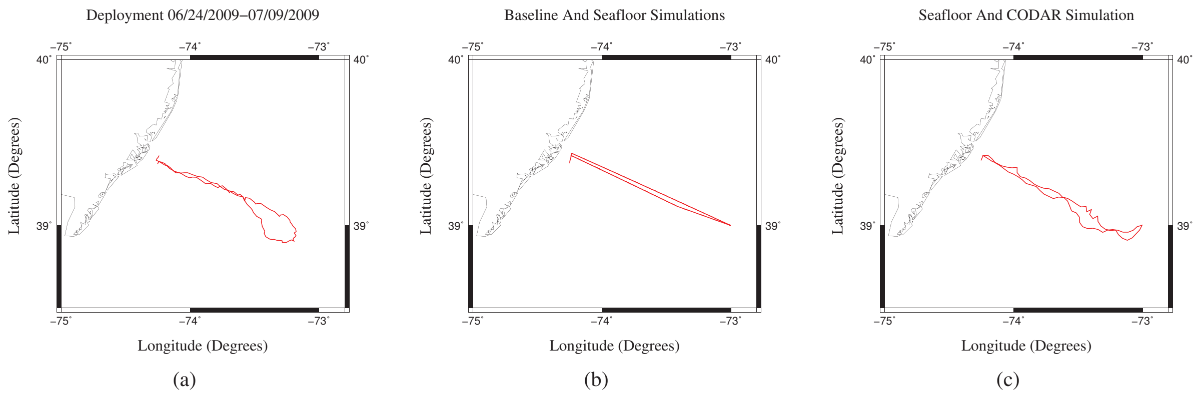

Fig. 11. (a) The flight path of the mission being simulated. (b) The flight path of the baseline and seafloor simulations. (c) The simulated mission using both seafloor and CODAR data.

TABLE III
SPEED DISTRIBUTION SIMULATION RESULTS

Mission	Seafloor	Currents	Time (days)	Energy (kJ)	Runtime (min)
Actual	N/A	N/A	14.84	N/A	N/A
Baseline	No	No	11.5	785	1.4
Seafloor	Yes	No	11.5	984	5.7
CODAR	Yes	Yes	14.89	1,235	20

This will increase the total number of inflections points in the mission which directly translates into more energy use because the buoyancy engine is activated at each inflection. The mission length and flight path for both SimShoebox and SimDist remain nearly identical to the baseline but the energy usage increase to 892kJ and 984kJ, respectively. The modeling of the seafloor is paramount so that missions may be more accurately predicted and planned for.

C. Seafloor And CODAR Models

The final model supported by our framework is that of the sea currents. The CODAR sea surface currents of the days surrounding the deployment of Fig. 11(a) were integrated and applied to the simulated mission. The flight map of SimDist is shown in Fig. 11(c). The SimDist mission flew for 14.89 days using 1,235kJ of energy and required 12 minutes to simulate. SimShoebox's mission flew for only 8.88 days, used 986kJ, and had a runtime of 5 minutes.

The presented simulation results indicate that the speed distribution model was more representative of the deployment in Fig. 11(a) than that of the speed model which is similar to the Shoebox. A summary of the simulations for SimDist is listed in Table III. The final SimDist mission using both the CODAR and seafloor resulted in a mission time slightly longer than that of the real deployment. This is however expected since the simulated mission flew a slightly different mission where the vehicle actually reached the waypoints and was not interrupted by an operator. Modeling the supervision as part of the mission is a difficult task because the intentions of the operator at the time are not known. Errors associated with the spatial and temporal resolution of the seafloor and CODAR data also add to the difficulty of recreating the original mission.

VI. RELATED WORK

The modeling of underwater gliders has been extensively studied in the previous work [1][2][3][4][11]. The primary focus lies in the formulation of hydrodynamic models that try to closely emulate the vehicle as it flies through the water. Our work differs in approach in that we use simpler mathematical models and make use of years of glider flight information. Our simulation environment also incorporates empirically derived energy costs of a subset of the vehicle's devices to assist in the planning and prediction of deployments.

VII. FUTURE WORK

We have begun the design of the second revision of the measurement infrastructure. Using the knowledge gathered from the deployments using the first revision, we are choosing more appropriate sensors for each measured component of the glider. Unlike the first revision, we plan to have the ability to customize the rate at which current readings are sampled and logged. This would also entail adding triggers so that only samples of interest are recorded, saving precious storage which would otherwise go to waste recording silent or noisy data. We will also add the ability to log data locally on the board while still maintaining the capability to send a subset of data to the science computer for transmission to shore via a satellite modem. Running the measurement board on a separate power source is also desirable so that longevity of the mission and the samples themselves are not influenced by the presence of the board. Finally, we would like to expand the number of glider components we monitor. Other devices such as the air pump (used to breach and keep the glider at the surface), and the iridium satellite modem use a great deal of energy over time due to the length and frequency that the vehicle surfaces. New sensor payloads such as an ADCP or an acoustic modem will require careful power and energy management as well.

In the future we will continue to improve the simulation environment by expanding and implementing more complex models. Integration of ROMS [9] may become an essential component to aid in the prediction and planning of future flights. Additionally, although energy models from the components we have measured have already been incorporated into the simulator, the focal point thus far has been the energy usage of the buoyancy pump. Refining the energy characteristics of the other devices in the simulator would lead to more accurate mission predictions. Once complete, we would like to simulate the deployment from February 2010 and compare the simulated energy usage against the actual energy usage measured by our measurement board.

During the development of the next revision of the measurement infrastructure we will continue to improve the current system to prepare it for additional deployments. Specifically, we are planning to fly to the edge of the continental shelf to gather more buoyancy pump samples at depths of up 100 meters, which is the operating depth of most of our gliders. The additional samples could help determining the accuracy of the buoyancy pump's energy cost function.

Finally, integration of the presented work with our previous work [12] is underway. The simulation framework will be used to execute and analyze missions specified in our programming language. The complete system will allow for the development and testing of complex missions. The Linux single board computers we have integrated into the Slocum glider allow for simulations to be run online and may assist in the steering of the vehicle so that dead reckoning error may be reduced.

VIII. Conclusion

We have described the implementation of a measurement and simulation infrastructure for the Slocum Glider. Energy cost models derived from two sea trials have been incorporated into the simulation environment. Using over four years of previous glider flight data we have constructed distributions to define the vehicle's speed over ground. Along with the use of a sea floor data set from NOAA, and sea surface current data from Rutgers University, we were able to simulate a vehicle's flight path, mission time, and energy usage. The framework has been evaluated against a simulator produced by the Slocum glider's manufacturer as well as a deployment off the coast of New Jersey. Simulation results indicate that the framework can produce sensible mission estimations with low computation costs.

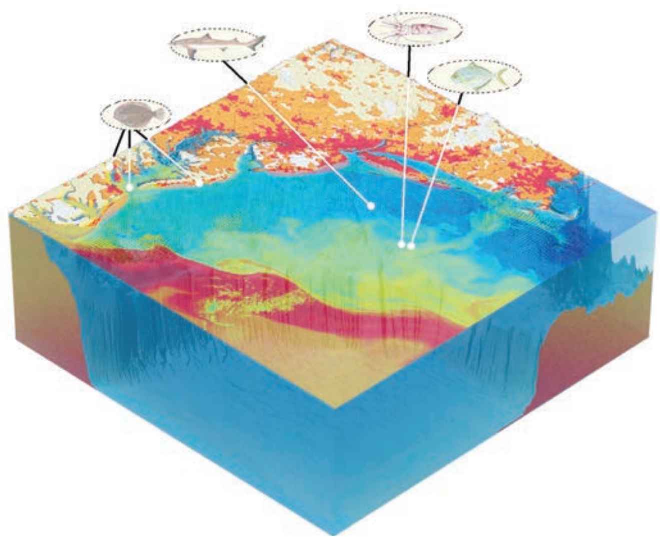
ABSTRACT: Ocean Observing Systems (OOS) now provide comprehensive descriptions of the physical forcing, circulation, primary productivity and water column properties that subsidize and structure habitats in the coastal ocean. We used generalized additive models (GAM) to evaluate the power of OOS remotely sensed ocean data along with *in situ* hydrographic and bottom data to explain distributions of 4 species important in the Mid-Atlantic Bight, USA, ecosystem that have different vertical habitat preferences. Our GAMs explained more abundance variation for pelagic species (longfin inshore squid and butterfish) than demersal species (spiny dogfish and summer flounder). Surface fronts and circulation patterns measured with OOS remote sensing as well as the rugosity and depth of the bottom were important for all species. *In situ* measurements of water column stability and structure were more useful for modeling pelagic species. Regardless of vertical habitat preference, the species were associated with vertical and horizontal current flows, and/or surface fronts, indicating that pelagic processes affecting movement costs, prey production and aggregation influenced distributions. Habitat-specific trends in abundance of 3 of the 4 species were well described by our OOS-informed GAMs based upon cross validation tests. Our analyses demonstrate that OOS are operationally useful for regional scale habitat modeling. Regional scale OOS-informed statistical habitat models could serve as bases for tactical ecosystem management and for the development of more sophisticated spatially explicit mechanistic models that couple ontogenic habitats and life history processes to simulate recruitment of organisms important to maintaining the resilience of coastal ecosystems.



Data and models integrated in Ocean Observing Systems capture ocean dynamics at scales required for regional habitat modeling and management.

INTRODUCTION

Species distributions reflect the habitat selection decisions individual animals make to maximize fitness under constraints imposed by their perceptual and movement capabilities. Variations in survival and reproduction are the consequences of con-

*Email: john.manderson@noaa.gov

strained habitat selection and the mechanistic underpinnings of spatial population dynamics. The diversity of habitats used by species, and effects of habitat variation on vital rates, including movements, determine the productivity, stability and resilience of regional populations (Secor et al. 2009, Tian et al. 2009, Kerr et al. 2010). Furthermore, the effects of habitat diversity and its loss on the resilience and stability of populations that serve as ecosystem keystones should be translated across a level of ecological organization to affect ecosystem productivity, resilience, and stability. Understanding the ways habitat effects on recruitment are translated into the emergent dynamics of regional populations important in maintaining the resilience of large marine ecosystems is crucial for the development of effective space-based ecosystem management, particularly in the face of rapid climate change (Mora et al. 2007, Hsieh et al. 2010). The development of statistical habitat models that are broad in scope and explicitly consider bottom features as well as the dynamic properties and processes of the water column (e.g. temperature, primary productivity, advection) known to regulate critical physiological, behavioral and demographic rates is a necessary first step toward this end.

Regional scale habitat models have been difficult to develop for coastal species, in part because data describing habitat variation at broad spatial but fine time scales have been unavailable. Ocean Observing Systems (OOS) now provide spatially and temporally comprehensive regional scale descriptions of pelagic features and processes required to understand the ways in which dynamic features of the ocean fluid affect the distribution and recruitment of fish living in it. Ocean Observing data include sea surface temperature and ocean color measured with satellite sensors, surface currents measured with networks of high-frequency (HF) radars deployed along the shore, and physical and optical properties measured by fleets of robots gliding beneath the ocean surface. The data describe the physical forcing, current flows, and sources and transport of detritus, primary and secondary productivity which structure, couple and fuel coastal ocean habitats and thus regulate the recruitment of animals using them. Remotely sensed data have been used to construct habitat models for open ocean pelagic predators, but are not commonly used for coastal species (Valavanis et al. 2008, Zainuddin et al. 2008, Becker et al. 2010, Mugo et al. 2010, Zydelis et al. 2011).

Presently, Ocean Observing data with the broadest spatial coverage are satellite measurements of ocean temperature and color, and HF radar measurements of surface currents. These data can be processed to describe upwelling and downwelling centers and the spatial dynamics of surface fronts where high primary productivity occurs or is concentrated. These products may therefore be most useful for identifying habitat associations of pelagic species. While surface data collected directly overhead of trawl samples may be less useful for describing habitats of demersal animals, particularly in deep water, the vital rates of demersal species are also regulated by surface processes, although effects may be downstream and delayed in time. Distributions of large demersal animals may be influenced to a greater degree by pelagic processes regulating movement costs and prey production, than by structural features of the bottom that may provide smaller and younger stages with predation refugia. Finally, surface features can serve as proxies for important subsurface properties and processes (Castelao et al. 2008).

We used generalized additive modeling to evaluate the power of Ocean Observing data, as well as *in situ* pelagic data and benthic data, to describe the distributions of 4 trophically important interacting species with different vertical habitat preferences in the Mid-Atlantic Bight US coastal ocean. We quantified the strength of species associations with mesoscale pelagic features described by OOS, as well as pelagic and benthic features measured with shipboard CTDs, acoustics and bottom grabs, emphasizing habitat characteristics likely to influence growth, dispersal, survival or reproduction. Finally, we discuss the potential value of current and future Ocean Observing assets and research for the development of regional scale habitat models that could serve as fundamental tools for understanding the role of marine habitat dynamics in ecosystem dynamics and the development of more effective space- and time-based ecosystem management strategies.

MATERIALS AND METHODS

Study area

Our study area was the Mid-Atlantic Bight (MAB), USA, where the dynamics of the coastal ocean are continuously monitored at broad spatial scales but fine time scales by the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS: http://maracoos.org; Fig. 1). The oceanography of the MAB is described in detail elsewhere (Beardsley & Boicourt 1981, Epifanio & Garvine 2001, Lentz 2008). Briefly, the broad, gently sloping continental shelf in

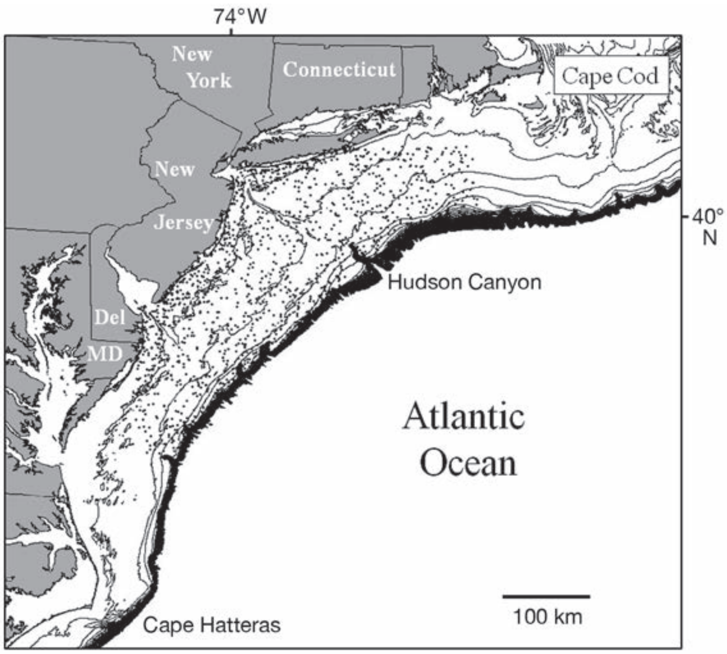

Fig. 1. Locations on the Mid-Atlantic Bight continental shelf, USA, of stations sampled during North East Fisheries Science Center fishery-independent bottom trawl surveys and considered in our analysis of longfin inshore squid, butterfish, spiny dogfish and summer flounder habitat

the MAB is incised by canyons and drowned river valleys that serve as important cross shelf transport pathways. Mean current flow is southwestward and driven by cold buoyant water derived from the northeast. Biological productivity is strongly seasonal. However, air and ocean temperatures, stratification, and wind and buoyancy forcing are extremely variable and superimpose complex, ecologically important variation on mean patterns. Mean southwestward current flows can be intensified by southward, downwelling favorable winds and estuarine discharge, or steered offshore by northward, upwelling favorable winds associated with approaching atmospheric fronts and summer sea breezes. Wind forcing results in sea surface set up and set down along the coast that produces cross-shelf, subsurface counter flows that are strongest along drowned river valleys. During the summer, areas of high primary productivity occur in estuaries and nearshore upwelling centers. During the spring, meanders in the shelf slope front produce upwelling of deep nutrient-rich oceanic waters that, with increasing solar radiation, promote an early bloom in the shelf slope sea (Marra et al. 1990, Ryan et al. 1999). Spring blooms fueled by nutrients supplied by winter water column overturning occur with the onset of stratification closer to shore, while blooms also occur on the shelf when stratification breaks down in the autumn. Organisms occupying the MAB exhibit complex seasonal cycles of reproduction and habitat use in response to the complex seasonal dynamics of ocean climate, circulation and primary productivity.

Species abundance data

We selected longfin inshore squid *Loligo pealeii*, butterfish *Peprilus triacanthus*, spiny dogfish *Squalus acanthias* and summer flounder *Paralichthys dentatus* for analysis because they exhibit differences in vertical habitat preference, are abundant in fishery-independent bottom trawl surveys and are trophically important interacting species in the MAB (Link et al. 2008). Butterfish and longfin squid are small pelagic species important in the transfer of energy from lower trophic levels to apex predators (Link et al. 2008). Both species reach maturity at a year or less of age and have very high reproductive rates (Hatfield & Cadrin 2002, Collette & Klein MacPhee 2002). Butterfish feed primarily upon zooplankton. Squid feed on small pelagic animals including butterfish.

Spiny dogfish and summer flounder feed upon squid and butterfish but generally spend more time deeper in the water column (Packer & Hoff 1999, Moustahfid et al. 2010, Staudinger 2006, Stehlik 2007). Spiny dogfish are not as surface oriented as squid and butterfish but still spend considerable amounts of time in the water column. They exert strong top down effects on the MAB food web. Summer flounder are subtropical flatfish more strongly associated with the seabed in the ocean and estuaries.

All 4 species migrate between lower latitude and/or offshore overwintering habitats to higher latitude, inshore habitats where they spend the summer. Longfin inshore squid, butterfish and summer flounder are abundant in the MAB throughout the year while spiny dogfish are more abundant in cooler waters to the northeast during the summer (Stehlik 2007).

We used collections of the 4 species made by National Marine Fisheries Service, Northeast Fisheries Science Center's (NMFS-NEFSC) autumn, winter, and spring fisheries independent bottom trawl survey (Fig. 1; www.nefsc.noaa.gov/epd/ocean/MainPage/ioos.html) in our statistical habitat modeling. Azarovitz (1981) described the design of the stratified random survey in detail. Winter surveys occurred in February, spring surveys from March to early May, and autumn surveys in September and October. Survey tows were made with a #36 Yankee trawl with a 10.4 m wide × 3.2 m high opening and rollers (12.7 cm stretched mesh [SM] opening, 11.4 cm SM cod end, 1.25 cm SM lining in the cod end and upper belly). The net was towed over the bottom at ~3.5 knots for 30 min. Distances the net was towed on the bottom averaged 3.5 km (95 % confidence limits 3.2 to 3.7 km). Tows were made throughout the 24 h day. Consecutive samples were collected approximately every 2 h (50th, 5th, and 95th quantiles: 2.07, 1.38, 3.53 h respectively) and 19 km apart (50th, 5th, and 95th quantiles: 19.02, 4.80, 41.88 km respectively) on each survey. Examination of available length and age frequencies confirmed that large age 1+ juveniles and adults dominated collections because the trawl mesh was relatively coarse and shallow coastal and estuarine nursery habitats were not sampled.

We selected the analysis domain for this study based upon the availability of remotely sensed data from the OOS. Bottom trawl samples collected from February 2003 through October 2007 between latitudes 37.14° and 40.85° N and longitudes 70.83° and 75.16° W fit within the domain (Fig. 1). An average of 101 stations was sampled during spring and autumn. An average of 70 stations was sampled during the winter.

Habitat data

For bottom data, we computed topographic characteristics of the bottom from the 3-arc-second NGDC Coastal Relief Model (www.ngdc.noaa.gov/mgg/coastal/coastal.html; cell size = 93 m; Table 1). We used circular moving window analysis in GRASS GIS to calculate median and standard deviations of bot-

[a]www.ngdc.noaa.gov/mgg/coastal/coastal.html; [b]http://walrus.wr.usgs.gov/usseabed; [c]http://maracoos.org/data; [d]variables that were redundant or not ecologically meaningful and therefore excluded in the final analysis

tom depth, aspect, slope, and curvature from the relief model (e.g. see Fig. 3; Neteler & Mitasova 2008). The window diameter was 2 km. Profile and tangential curvature measured the concavity (negative values indicate valleys) and convexity of the bottom (positive values indicate ridges) parallel and tangential to major axes of the bottom slope. Sediment grain sizes were selected from a map interpolated from the usSEABED data base (Reid et al. 2005). The sediment map had a spatial resolution of 2 km and was constructed using sample bias correction, maximum *a posteriori* resampling, and a spline-in-tension algorithm (Goff et al. 2006, 2008).

For pelagic data, we used conductivity, temperature and depth (CTD) profiles collected during each NEFSC trawl survey to describe bottom temperature and salinity, water column structure and stability (Table 1; www.nefsc.noaa.gov/epd/ocean/MainPage/ioos.html). We considered the 'mixed layer' depth at which density was 0.125 kg m^{-3} higher than the surface (Levitus 1982), a stratification index calculated as the difference in seawater density between the surface and 50 m, and Simpson's potential energy anomaly (PE; Simpson 1981, Simpson & Bowers 1981). We calculated Simpson's PE within the upper 30 m of the water column because the stability index calculated for the entire water column was correlated with bottom depth.

A network of HF radar provided remotely sensed measurements of surface currents (Table 1; http://maracoos.org; frequency = 5 MHz; Barrick et. al. 1977). Radial current vectors from the network were combined to produce hourly surface current maps (resolution = 6 km). We de-tided the raw time series at each HF radar grid point using a least-squares fit of the 5 strongest principal body tide constituents (M2, S2, N2, K1, and O1). These data were then low pass filtered with a cutoff period of 30 h. We only used data for grid points with signal returns of >25% yr^{-1}. We calculated 8 d average cross-shore and along-shore velocity, variance in velocity, divergence (vertical velocity) and vorticity within 10 km of each trawl. Divergence and vorticity were calculated using finite difference. Divergence was calculated as the vertical current velocity in m d^{-1} at a depth of 1 m. Vorticity was normalized by the local Coriolis parameter. We also calculated indices describing seasonal trends in divergence and vorticity. Instantaneous divergence values were assigned a new value of –1 if values were <–0.1 m d^{-1}, 0, if between –0.1 and +0.1 m d^{-1}, or +1 if values were >+0.1 m d^{-1}. These new values were averaged for each grid point to produce a mapped index of upwelling and downwelling potential for each season and year (e.g. see Fig. 3). Seasonal trends in vorticity were calculated similarly using threshold values of ±0.02. Values for the trawl samples were extracted from the grids.

Satellite remote sensing provided surface temperature, chlorophyll *a* (chl *a*), raw light absorption and backscatter within 10 km of each trawl tow (Table 1). Moderate Resolution Imaging Spectrometer (http://oceancolor.gsfc.nasa.gov) data were binned to 1 km resolution using standard data quality flags. We considered measurements of sea surface temperature, chlorophyll (mg m^{-3}; e.g. see Fig. 3), and normalized water-leaving radiance (W m^{-2} st^{-1} μm^{-1}) at 412, 443, 488, 531, 551, and 667 nm in our analysis.

Ensemble clustering was applied to satellite sea surface temperature and normalized water-leaving radiance at 443 and 555 nm to classify water masses using the methods of Oliver et al. (2004) and Oliver & Irwin (2008). Clustering identified 27 water masses within the study domain. We made time series maps of the strengths of gradients along frontal boundaries between these water masses (e.g. see Fig. 3) and used them to compute distance (d_{km}) to, and gradient strength (G) of the nearest front for each trawl sample. We then calculated a frontal index (FI) for each station using the equation:

$$FI = \ln(G/d_{km} + 1) \quad (1)$$

Values for the frontal index were therefore higher for samples nearer to stronger fronts.

Many of 27 water masses identified with ensemble clustering contained 5 or fewer trawl samples. Thus, before final assignment of the samples to water masses, we used k–means clustering of the original satellite data to reduce the number of water masses from 27 to 8. Following this clustering, each of the 8 water masses contained at least 20 bottom trawl samples.

Analysis

GAMs

We developed our statistical habitat models for large juvenile and adult stage squid, butterfish, dogfish and summer flounder, using generalized additive models (GAM) implemented with the mgcv package in R software (Wood 2006). GAM is a nonparametric multiple regression technique that does not require shapes of abundance responses to habitat variables to be specified *a priori*. It has been used to statistically model ecological relationships, including habitat associations, and performs well in comparison with other methods (Pearce & Ferrier 2000, Ciannelli et al. 2007, Ficetola & Denoël 2009). Like all regressions, GAMs constructed with collinear independent variables perform poorly. We therefore eliminated intercorrelated variables prior to modeling, retaining those most likely to affect important physiological or behavioral processes (Table 1).

We standardized species abundances by trawl tow distances and found they were best modeled using an over-dispersed Poisson distribution. Using this distribution required that we round abundances to the nearest integer. Abundance in bottom trawls can vary with time of sampling if animals exhibit diel behavioral cycles, especially vertical migration (e.g. Brodziak & Hendrickson 1999). As a result, we considered solar elevation at trawl locations and times as a covariate in GAMs.

To construct GAMs we used a backward stepwise procedure to select habitat covariates that minimized the generalized cross validation statistic (GCV, Wood 2006). We set gamma to 1.4, which increased the penalty for models of greater complexity (higher degrees of freedom). We set the maximum basis dimension of smoothers (k) to 4, which limited the complexity of the response functions to the nonparametric equivalent of a 3rd degree polynomial, and thus a Gaussian-like response. These conservative settings reduced our chances of over fitting the models. We used smoothing splines to model single term covariates which we eliminated beginning with those with the highest p-values in approximate *F*-tests. We retained only those habitat covariates producing lower GCV and significant reduction in residual deviance at the $p < 0.05$ level in analysis of deviance of nested models, which were also likely to affect the animals through mechanisms we understood. We examined residual and convergence diagnostics throughout the modeling process.

Following the construction of single term models, we evaluated first order interactions among retained covariates using tensor product smooths (Wood 2006). We found that nearly all significant first order interactions included sea surface temperature (SST), which was seasonally discontinuous between the autumn (warm SST > 17°C) and the winter and spring (SST < 15°C) surveys. As a result, we constructed a factor for season based upon SSTs (warm [autumn] vs. cold [winter & spring]), and determined whether abundance responses to the habitat covariates were seasonally dependent. Seasonally dependent habitat responses were retained if they produced lower GCVs and residual deviance in analysis of nested models ($p < 0.05$). Once we formulated these final models we added spatial co-variates (latitude and longitude) to identify residual spatial variation in abundance that was not well described by retained habitat covariates. We also included log-transformed abundances of squid and butterfish as covariates in spiny dogfish and summer flounder GAMs to evaluate the effects of prey distributions on distributions of the predators.

We used deviance partitioning (~variance partitioning) to quantify the independent and joint effects on species distributions of habitat covariates included in the final models which we organized into 3 sets: mesoscale pelagic features described by OOS; pelagic features based on CTD casts and benthic features measured with acoustics or bottom grabs (Borcard & Legendre 1994, Cushman & McGarigal 2002). We used partial GAM regression and nested analysis of deviance to compute independent and intercorrelated effects of the 3 variable sets on abundance patterns.

Model evaluation

We evaluated our GAMs using a cross validation out-of-sample prediction procedure that bootstrapped Spearman correlations between standardized abundance and abundance predicted with habitat covariates in the final GAMs. In each of 1000 iterations, 10% of the observations were randomly selected using a uniform distribution and set aside as test data. The remaining training observations were used to fit abundance to the habitat covariates included in the final GAMs. At each iteration the trained GAM was used to predict the relationship between habitat covariates and abundance in the test data. Predicted abundances were then compared with measured abundances in the test data using Spearman's rho. We calculated 50th, 5th, and 95th quantiles to estimate median and 95% confidence intervals for the bootstrapped rhos.

Demonstration projection of a habitat model

We modified the final summer flounder habitat GAM to accept available raster data layers for the autumn of 2008, and qualitatively compared this model projection with animal collections made from September 3 through November 13 during the NEFSC bottom trawl survey. We selected autumn 2008 for the demonstration because it was nearest in time to surveys used to train the habitat model (2003 to 2007) and because 2008 was the first year the

MARACOOS HF radar network continuously monitored surface currents throughout the MAB coastal ocean from Cape Hatteras to Cape Cod. The October 1, 2008 model projection used 8 d averaged satellite data and a 32 d rolling 'seasonal' trend in divergence (see Fig. 3). In the demonstration, we eliminated subsurface measures of water column properties because estimates are not currently accessible in near real time using operational remote sensing assets or models.

RESULTS

The explanatory power of GAMs made for the 2 pelagic species, squid and butterfish, was higher than for models made for spiny dogfish and summer flounder (Table 2, Fig. 2). Our models accounted for 73% of abundance variation for pelagic species, and ~50% of the variation for the demersal species. Models for pelagic species incorporated more pelagic habitat covariates measured with *in situ* CTD sampling. Models for demersal species did not, however, accept more of the benthic habitat covariates measured at relatively coarse spatial grains. Benthic covariates did not have greater explanatory power in demersal species models. Responses of the animals to many of the habitat covariates were seasonally dependent, and habitat distributions were better described during the winter and early spring than during the autumn when surface waters were stratified and animals were migrating, or soon to migrate, to overwintering habitats.

Bottom depth and variations in bottom depth (SD depth) met selection criteria in GAMs for all 4 species, and associations with seabed characteristics were seasonally dependent in every case (Table 2; see the Supplement at www.int–res.com/articles/suppl/m438p001_supp.pdf). During winter and early spring when temperatures were cold, the animals were abundant in deeper, offshore waters. Squid, butterfish, and summer flounder were most abundant over bottoms with depths ranging from 50 to 150 m. Spiny dogfish were more abundant in shallower habitats (<75 m). Deep overwintering habitats for squid and summer flounder were topographically complex (high STD depth) and located in the outer Hudson shelf valley and along the edge of the continental shelf. During winter, dogfish were also abundant over complex bottoms. Butterfish were more common over smooth bottoms. During autumn, abundance varied with depth only for butterfish which were rare over bottoms deeper than 150 m. Butterfish preferred complex bottoms in the nearshore during the autumn.

Bottom water temperature met selection criteria in GAMs for all 4 species (Table 2, see Supplement). Temperature responses of longfin squid, butterfish, and summer flounder were not seasonally dependent. All 3 species were rare where bottom temperatures were <6.5°C. Summer flounder, butterfish and squid were also uncommon on the continental shelf where bottom temperatures were warmer than 12.5°C, 16°C, and 20°C, respectively. In contrast, the temperature response of spiny dogfish was seasonally dependent. The sharks overwintered where bottom water temperatures were warmer than 7°C. During the autumn, dogfish preferred cool temperatures measured in the northern part of the study area.

Water column stability measured *in situ* and indexed as Simpson's PE anomaly for the upper 30 m of the water column met model selection criteria for squid, butterfish and summer flounder, while the abundance of butterfish also varied with mixed layer depth (Table 2, see Supplement). Summer flounder were consistently more abundant where the water column was stable in the vicinity of estuarine plumes during the autumn and the outer continental shelf during the winter and spring. Both pelagic species were more abundant where the water column was unstable during the autumn. In the winter, butterfish were more abundant where the water column was stable and the mixed layer was deep near the shelf slope front (see below, this section). Water column stability and stratification measured *in situ* varied negatively with surface current velocities and positively with current variances measured with HF radar. This produced relatively high, intercorrelated habitat effects in GAMs for the pelagic species (Table 2, Fig. 2).

Pelagic habitat characteristics measured remotely with satellites and HF radar did not have consistently greater explanatory power in models for the pelagic species than the demersal species (Table 2, Fig. 2). At least one remotely sensed pelagic characteristic met selection criterion for each species and the independent effects of remotely sensed variables were actually slightly higher in the GAM for summer flounder than for the pelagic species (Table 2, Fig. 2, see Supplement).

Summer flounder, butterfish and squid were most abundant in areas where the index of surface current divergence, and thus upwelling potential, was high (Table 2, Fig. 3, see Supplement). This response was seasonally dependent for the 2 pelagic species, but not for summer flounder.

Table 2. Analysis of deviance from generalized additive habitat modeling of longfin inshore squid, butterfish, spiny dogfish and summer flounder abundances in the Mid-Atlantic Bight coastal ocean (see also Fig. 2). Partial deviance is the additional deviance 'explained' by each variable after effects of other variables were removed. Null model is an approximation of the total deviance (~ variance) in abundance data. % of Null expresses the deviance and partial deviance as a percentage of the Null Model for each species. The decrease in the generalized cross validation statistic (ΔGCV) is indicated in the last column. Only variables that resulted in an increase in GCV when they were removed in backward selection were included in the final models and reported here

[a]Response to habitat variable was seasonally dependent and different during cruises conducted when water was warm (autumn) and cold (winter and early spring)

During autumn, summer flounder was associated with nearshore areas where chl *a* concentrations were relatively high (Fig. 3, see Supplement). These areas were in close proximity to estuarine plumes. The animals were rarely collected where surface chl *a* was highest during winter and spring.

Squid, butterfish and summer flounder abundance varied with proximity to, and the strength of, surface fronts identified with satellites (Table 2, Fig. 3, see Supplement). Associations with fronts were strong during cold seasons but weak or absent during the autumn when the water column was warm and stratified. The pelagic species were associated with fronts on the outer continental shelf during the winter and spring. Summer flounder were rarely collected close to these strong fronts.

Although proximity to fronts between water masses was important in 3 of 4 habitat models, water mass type only met model selection criterion for longfin squid (see Supplement). Squid were slightly more abundant in water masses of moderate temperature, salinity, and primary productivity that occurred over intermediate bottom depths.

Squid and butterfish appeared to respond to cross shelf surface current velocities (see Supplement). During autumn, the animals were common where strong surface currents were directed offshore. They were abundant during winter and spring where high surface current velocities were directed inshore. The pelagic species also preferred areas where surface current velocities were relatively consistent (low variance in velocity). The response of spiny dogfish to variance in velocity was similar.

During the winter and spring, summer flounder and spiny dogfish were associated with the pelagic species they prey upon on the outer continental shelf (Table 2, Fig. 2, see Supplement). Both predators were abundant where squid were abundant, while summer flounder were also associated with butterfish.

Maps of residual spatial variation made by adding spatial covariates indicated that abundances of squid and butterfish were lower in the nearshore off Long Island, New York, than predicted based upon the habitat covariates included in the final models (Table 2, see Supplement). Squid were more abundant during the winter offshore south of Hudson shelf valley, while butterfish abundance was higher than predicted in the autumn just southeast of the Sandy Hook peninsula where the Hudson-Raritan estuary discharges into the coastal ocean. Dogfish abundance was overestimated at the mouth of the Hudson-Raritan estuary and along the continental shelf break based upon retained habitat covariates. Finally, there was a cross shelf gradient in errors in the GAM for summer flounder, which were less abundant than predicted in the nearshore continental shelf, but more abundant offshore north of the Hudson Shelf Valley.

The out-of-sample prediction test indicated that habitat-specific trends in abundances of longfin inshore squid, spiny dogfish and summer flounder were well described by our GAMs (Fig. 4). Bootstrapped rank correlations between predicted and actual catches were >0.7 and confidence intervals were relatively narrow for squid and spiny dogfish. For the butterfish model, correlations between pre-

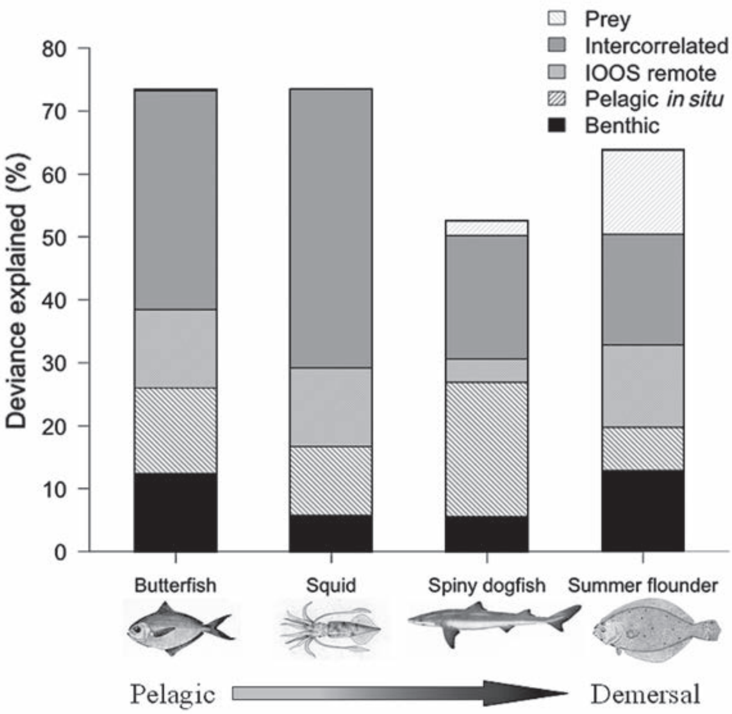

Fig. 2. Partial deviance (~variance) components calculated from generalized additive model (GAM) habitat modeling for 4 species with different vertical habitat preferences in the coastal ocean (see Table 2 and the Supplement available at www.int-res.com/articles/suppl/m438p001_supp.pdf). Less of the abundance variation was 'explained' for demersal than for pelagic species, whose distributions appeared to be more directly affected by water column stability and mixed layer depth measured *in situ*. These variables were correlated with HF radar surface current measurements. Percentages depicted for Prey, IOOS remote, Pelagic *in situ* and Benthic habitat feature groups are partial components after intercorrelated effects (also shown) were removed. Spatial covariates were not included in this analysis

dicted and actual abundances were weaker and confidence intervals were wide.

Actual catches of summer flounder during autumn 2008 generally matched the demonstration projection of the statistical habitat model we modified to accept OOS ocean data for October 1. Catches were relatively high offshore south of Martha's Vineyard, and in shallower water from the mouth of Long Island Sound west to the mouth of the Hudson-Raritan estuary to central New Jersey.

DISCUSSION

Broad scale dynamic habitat models for species contributing resilience to large marine ecosystems could be useful for space- and time-based ecosystem management. However, operational habitat models require sustained collection of high resolution data describing pelagic and benthic processes affecting the physiologies, behaviors and ecologies of important species at the scale of large marine ecosystems. These kinds of data are much too expensive and time consuming to collect using traditional shipboard techniques. OOS are designed to measure ocean variability at the space–time scales necessary to describe the fundamental physical and biological processes driving the spatial dynamics of coastal marine ecosystems (Schofield et al. 2008). It is therefore not surprising that OOS satellite and HF radar descriptions of mesoscale oceanographic features and processes were useful for modeling the habitats of several ecologically important species in the Mid-Atlantic Bight.

The availability of high resolution, spatially explicit time series data for the Mid-Atlantic Bight allowed us to build models of greater explanatory power than would have been possible using shipboard data alone. We built our GAMs conservatively, constraining the complexity of smoothers, increasing the penalty for model complexity, and considering only habitat features affecting ecological processes. Nevertheless, our models explained 50 to 70% of the variation in abundance of 4 species with diverse vertical habitat preferences. Furthermore, out-of-sample prediction capabilities of 3 of our 4 models were high. GAM models developed using just shipboard measurements of pelagic and benthic habitat heterogeneity typically explain between 10 to 50% of abundance variation and generally have poorer out-of-sample prediction capabilities than we measured (e.g. Stoner et al. 2001, 2007, Jensen et al. 2005). Becker et al (2010) also demonstrated that habitat models built with remotely sensed ocean data of the proper resolution have predictive capabilities as good or better than those made with analogous shipboard data alone.

As OOS are designed to sample at the space–time scales necessary to describe the physical and primary production dynamics of the coastal ocean, we were able to consider several fundamental processes controlling ecosystem productivity in our statistical habitat models. Measurements of vertical current velocities, and locations and strengths of fronts were the most valuable of these descriptors of processes known to regulate and structure coastal ocean food webs (Olson et al. 1994, Bakun 2010). Measurements of vertical current velocities allowed us to consider

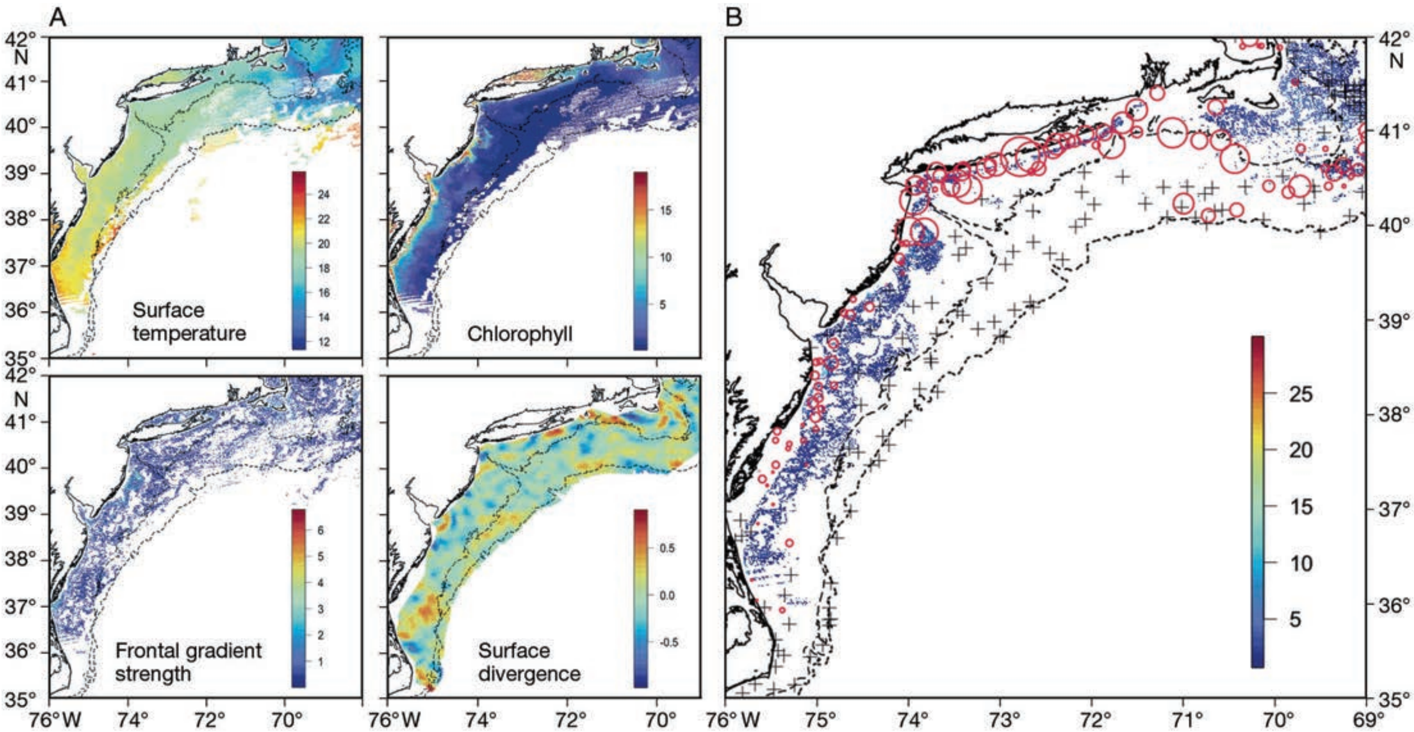

Fig. 3. Pelagic habitat gradients and predicted and realized summer flounder catches during autumn 2008. (A) Pelagic habitat variables (8 d average except for divergence which was 32 d) on October 1, 2008 that were used to project a modified generalized additive model (GAM) habitat model for summer flounder. The modified GAM did not include bottom temperature which was too sparsely measured during autumn 2008, and gradient index was replaced with gradient strength to make 'forecasting' tractable. The modified model included log transformed SD of bottom depth as well as the 4 gradients shown in panel A. (B) Summer flounder abundance projected for October 1, 2008 from the modified GAM habitat model in the color gradient. The open red symbols are scaled to the catch of summer flounder per unit effort (CPUE) in Northeast Fisheries Science Centre bottom trawl tows from September through mid-November 2008. + indicates tows in which fish were absent

spatial and temporal variation in upwelling and downwelling potential in our models. Summer flounder were consistently abundant in areas of the coastal ocean where the potential for upwelling was high, while butterfish and squid showed seasonally dependent associations with areas of upwelling. Strong gradients in temperature, salinity, and/or chl *a* are characteristic of ocean fronts where the interaction of circulation with the buoyancies and behaviors of organisms results in the concentration of food web constituents along them (Helfrich & Pineda 2003, Genin et al. 2005, Bakun 2010). Our frontal index, which integrated the strength of, and distance to, the nearest frontal gradient met the selection criterion in 3 of our 4 models. The pelagic species, longfin inshore squid and butterfish, were collected near strong surface fronts on the outer continental shelf during winter and early spring. During the same season, summer flounder were more abundant inshore of these strong fronts.

If indices of surface divergence and fronts between water masses referenced physical processes controlling the spatial structure and dynamics of coastal ocean food, we might have expected species responses to be similar and stronger, and satellite measurements of primary productivity to meet selection criterion in more than one of our GAMs. However, we modeled secondary and tertiary consumers with trophic positions ranging from 3.5 (butterfish) to 4.5 (summer flounder), using only surface habitat features measured directly overhead of trawl samples (Bowman et al. 2000, Hunsicker & Essington 2006, Smith & Link 2010). As these animals feed at high trophic levels, they may, under many circumstances, be distributed downstream and later in time than the physics and primary productivity that ultimately supports them (Yamamoto & Nishizawa 1986, Olson et al. 1994, Bakun 2010). These sorts of space-time lags are highly likely for demersal species like summer flounder and spiny dogfish in deep overwintering habitats that are linked by advection and prey behavior to primary production at the surface along the shelf slope front (Linder et al. 2004, Johnson et al. 2007). Demersal predators at high trophic levels

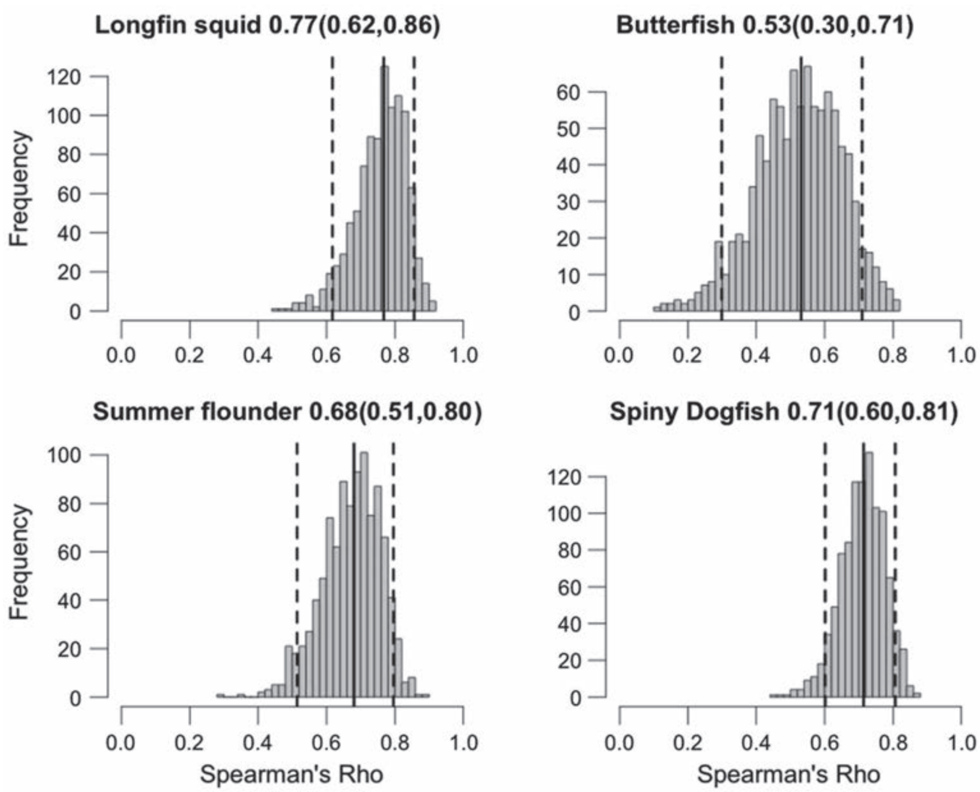

Fig. 4. Bootstrapped (1000 iterations) Spearman correlations (rho) between actual abundances and abundances predicted using habitat covariates in final generalized additive models (GAMs) for each of the 4 species generated with the cross validation out-of-sample prediction procedure (see 'Materials and methods'). Solid lines indicate median correlation while dashed lines are 5th and 95th quantiles for the bootstrapped rho values

should be more strongly associated in space and time with the prey they directly consume than with lower trophic levels. We found spiny dogfish and summer flounder to be strongly associated with the squid and butterfish they feed upon during the winter and spring (Torres et al. 2008, Moustahfid et al. 2009, Smith & Link 2010, Staudinger & Juanes 2010). In our analyses, the predators were not associated with these prey during autumn. However, during warmer months, including the autumn, spiny dogfish are more abundant north of our study domain, while estuaries are important nurseries and summer feeding habitats for summer flounder that are not sampled in the NEFSC fishery independent bottom trawl surveys (Packer et al. 1999, Stehlik 2009). Thus seasonal changes in the importance of prey in our statistical models for the demersal predators were probably related simultaneously to limitations of the data we analyzed and to seasonal changes in habitat overlap between the specific predators and prey.

Primary productivity as indexed by satellite estimates of chl *a* only met selection criteria in the model for summer flounder during the autumn migration and spawning period. (Fig. 3, see Supplement). Abundance of the flatfish increased with increases in chl *a* to a threshold, and the animals were associated with plumes of moderately high chl *a* occurring outside the mouths of several large MAB estuaries where upwelling potential was also high (Fig. 3). Areas of coastal ocean impacted by estuarine plumes are optically complex, but the high concentrations of colored dissolved organic matter and detritus that confound satellite-based estimates of phytoplankton production also contribute to high productivity (Moline et al. 2008, Pan et al. 2010). The association of summer flounder with estuarine plumes may be purely coincident with migratory pathways between shallow estuarine and coastal feeding habitats and overwintering habitats offshore. However, Berrien & Sibunka (1999) reported high densities of summer flounder eggs that have stage durations of 48 to 72 h in these same locations (Johns et al. 1981). We speculate that coastal ocean areas impacted by estuarine plumes where upwelling occurs and productivity is high could serve as high quality spawning grounds that place eggs in close proximity to optimal feeding habitats for larvae which are at a lower trophic level of ~3 (Grimes & Kingsford 1996). These same areas also have physical transport mechanisms likely to deliver larvae south and west to important estuarine nurseries (Epifanio & Garvine 2001, Lentz 2008, Tilburg et al. 2009, Zhang et al. 2009, Gong et al. 2010). Spawning habitat selection and suitability should be largely defined by conditions promoting the development, survival and successful transport of early life stages to juvenile nurseries rather than by the immediate requirements of adults.

Distributions of the 2 pelagic species were related to horizontal surface currents in our statistical habitat models. During autumn migration, squid and butterfish were more abundant in areas where higher velocity surface flows (and low variance) were directed offshore, while the species were associated with high velocity (low velocity variance) onshore surface flows during the spring. Most swimming and flying animals exploit complex 3-dimensional flows to conserve energy, particularly during long-distance migrations (Liao 2007, Mandel et al. 2008, Mansfield et al. 2009, Stehlik 2009). Associations of the pelagic species with specific surface flows in our models may have reflected the efficient use of cross shelf transport pathways during seasonal migrations. However, the animals were collected in trawls on the bottom where current flows can be different to seasonally complex surface flows (Lentz 2008, Gong et al. 2010). Furthermore, areas with higher velocity, low variance surface flows also tended to have weakly stratified water columns with shallow mixed layers. These are also characteristics of productive habitats (Mann & Lazier 2006, Bakun 2010). The inverse relationship between horizontal surface currents and water column stratification and stability was largely responsible for the inter-correlated habitat effects and the large amount of deviance explained in our models for pelagic species (Fig. 2). Mechanistic studies are therefore required to determine whether responses of the 2 pelagic species captured by our models reflected preferences for cross shelf transport pathways useful for energy efficient migration, physical conditions promoting high primary productivity, or for areas where both processes occur simultaneously.

The habitat associations of all 4 species, regardless of vertical preference, were better described by the pelagic than the benthic data available to us. Sediment grain sizes estimated at a spatial resolution of 2000 m did not meet selection criterion in any of our GAMs and species associations with bottom depths and seabed complexity measured at a grain of 93 m and resolution of 2 km were seasonally dependent in nearly every case. The interactions between bottom depth and season captured inshore–offshore migrations that were probably more directly related to the seasonal dynamics of temperature and the temperature preferences of the animals than to depth preferences. All of the species except spiny dogfish showed a seasonally independent response to bottom water temperature with a minimum threshold of ~6.5°C. The animals were concentrated in deep water near the edge of the continental shelf during the winter and early spring when water temperatures are generally warmer and less variable offshore than inshore. Abundance relationships with bottom habitat complexity could have reflected species associations with refuges from predation or current flow if our coarser grained index served as a proxy for bottom complexity at scales of tens of centimeters to tens of meters. However, responses to bottom habitat complexity were also seasonally dependent and complex for 3 of the 4 species, and therefore probably aliased other characteristics of overwintering habitats along submarine valleys and canyons on the outer continental shelf. Animals respond to centimeter to 100 m scale variability in bottom characteristics, and the data available to us were just too coarse to describe benthic habitat heterogeneity that might have directly affected the survival and energy budgets of the animals (Abookire et al. 2007, Liao 2007, Stoner et al. 2007, Gray & Elliott 2009). Centimeter to meter scale descriptions of the structural complexity of the seabed have been shown to increase the fit of habitat models (Abookire et al. 2007, Stoner et al. 2007) and the predictive capability of several of our models might have increased if data describing bottom habitat heterogeneity at finer, ecologically relevant scales had been available for our study domain (e.g. Harris & Stokesbury 2010). Higher resolution bottom data might have improved our model for longfin inshore squid, which deposit egg masses on hard structures located on sand and muddy substrata (Jacobson 2005). However, it is also true that bottom characteristics may be less important to large animals even when they are strongly demersal. Habitat associations of age 1+ summer flounder on the continental shelf are poorly described by fine scale characteristics of the seabed identified with side scan sonar or underwater video (Lathrop et al. 2006, Slacum et al. 2008). Our results are consistent with speculation that distributions of the flatfish on the continental shelf are determined primarily by mesoscale oceanographic features controlling patterns of productivity and prey distributions rather than by fine-scale seabed characteristics (Slacum et al. 2008).

CONCLUSIONS

Resource managers are turning increasingly to spatial management as a tool for conserving marine populations and ecosystems (Pérez-Ruzafa et al. 2008, Worm et al. 2009, Edwards & Plagányi 2011). Regional scale habitat modeling could serve as the foundation for tactical decisions as to where and when to site marine protected and closed areas designed to conserve species that provide essential ecosystem services. While much of the seabed remains unmapped, variability in the physical structure, dynamics and productivity of the water column is being measured and mapped at ecologically relevant space/time scales with remote sensing technology integrated into OOS. Furthermore, all OOS are actively developing ensembles of oceanographic models that assimilate data from sensors on satellite, HF radar, underwater robot, and fixed mooring platforms to make spatially and temporally explicit hindcasts and forecasts of the structure and dynamics of the coastal ocean including subsurface features (e.g. Zhang et al. 2010a,b,c). Many of the pelagic features and processes currently measured and modeled by OOS determine patterns of habitat suitability for species and their life stages and could be considered in spatial management (Game et al. 2009, Watson et al. 2011).

In our view, several avenues of research need to be pursued in order to develop habitat models useful for spatial management. These include investigation of the resolution and ranges of habitat variability measured with OOS resulting in biological responses, including the identification of space–time lags between variability in physical and primary production dynamics and responses of important upper level consumers, particularly those associated with the bottom. There is also a need for biological data, in addition to trawl net surveys, to be integrated into OOS (e.g. Kloser et al. 2009, Žydelis et al. 2011). Currently, the data available for broad scale habitat modeling are fisheries-independent surveys designed for stock assessment, not habitat assessment. These surveys are highly selective with respect to season and organism size and often do not sample habitats used during important periods in the life history of many species. Infrequent traditional net surveys cannot be used to distinguish dispersal corridors that many animals move through quickly from areas in which fewer individuals take up longer term residency because habitat resources meet the requirements of particular life history stages. Finally, habitat models based on abundance assume that organisms evaluate habitat quality accurately, without perceptual and movement constraints, and therefore reach abundances at equilibrium with habitat carrying capacity without time delays. This is probably rarely the case, particularly in regions like the Mid-Atlantic Bight where important habitat dimensions are highly dynamic in time and space and many animals are highly migratory. Integration of telemetry and fishery hydroacoustics data into regional OOS (e.g. Kloser et al. 2009, Zydelis et al. 2011) would be useful for addressing some of the sampling biases and assumptions inherent in habitat models based upon traditional fisheries survey data.

We view statistical habitat models informed by OOS, such as those we have developed here, as a first step toward the development of operational mechanistic habitat models: As hypothesis-generating tools that can be coupled with OOS products to perform mechanistic studies of the effects of pelagic, as well as benthic, habitat heterogeneity on the processes of growth, survival, dispersal and reproduction that underlie spatial population dynamics (Kritzer & Sale 2006, Buckley et al. 2010). This type of adaptive, iterative approach could be a cost-effective way to develop mechanistic models with scopes broad enough to meet the requirements of spatial resource management in the sea.

Acknowledgements. We thank S. Lucey, M. Taylor and J. Goff for generously providing us with the data used in our analysis, and S. Gray for his contributions to stimulating discussions about the role of the Integrated Ocean Observing System (IOOS) in fisheries science and management. B. Phelan also provided much needed support. We thank A. Stoner and 3 anonymous reviewers whose comments helped us to improve the manuscript. The NOAA Fisheries and the Environment Program (NA08NMF450626) provided primary support for this research. The authors also thank the following agencies for additional support during this project: NASA Biodiversity NNG06GH75G1/3, NASA New Investigator Program NNH07ZDA001N, NOAA IOOS Office (MARACOOS Grant NA01NOS4730014 and NA07NOS 4730221) and Delaware Sea Grant (NA10OAR4170084).

ABSTRACT

For this manuscript we use a 9-year time series of Sea-viewing Wide Field of view Sensor (SeaWiFS), HF radar, and Webb Glider data to assess the physical forcing of the seasonal and inter-annual variability of the spatial distribution in phytoplankton. Using Empirical Orthogonal Function (EOF) analysis, based on 4-day average chlorophyll composites, we characterized the two major periods of enhanced chlorophyll biomass for the MAB in the fall–winter and the spring. Monthly averaged data showed a recurrent chlorophyll biomass in the fall–winter months, which represented 58% of the annual surface chlorophyll for the MAB. The first EOF mode explained $\sim$33% of the chlorophyll variance and was associated with the enhanced phytoplankton biomass in the fall–winter found between the 20 and 60 m isobaths. Variability in the magnitude of the enhanced chlorophyll in fall–winter was associated with buoyant plumes and the frequency of storms. The second EOF mode accounted for 8% of the variance and was associated with the spring time enhancements in chlorophyll at the shelf-break/slope (water depths greater than 80 m), which was influenced by factors determining the overall water column stability. Therefore the timing and the inter-annual magnitude of both events are regulated by factors influencing the stability of the water column, which determines the degree that phytoplankton are light-limited. Decadal changes observed in atmospheric forcing and ocean conditions on the MAB have the potential to influence these phytoplankton dynamics.

1. Introduction

The Mid-Atlantic Bight (MAB) is a biologically productive continental shelf that is characterized by consistently high chlorophyll biomass (>1 mg chlorophyll m^{-3}), which supports a diverse food web that includes abundant fin and shellfish populations (Yoder et al., 2001). The MAB's shelf extends out for several hundred kilometers and the associated water mass is bounded offshore by the shelf-break front. While the shelf-break front is often near the geological shelf-break, the surface outcrop of the front can extend beyond the continental slope (Wirick, 1994). In the nearshore regions there are numerous inputs from moderately sized, yet heavily urbanized, rivers (Hudson River and Delaware River), which are sources of fresh water, nutrients, and organic carbon to the MAB (O'Reilly and Busch, 1984). The waters on the MAB exhibit considerable seasonal and inter-annual variability in temperature and salinity (Mountain, 2003). In late spring and early summer, a strong thermocline (water temperatures can span from 30 to 8 °C in <5 m) develops at about the 20 m depth across the entire shelf, isolating a continuous mid-shelf "cold pool" (formed in winter months) that extends from Nantucket to Cape Hatteras (Houghton et al., 1982; Biscaye et al., 1994). The cold pool persists throughout the summer until fall when the water column overturns and mixes in the fall (Houghton et al., 1982), which presumably replenishes nutrients to the surface waters on the MAB shelf. Thermal stratification re-develops in spring as the frequency of winter storms decrease and surface heat flux increases (Lentz et al., 2003).

In temperate seas, seasonal phytoplankton variability has been related to stratification, destratification, and incident solar irradiance (Cushing, 1975; Longhurst, 1998; Dutkiewicz et al., 2001; Ueyama and Monger, 2005). During late winter and early spring, increasing solar illumination combined with decreasing wind result in shallower surface mixed layers, which allows for increased phytoplankton growth prior to the development of the thermal stratification (Stramska and Dickey, 1994; Townsend et al., 1994). As the physical regulation of water column turnover is spatially variable along the MAB, the temporal patterns in phytoplankton biomass are not always spatially coherent within the East Coast shelf/slope ecosystem (Yoder et al., 2001). While it has long been appreciated that seasonal phytoplankton blooms are important in shelf and slope waters of the MAB (Riley, 1946, 1947; Ryther and Yentsch, 1958), a 7.5-year (October 1978–July 1986) time series of the coastal zone color scanner (CZCS) imagery found that the maximum chlorophyll concentration appeared during

doi:10.1016/j.csr.2011.05.019

fall–winter on the continental shelf waters and that slope waters possessed a secondary spring peak in addition to the a fall–winter bloom (Yoder et al., 2001). Ryan et al. (1999) used CZCS imagery from 1979 to 1986 and found an annual enhancement of chlorophyll at the shelf-break of the MAB and Georges Bank during the spring transition from well-mixed to stratified conditions. The shelf-edge system was similar to inner shelf waters in terms of seasonal heating and cooling; however, meanders at the shelf slope were associated with iso-pycnal upwelling that supplied nutrients to the euphotic zone and enhanced chlorophyll biomass (Ryan et al., 1999). Despite past efforts, understanding what regulates the magnitude of these seasonal patterns remains an open question, which is especially important as the MAB has experienced significant changes in water properties over the last few decades (Mountain, 2003).

Many factors are known to regulate the upper mixed layer dynamics on the MAB. These features include wind driven mixing (Beardsley et al., 1985) as well as surface buoyant plumes that frequently extend over significant fractions of the MAB shelf (Castelao et al., 2008a; Chant et al., 2008a). These features are superimposed upon the seasonal warming that drives the stratification of the MAB. This seasonality of shelf stratification regulates the phasing and potential magnitude of the fall–winter and spring enhancements in chlorophyll concentration. For this manuscript we use a 9-year time series of Sea-viewing Wide Field of view Sensor (SeaWiFS), HF radar, and Webb Glider data to assess the physical forcing of the seasonal and inter-annual variability of the spatial distribution in phytoplankton.

2. Methods

2.1. Ocean color remote sensing data

Time series of surface chlorophyll concentration in the MAB was studied using 4-day averaged composites of SeaWiFS satellite imagery collected from January 1998 to December 2006. We used 4-day average composites as they provided reasonable coverage for our study site and could resolve the dynamics of the chlorophyll over both seasonal and higher frequency scales (days to weeks) often observed in MAB. The 4-day average decreased the cloud contamination that heavily degraded the utility of the 1-day images. Many phytoplankton bloom events occur over time scales much shorter than a month in these waters. For example chlorophyll associated with buoyant plume events can last for the time scale of 4–5 days (Schofield et al., submitted for publication) and summer upwelling on average lasts for <7 days in the MAB (Glenn et al., 2004). Longer term averaging underemphasizes these shorter-lived phytoplankton bloom events that can explain up to 44% of the variability observed in daily satellite imagery (Yoder et al., 2001). The spatial resolution of the original images were 1.1 km, however, data were re-gridded to 5.5 km in order to identify the principal modes of variability in the data set by Empirical Orthogonal Function (EOF) analysis. Given the high spatial heterogeneity in the nearshore waters and the increasing error in satellite estimates of chlorophyll in shallow waters, we excluded regions with water depths shallower than 10 m for this analysis. We also excluded data for water depths deeper than 2000 m, as our focus was on the shelf and shelf-break region. Finally we excluded data from large inland Bays (Long Island Sound, Delaware Bay and Chesapeake Bay; Fig. 1). Monthly chlorophyll concentration was calculated by taking the geometric mean at each pixel. We chose to use the geometric rather than the arithmetic mean because the distribution of chlorophyll measurements in continental shelf and slope waters is approximated by a log–normal distribution (Campbell, 1995; Yoder et al., 2001).

Ocean color satellite remote sensing has limitations in coastal waters. Satellite coverage is limited by cloud cover especially in the winter months, which is characterized by frequent storms. Storms also can produce buoyant plumes that contain significant amounts of sediment and colored dissolved organic matter. The presence sediment and CDOM can influence the accuracy of the satellite-derived estimates of chlorophyll that can result in errors as large as 50–100% in the nearshore waters of the northeast United States (Harding et al., 2004). Finally, ocean color remote sensing does not provide information on subsurface phytoplankton peaks, below the detection limit of the satellite, which are often present in the MAB. While we acknowledge these shortcomings, satellite estimates of chlorophyll remains one of the only techniques that can provide decadal spatial time series over ecologically relevant scales.

We also calculated the monthly climatological sea surface temperature (SST) for each pixel based on 4-day averaged Advanced Very High-Resolution Radiometer (AVHRR) data sets from 1999 to 2006. The AVHRR data sets were collected by a satellite dish maintained by Rutgers University Coastal Ocean Observation Lab and processed using SeaSpace AVHRR processing software. Monthly SeaWiFS Level 3 photosynthetically available radiation (PAR) data from 1998 to 2006 were downloaded from http://oceancolor.gsfc.nasa.gov. The PAR data sets have the resolution of 9 km and the climatology of PAR was calculated based on the 9-year monthly data sets.

The mean satellite-derived chlorophyll fields were used as inputs to the Hydrolight 4.3 radiative transfer model (Mobley, 1994) to estimate the depth of the 1% light levels. For the Hydrolight simulations, we used default settings and assumed a constant backscatter to total scatter ratio of 0.05 based on data collected in this region (Moline et al., 2008). We assumed there was no inelastic scattering and kept wind speeds at zero. The surface flux of light was calculated using a semi-empirical sky model (Mobley, 1994) for the MAB at local noon on a cloudless day. We assumed that water column was infinitely deep. These Hydrolight simulations assumed no vertical structure in the phytoplankton biomass. We used this approach even though during the stratified season there can be subsurface chlorophyll layers however, satellite-derived chlorophyll estimates were used as the input to the Hydrolight simulation and these estimates are exponentially weighted to the surface waters (Mobley, 1994); therefore it is unlikely that satellite estimates included any significant proportion of the subsurface populations found at the base of the pycnocline in the late spring and summer months. Given this we did not impose a vertical structure for chlorophyll. For these simulations we treated the MAB as Case I waters (Johnson et al., 2003). This assumption is sometimes not the case when the Hudson River carries significant amounts of detritus and colored dissolved organic matter (CDOM) offshore onto the MAB (Johnson et al., 2003). Despite the optical complexity of these waters, SeaWiFS can accurately and reliably capture seasonal and inter-annual variability of chlorophyll a associated with variations of fresh water flow (Harding et al., 2004), which can increase chlorophyll biomass by an order of magnitude. To assess the impact of Case II conditions on our Hydrolight estimates of the 1% light depth, we used optical data collected as part of the LaTTE experiment (Chant et al., 2008b), which in part focused on characterizing the optical properties of the Hudson River waters being transported out onto the MAB (Moline et al., 2008). During the LaTTE experiment, data were collected from the Hudson River outflow over time with a WETLabs, Inc. absorption/attenuation meter using the methods outlined in Schofield et al. (2004). The waters were influenced by the Hudson River, which was characterized by significant contributions of chlorophyll and CDOM providing Case II waters. These measurements of the optical properties were inputted into the Hydrolight model to provide an estimate for light propagation in the Case II characteristics for MAB waters.

2.2. Winds and surface current observations

Wind data were obtained from moored buoys deployed by the National Data Buoy Center (NDBC) (http://www.ndbc.noaa.gov/maps/Northeast.shtml). We used data collected by mooring 44025 (Fig. 1) located at 40.25°N, 73.17°W with a water depth of 36 m and mooring 44014 (Fig. 1) located at 36.61°N, 74.84°W with a water depth of 48 m. The reason we chose these two moorings was because 44025 was located at the mid-shelf region while 44014 was located at shelf-break/slope region. We used the daily wind speed data to calculate the stormy frequency. The wind data used for calculating the correlation coefficient between the surface currents measured by CODAR and wind speed were based on the time series of the 6 years (2002–2007) wind measured at NDBC 44009 (Fig. 1) located at 38.46°N, 74.70°W with a water depth of 28 m. We used this mooring as it was central to a recently completed long-term analysis of the circulation on the MAB (Gong et al., 2010). The wind data for 44009 were decomposed into along-shelf and cross-shelf directions (30 degree rotation) and low-passed with a 33-hour filter. Shore-based High Frequency (HF) radar systems were used for surface current measurements. The radar network was a fully nested array of surface current mapping radars (Kohut and Glenn, 2003; Kohut et al., 2004). Hourly surface currents were measured with an array of CODAR HF Radar systems consisting of 6 long-range (5 MHz) and 2 high-resolution (25 MHz) backscatter systems from the start of 2002 to the end of 2007. For all systems measured beam patterns were used in surface current estimates (Kohut and Glenn, 2003). Details of HF radar development and theory can be found in Crombie (1955), Barrick (1972), Stewart and Joy (1974), Barrick et al. (1977). All CODAR surface currents were de-tided using the T_TIDE Matlab package (Pawlowicz et al., 2002) before further analysis is performed. The averaged seasonal surface current responses for the dominant winds were calculated for the well-mixed winter (December–March), the transitional seasons (April–May, October–November), and stratified summer (June–September; Gong et al., 2010).

2.3. River discharge and glider data

The monthly river discharge data were downloaded from http://nwis.waterdata.usgs.gov/nwis. The total river discharge into to the MAB was represented by the sum of the discharges from Mohawk River at Cohoes, NY (42.79°N, 73.71°W), Passaic River at Little Falls, NJ (40.89°N, 74.23°W), Raritan River below Calco Dam at Bound Brook, NJ (40.55°N, 74.55°W), Hudson River at Fort Edward, NY (43.27°N, 73.60°W), and Delaware River at Trenton, NJ (40.22°N, 74.78°W).

Webb Slocum gliders were used to obtain subsurface measurements over the shelf. The Webb gliders occupy a cross-shore transect across the MAB beginning in 2005 (Schofield et al., 2007); however, the coverage in each month is not always complete. The cross-shelf transects typically take on average 4–5 days and are appropriate for comparing to the 4-day averaged satellite imagery. The cross-shore transect typically spans the 15–100 m isobaths (Fig. 1). The gliders were outfitted with CTDs (Sea-Bird Electronics, Inc.) and occasionally with optical backscatter sensors (WETLabs, Inc.). For this effort we were able to utilize the data collected from 19 cross-shore transects; however, the coverage was not uniform over the year. There were 7 transects available during the fall and winter; however, many of the early transects consisted of a glider that was not outfitted with a fluorometer or a backscatter sensor. Only 2 of 7 transects in fall and winter had any optical sensors present on board. Unfortunately no fluorometry data is available for the winter season and only one transect had only partial data of optical backscatter. There were twelve transects that were available for both the spring and summer and all the gliders were outfitted with optical backscatter and chlorophyll fluorometers. We compared individual transects and to specific satellite imagery and also averaged the glider observations (Castelao et al., 2008b). While the glider data were sparser than the satellite and CODAR data, it represented the densest concurrent subsurface data available for the MAB.

2.4. EOF and cluster analysis

EOF analysis is the mapping of the multi-dimensional data sets onto a series of orthonormal functions and is useful in compressing the spatial and temporal variability of large data sets down to the most energetic and coherent statistical modes. EOF results can be quite informative; however, they do not necessarily demonstrate causality and should be interpreted with caution. This method was first applied by Lorenz (1956) to develop the technique for statistical weather prediction. These approaches have been extremely useful for analyzing ocean color images, which have long time series and significant spatial variability (Baldacci et al., 2001; Yoder et al., 2001; Brickley and Thomas, 2004; Navarro and Ruiz, 2006). As EOF requires data sets without spatial gaps, we only used images that had less than 20% of pixels removed because of clouds. Additionally, prior to performing EOF analysis, any gaps in the data, due to clouds, were replaced by the average of the surrounding 8 non-cloud pixels. Using the criteria of less than 20% cloud cover, our final data set resulted in total of 468 4-day composites images with sufficient temporal resolution to resolve short-lived chlorophyll events. The numbers of images in each month used in the EOF analysis are presented in Fig. 2. EOF analysis was performed after subtracting the temporal mean of each pixel over the entire time series.

Additionally, we analyzed the chlorophyll variability using a cluster analysis. This was used to access to what degree the different

environmental conditions were associated with the chlorophyll concentrations over the 9-year data sets. Cluster analysis was carried out using Ward's method to minimize the sum of the squares of any two hypothetical clusters that can be formed at each step (Ward, 1963) in order to emphasize the homogeneous nature of each cluster. The cluster analysis was conducted using storm frequency, maximum chlorophyll concentration and mean river discharge during winter time (Dec.–Jan.) and carried out in SAS 9.1. The cluster analysis was complemented with regression analysis based on storm frequency, maximum chlorophyll concentration and mean river discharge.

3. Results

3.1. Seasonal cycle

For the MAB (shaded gray area in Fig. 1), the spatially averaged monthly chlorophyll concentration revealed an annual cycle characterized by high values during fall–winter months (October–March), which decreased until it reached lowest values during the highly stratified summer months (Fig. 3). The integrated chlorophyll from October to March represented 58% of the annual chlorophyll. The fall–winter peak in chlorophyll began in the late fall and it persisted throughout the winter into early spring of the next year. The enhanced phytoplankton biomass in the fall–winter was most obvious in 2005 when there were high chlorophyll concentrations in November, which remained high until March 2006. There was significant inter-annual variability in the magnitude of the fall–winter events, for example in 2002–2003 the fall–winter chlorophyll biomass was not as elevated as in the other years of this study.

The significance of the EOF modes for the spatial and temporal variability in chlorophyll was tested following methods described by North et al. (1982). The error produced in the EOF due to the finite number of images was $\delta\lambda \approx \lambda(2/n)^{1/2}$, where λ is the eigenvalue and n is the degree of freedom. Only the first two modes were found significant. Spatial coefficients are presented in Fig. 4A and C. The color of the coefficient is directly related to the amplitude of the spatial coefficient. Temporal amplitudes of the EOF modes are presented in Fig. 5A. Therefore, the combination of the spatial and temporal variability can be obtained multiplying the spatial coefficient by the temporal amplitude. In our case, the first mode (Fig. 4A) explained 33% of the total variance, and was related with the seasonal enhanced chlorophyll in the fall–winter. It explained most of the variance between the 20 and 60 m isobaths. All the spatial coefficients were positive with the maxima found nearshore and decreasing offshore. Consequently, when they were multiplied by positive temporal amplitudes the whole field increased with respect to the chlorophyll climatology. The temporal amplitude with a 4-day interval showed high values in the fall–winter almost every year. Sometimes, there was a small increase of temporal amplitude in summer when the overall chlorophyll concentration was low (<1 mg m^{-3} Chl) except for the nearshore waters (<30 m water depth) where summer upwelling is common (Glenn et al., 2004). The spatial and temporal coefficients suggested that in the middle and outer shelf the fall–winter enhanced chlorophyll was dominant.

The satellite-derived EOF Mode 1 was consistent with the available glider observations (Fig. 6). The average sections for salinity (Fig. 6A), temperature (Fig. 6B), and optical backscatter (Fig. 6C) for the winter season showed very little vertical structure, although there was a significant cross-shore gradient. Salinity increased with distance offshore with highest values beyond 60 km from shore (Fig. 6A). Associated with the inshore lower saline waters were optical backscatter values that were 4–5 fold higher than those found in the offshore waters. The cross-shore extent of high backscatter values corresponded to the boundaries of satellite EOF Mode 1 (near 60 m isobaths) along the glider transects; however it should be noted that the optical backscatter measurements are also sensitive to the presence of sediments and plankton; however the lack of vertical structure in the glider optical data suggests that the winter satellite chlorophyll estimates are not biased by the subsurface layering in the phytoplankton populations.

The second EOF mode (Fig. 4C) explained 8% of the normalized variance and the spatial variability in mode 2 identified two different zones. The first zone had negative spatial coefficients and was located in the coastal areas within the 60 m isobath. The second zone had positive spatial coefficients located between the 80 and 150 m isobaths and extended to the MAB shelf-break front (Linder and Gawarkiewicz, 1998). Given this, the second mode applied to depths greater than 80 m and explained up to 32% of the chlorophyll local variance at those locations (Fig. 4D). The amplitude time series of the second EOF mode (Fig. 5B) generally showed positive values during spring, so when multiplied by positive spatial coefficients (yellow and red region in Fig. 4C) the whole field indicated an increase in the chlorophyll concentration over the shelf-break/slope during spring. Vice versa, the negative amplitudes multiplied by negative spatial coefficients (dark blue region in Fig. 4C) indicated that chlorophyll concentration increased such as seen in New Jersey and Long Island coastal areas during the summer months in 2001 and 2002. The increases of chlorophyll concentration in the shallow coastal area during summer might be correlated with upwelling events. Our results confirm the conclusion by Glenn et al. (2004) that the coastal regions of New Jersey in the summer of 2001 had one of the most significant upwelling events over the 9-year records (1993–2001; Moline et al., 2004), which resulted in high phytoplankton biomass. Mode 2 also exhibited enhanced chlorophyll in the fall both on the shelf and over the continental slope. The spring glider observations did exhibit

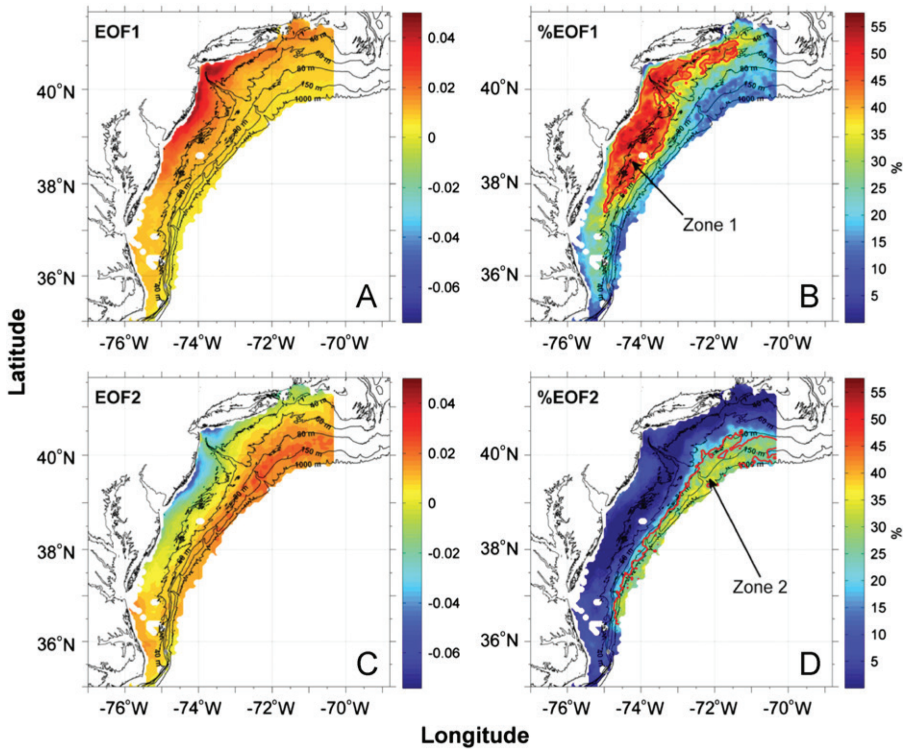

Fig. 4. The EOF modes for chlorophyll in MAB. Left panels are the first two EOF modes, right panels are percentage of the local variance explained by each mode.

enhanced particle concentrations (as detected by the optical backscatter data), both in nearshore (shallower than 30 m) and offshore (deeper than 80 m) waters (Fig. 6C, bottom panel). The enhanced particle concentrations in offshore waters were detectable during the spring, consistent with the EOF mode 2 measured by satellite. In contrast to the winter months, the spring optical data showed significant vertical heterogeneity, with the highest values found at depth. The enhanced backscatter values have been related to storm/wave/tidally driven resuspension processes (Glenn et al., 2008). The enhanced sea surface optical backscatter was associated with increased water column salinity. Low salinity water consistently had higher backscatter values in the surface (Fig. 6A, C, bottom panel).

The chlorophyll climatology in the MAB was analyzed for the two spatial zones delineated by the EOF analysis. The middle and outer shelf region (Zone 1 enclosed in Fig. 4B where the local variance were larger than 40%) identified by the first EOF mode showed mean chlorophyll concentration that ranged between 1.3 and 2.3 mg m^{-3} with highest values observed in fall–winter, and lowest values observed during summer (Fig. 7A, dotted thin line). The highest chlorophyll values were inversely related to the seasonal cycle of PAR and SST, which were highest in June and August respectively. There was a two-month phase lag between PAR and SST. The measured PAR values would lead to light limitation in phytoplankton photosynthesis based on the available photosynthesis-irradiance measurements.

Six years of surface HF radar current data showed that during winter the mean surface flow on the New Jersey shelf was generally offshore and down-shelf (Fig. 8A). Based on wind data from NDBC moored buoy 44009, winter was characterized by strong northwest winds, which we define as a mean velocity of 9.1 m s^{-1} and occur 39% of the time (Gong et al., 2010). Based on the extensive spatial and temporal analysis conducted by Gong et al. (2010), we analyzed the correlations between winds and surface transport during the winter. The cross-shelf wind and cross-shelf surface currents had strong correlations ($R^2 > 0.7$) during the late fall and winter (Fig. 7A, black bold line). Since winds were predominantly from the northwest in winter, cross-shelf flow was observed during this time (Fig. 8A, Gong et al., 2010). The strong northwest winds thus increased the transport of inner shelf fresh and nutrient rich water across the middle of the shelf (Gong et al., 2010). As this occurred when chlorophyll concentrations were high (Fig. 7A, thin line with dot), we hypothesize that the cross-shelf transport of fresh water induced intermittent surface stable layer, that promoted phytoplankton growth. Moreover, the cross-shelf transport may carry coastal phytoplankton populations from the nearshore (<20 m depths) out across the areal extent of EOF zone 1. Therefore, the highest phytoplankton concentrations occurred when the cross-shelf currents were correlated with cross-shelf wind in the late fall and winter. Simulations using passive particle tracers support this interpretation (Gong et al., 2010).

The second EOF mode explained more than 25% of the variance at the shelf-break/slope region (zone 2 enclosed in Fig. 4D). The spatially averaged chlorophyll concentration in zone 2 exhibited a maximum chlorophyll concentration in spring that fluctuated between 0.3 and 1.5 mg m^{-3} over the year. Chlorophyll concentrations began to increase as PAR began to increase. The chlorophyll concentration began to decline as SST began to increase late in spring. The second peak of chlorophyll concentration appeared in fall with a peak of 0.9 mg m^{-3} as climatological means of PAR and SST began to decrease.

The six-year climatology of seasonal flow on the shelf during spring was mostly down-shelf towards the southwest (Fig. 8B). Northeast (along-shelf) winds were more common in spring and fall. The response of surface flow under northeast winds was most energetic during the transition seasons (Gong et al., 2010). Therefore, the high correlation coefficient between along-shelf wind

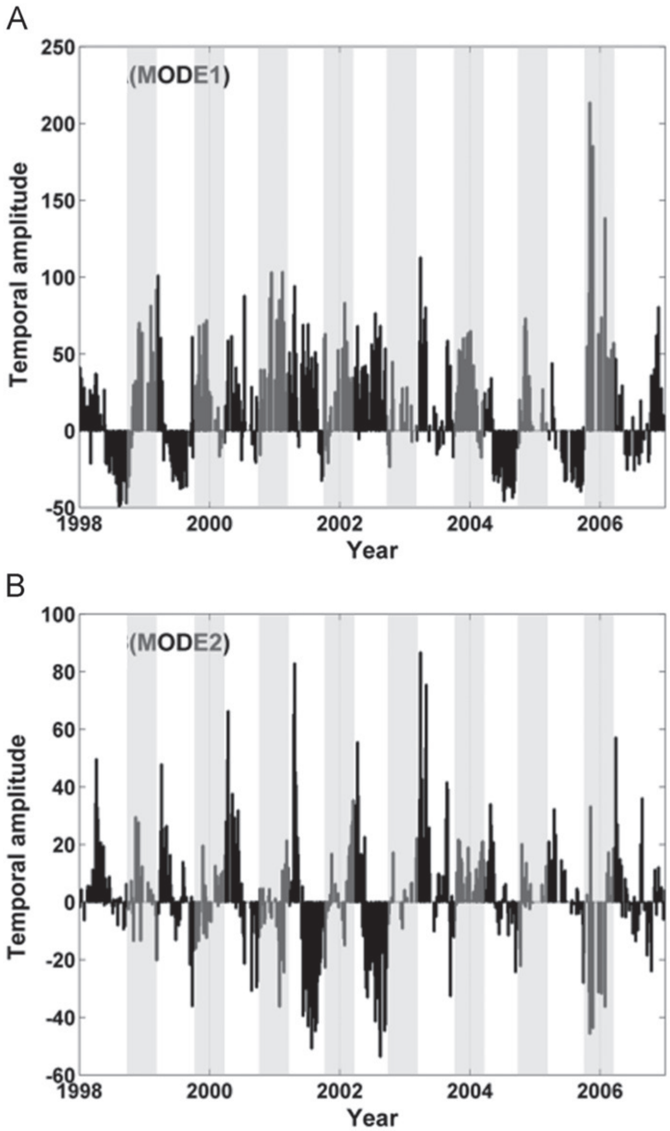

Fig. 5. Time series of the amplitude of the first two EOF modes. The gray transparent bars indicate the winter months.

and along-shelf current appeared during the transitional periods (April–May and October–November; Fig. 7B, black bold line), when the water column was stratifying in spring and as stratification was eroded in fall. The northerly winds potentially bring up shelf bottom boundary layer water through shelf-break upwelling, which is a source of nutrients and could contribute to enhanced chlorophyll in spring and fall (Siedlecki et al., 2008).

In EOF zone 2, there was another small peak of chlorophyll concentration during strongly stratified month of August. Phytoplankton growth earlier in the season would have depleted the nutrients in this region. Potentially onwelling along the slope, due to prevailing southerly wind, might have provided a source of nutrients (Siedlecki et al., 2008).

3.2. *Mechanisms underlying the inter-annual chlorophyll variability*

Over the 9-year time series, the magnitude of the enhanced chlorophyll in the fall–winter varied between 1.9 and 5.2 mg chl a m^{-3} (Fig. 9). One factor underlying the inter-annual variability was the presence of buoyant river plumes. In our data, the largest winter phytoplankton event occurred in 2006 and was associated with sustained high river discharge through the winter (Fig. 9). While precipitation that year was normal, it was a warm winter and runoff was high as ice and snow formation was low. The 2006 river discharge event was observed by a Webb glider as a mid-shelf low salinity plume (as indicated by declines of 2 salinity units) in the upper mixed layer (Fig. 10B). The January 2006 winter plume was also evident as enhanced chlorophyll biomass in the SeaWiFS chlorophyll 4-day composite image from January 25th to 28th (Fig. 10A). The river plume is often transported out onto and south across the MAB under northwest wind conditions (Chant et al., 2008b). The plume can promote phytoplankton growth by stabilizing the upper water column and by transporting chlorophyll rich water from the estuary out onto the outer shelf offshore (Malone et al., 1983; Cahill et al., 2008). Additionally the river transports CDOM and non-pigmented particulate matter that can also lead to a 50–100% overestimate of chlorophyll (Harding et al., 2004). This suggests that years of high river discharge have the most biased satellite imagery. In spite of the potential satellite bias, the large river plume in 2006 contributed to the winter bloom as the river also transports extremely high concentrations of phytoplankton (Moline et al., 2008). While 2006 was the most sustained winter river discharge event, there were significant fall–winter discharge events in 1998, 2004, and 2005, which were also associated with winter blooms (Fig. 9); however, there were two years (1999–2003) where no clear relationship between river discharge and winter bloom was found suggesting other factors are also important.

Another major factor influencing the inter-annual variability in the winter bloom magnitude was the frequency of storms. Storm-induced mixing lowers the irradiance available to the phytoplankton as cells are circulated deep in the water column. The role of the storms was difficult to study as storm periods are associated with heavy cloud cover. We measured storm frequency during the months of January and February using the NOAA moored buoy 44025 where a stormy day was defined as one when wind speeds exceeded 10 m s^{-1}. There was a significant inverse relationship between the percent of stormy days (storm) in the winter and maximum winter chlorophyll concentration (chl a; Fig. 11A): chl a$=4.34-0.05$ storm ($R^2=0.18$, $P=0.005$). In the winter, even small storms are able to induce significant mixing in the water column (Dickey and Williams., 2001; Glenn et al., 2008), which can increase overall light limitation of the phytoplankton populations. We hypothesize that the storm frequency and the river discharge are important to the winter phytoplankton as both impact the stability of the water column. Including winter river discharge in the estimation of the magnitude of the chlorophyll concentration improved the regression statistics (chl a$=4.04-0.05$ storm$+0.000309$ river ($R^2=0.21\%$, $P=0.02$)).

We performed a cluster analysis to explore the relationship between winter storm frequency, chlorophyll concentration and river discharge. Results from the ten years record clustered into two groups: one was 1998, 2000, 2003, 2004, and 2005; another was 1999, 2001, 2002, 2006, and 2007. As shown in Fig. 11A, these two clusters were separated at a winter storm frequency of 27%, which we hypothesize is the threshold where mixing is sustained to decrease overall seasonal winter phytoplankton concentrations.

The spring bloom occurred at the shelf-break/slope region. The spring bloom began in late March (mean start date was March 22nd) where we defined the start of the bloom as when the chlorophyll concentrations rise 5% above that year's annual median (Siegel et al., 2002). The initiation of the spring bloom was phased around 16 days after the onset of sea surface temperature warming on the MAB. This is consistent with the hypothesis that blooms begin as the water column stratifies and phytoplankton are maintained within the euphotic zone. Given this hypothesis, the

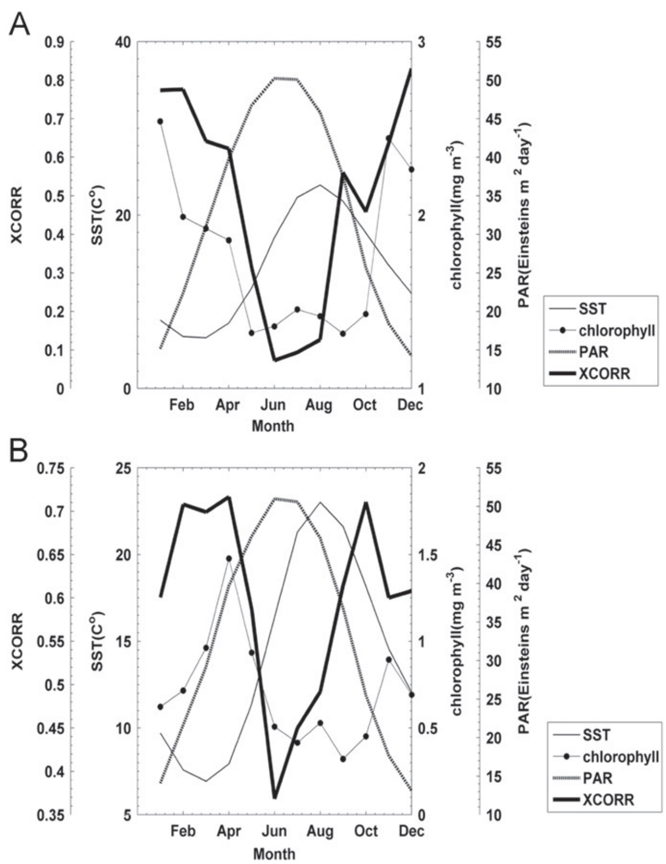

Fig. 7. Monthly climatology of SST (thin black line, °C), PAR (dash line, Einstein's m^{-2} day^{-1}) and chlorophyll (thin line with dot, mg m^{-3}) averaged over the two regions (zone 1 and zone 2 in Fig. 4) identified by the EOF analysis. Value averaged over zone 1 is shown on panel (A) together with correlation coefficient between cross-shelf wind and cross-shelf current (bold black line). Value averaged over zone 2 is shown on panel (B), together with correlation coefficient between along-shelf wind and along-shelf current. In both panels, correlation analysis used wind observations from NDBC 44009 station, and HF radar currents along the cross-shelf line, which is coincident with the glider endurance line (see Fig. 1 for location).

timing of the spring bloom should be sensitive to weather conditions in the early spring that can precondition the shelf's stratification rate. Additionally, the timing of bloom can be important to the magnitude of the spring bloom. If a bloom starts late, it may miss the 'window of opportunity' with optimum mixing and light conditions, resulting in a reduced bloom magnitude (Henson et al., 2006). Using all available data there was not a significant relationship between the magnitude of the spring bloom and number of stormy days in early spring (February–March); however, this was largely due to the spring 2003, which had a very high chlorophyll concentration despite moderate stormy conditions. Excluding 2003, there was a significant relationship (Chl a$=3.62-0.0745$ storm, $R^2=0.38$, $P=0.001$, Fig. 11B).

4. Discussion

Our 9-year of SeaWiFS chlorophyll data set showed two distinct zones for phytoplankton activity on the MAB. The middle and outer shelf region was associated with the recurrent winter phytoplankton blooms. The outer shelf-break/slope region was associated with the spring bloom. Although blooms in these two regions were separated in both space and time; however the magnitude of both blooms were both influenced by factors impacting water column stability.

Winter and spring phytoplankton blooms represent the major biological events in the MAB. The most recurrent and largest phytoplankton bloom occurs in winter (Ryan et al., 1999, 2001; Yoder et al., 1993, 2001, 2002), beginning in late fall and lasting through February. The winter bloom begins as the seasonal cooling erodes water column stratification, which results in the convective overturn of the water column. This process is accelerated by the passage of late fall storms (Glenn et al., 2008). The erosion of the stratification allows nutrient rich bottom waters to reach the surface alleviating nutrient limitation of phytoplankton within the euphotic zone. The spring bloom occurs on the outer shelf as seasonal warming begins to stabilize and stratify the water column. This is consistent with classical view advanced by Sverdrup (1953), and refined by Townsend et al. (1992) and

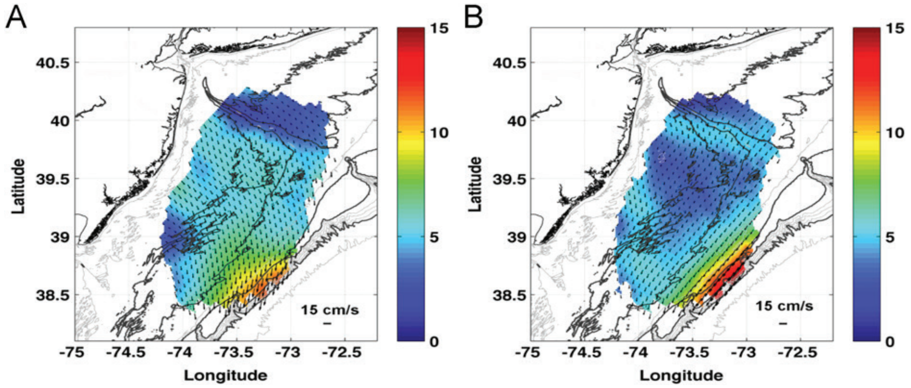

Fig. 8. Seasonal surface currents on the New Jersey Shelf (cm s^{-1}), vectors represent the current field and the color map is the magnitude of velocity: (A) Winter (December–February) (B) Spring (March–May).

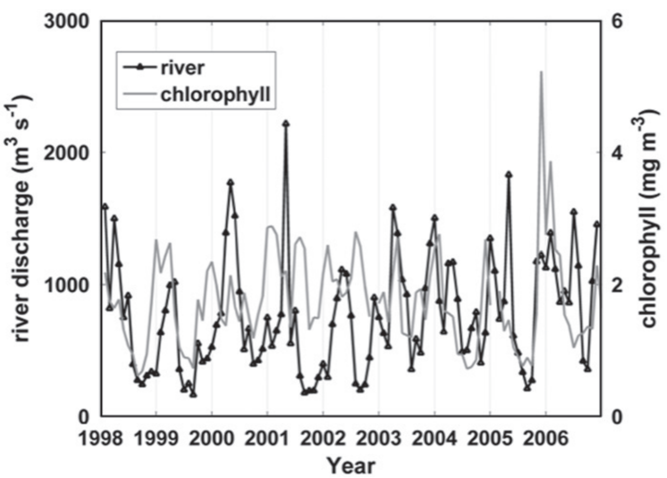

Fig. 9. Monthly and spatial averaged chlorophyll concentration (gray line) for area (zone 1 in Fig. 4(B)) depicted by the EOF mode 1 (mg m^{-3}). The triangle marked black line represents the monthly mean river discharge in $m^3\ s^{-1}$.

Huisman et al. (1999), that phytoplankton blooms are initiated in nutrient replete waters when vertical mixing rates are slow so that phytoplankton photosynthetic rates are sufficient to support significant phytoplankton growth. Thus light regulation is central to both the winter and spring phytoplankton blooms on the MAB.

The winter blooms over the middle and outer shelf spanned the 20–60 m isobath as delineated by EOF mode 1. We hypothesize that this depth range reflected the zone where a significant fraction of the water column had sufficient light to support phytoplankton growth. We used the satellite chlorophyll and the Hydrolight radiative transfer model to estimate the depth of the 1% light level for EOF mode 1 region. In the EOF mode 1 region, the mean water depth was 41 m and the calculated mean 1% light depth was close to 20 m; therefore 49% of the water column was above the 1% light levels (Table 1). This is significant as the winter blooms occur during the dimmest months of the year and incident light levels on the ocean surface are low. Even on the offshore side of the winter bloom at around 60 m a significant fraction of the water column resides above the 1% light level, which allows for significant photosynthesis (Falkowski and Raven, 2007). These calculations assume that the attenuation of light is only due to water and chlorophyll. In the MAB, especially when Hudson River water is present, there are other optical constituents (CDOM, detritus) that attenuate the light (Johnson et al., 2003). To assess the potential impact of the presence of Case II waters on the estimates of the 1% light depth, we combined the available optical measurements made in the Hudson River with Hydrolight. The turbidity of the Hudson River during the LaTTE experiment decreased as the water flowed offshore; therefore we calculated the impact for two scenarios. Scenario 1 was using data collected within the Hudson shelf valley where influence of Hudson River runoff was small. Scenario 2 was the offshore Hudson River, which represented turbid conditions within the Hudson River plume on the MAB. For these waters where river water was present, the depth 1% light level decreased to 10–20 m depending on the rivers turbidity; however despite the increase in turbidity 25–50% of the water column in EOF mode 1 would remain above the 1% light level (Table 1). Thus in winter, phytoplankton appears to have sufficient light to grow when storm activity remains below the critical threshold of mixing.

The spring bloom occurred further offshore than the winter bloom and extended inshore of the MAB into shelf-break/slope area. Climatological temperature and salinity observations generally placed the foot of the front at the 80 m isobaths (Wright, 1976); however, the front location can vary by as much as 20 km (Linder et al., 2004). Therefore, the shelf-break front can possibly affect the offshore extent of the winter bloom and generally coincides with offshore extent of the spring bloom. The shelf-break and slope area range from 200 to 681 m water depths and based upon the mean satellite measured chlorophyll the 1% light depth was 33 m. This euphotic zone represents 5–17% of water column. Therefore the phytoplankton blooms occur only after the solar radiation began to increase which increases the flux of light to the surface ocean and also helps stabilizing the water column by warming the surface water. This allows the cells to overcome chronic light limitation in a deeply mixing water column (Sverdrup, 1953).

The temporal amplitude of the EOF analysis (Fig. 5) demonstrates the seasonal timing of chlorophyll blooms was consistent between years; however, there was considerable inter-annual variability in the magnitude of the winter and spring blooms. The variability in the magnitude of the blooms was associated with factors that alter the water column stability. Winters with low storm activity were characterized by having large winter phytoplankton blooms. Additionally the middle and outer shelves can be significantly influenced by the Hudson River that can deliver large buoyant plumes (Castelao et al., 2008a). These buoyant plumes stabilize the water column and transports chlorophyll from estuaries onto the shelf (Moline et al., 2008). In contrast, the spring bloom requires the shelf-break/slope water to stratify before the bloom can occur. Once the system is stratified, the pycnocline on the MAB is extremely strong and is generally not disrupted until later autumn when wind mixing and surface cooling lead to convective overturn (Biscaye et al., 1994). Given this,

(B) Salinity cross-section measured with a glider along the transect shown in panel (A). The glider measurement is from 2006 January 18th to 23rd.

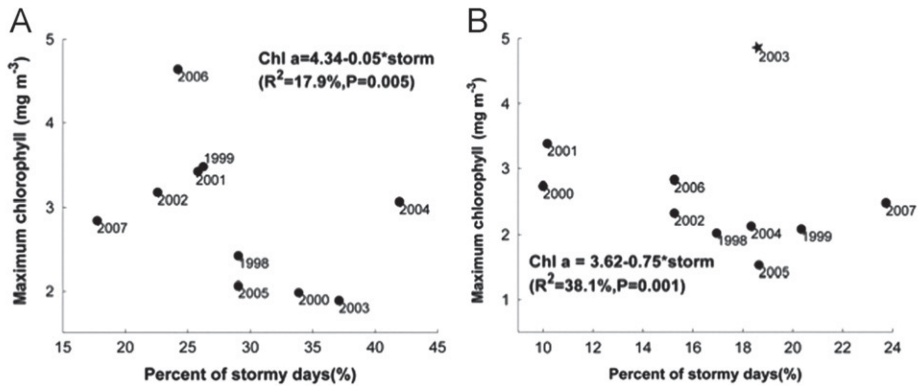

Fig. 11. (A) Percentage of stormy days against maximum SeaWiFS chlorophyll concentration (mg m^{-3}) in the area depicted by EOF mode 1, (B) Percentage of stormy days against maximum SeaWiFS chlorophyll concentration (mg m^{-3}) in area depicted by EOF mode 2. In panel (A), wind observations are from NDBC 44025 during Dec.–Jan., while in panel (B), winds are from NDBC 44014 during Feb.–Mar.; the star for 2003 marks it as an outlier.

Table 1
Chlorophyll (mg m^{-3}) and light environment for the two regions defined by the EOF analysis in the MAB. For the shelf waters the 1% light depth was calculated using Hydrolight combined with optical data collected during the LaTTE experiment (Chant et al., 2008b, Moline et al., 2008).

Parameter	Shelf (zone 1)	Shelf-break (zone 2)
Mean Chl a (mg m^{-3})	1.7	0.7
Maximum Chl a (mg m^{-3})	4.9	2.1
Minimum Chl a (mg m^{-3})	0.6	0.2
Mean 1% Light depth (m)	20	33
Maximum 1% Light depth (m)	12	27
Minimum 1% Light depth (m)	36	55
Mean Water Depth (m)	41	200–681[a]
Percent of water column above the 1% light (%)	49	5–17
Shelf valley ac-9 data 1% light depth (m)	20	
Offshore Hudson River ac-9 data 1% light depth (m)	10	

[a] Much of zone 2 occurs over the continental slope. Therefore we show the depths at the inner edge of the continental slope and the mean depth of zone 2.

the factors influencing the stratification rate are the key variables to predicting the shelf-break/slope phytoplankton bloom. In the work of Lentz et al. (2003), they suggest that the direction, magnitude, and timing of spring wind stress events play an important role in inter-annual variations in stratification. For the unique year 2003, precipitation, river runoff, sea surface temperature, and air temperature were not unusual and could not account for the high spring time chlorophyll concentration. The late winter 2003 were characterized by strong southwest winds; however, by early spring the winds shifted northeast. This resulted in predominately down-shelf and onshore transport. These northeast winds were not extremely strong in magnitude but they were sustained throughout the spring. Compared with other years, the 2003 spring had higher frequency of down-shore (53 days compared with the 11 year mean of 41 days) and towards-shore (48 days compared with the 11 year mean of 41 days) winds. Under such wind conditions, there was convergence in the bottom waters at the shelf/slope, which can result in upwelling conditions that promote phytoplankton blooms (Siedlecki et al., 2008). Therefore, while regional pre-spring wind does impact the magnitude of the spring bloom, this relationship is not particularly robust as it can be overcome by local winds. The correlation between storminess and bloom magnitude was consistent with open ocean sites (Henson et al., 2006) where storms delay the stratification of the upper ocean.

Since the MAB hydrography strongly influences the spatial and temporal patterns in satellite chlorophyll, understanding these processes is critical as the shelf water of MAB is experiencing significant changes in its temperature, salinity (Mountain, 2003). Since the 1990s, the shelf water, which is the primary water mass in the MAB, has become warmer, fresher, and more abundant than during 1977–1987. This has been correlated with transport of Scotian Shelf water and slope water and local atmospheric heat flux (Mountain, 2003). These changes are likely to influence the stratification dynamics on the MAB. The freshening of the ocean can enhance vertical stratification that has been shown to be critical to the timing and magnitude of phytoplankton blooms (Ji et al., 2007). Additionally winter wind stress has increased in the last decade on the MAB and these changes have been associated with decadal declines in chlorophyll biomass in the fall and winter (Schofield et al., 2008). Given this, future work should focus on determining the critical thresholds between water stability and phytoplankton growth. While maximum chlorophyll concentration was affected by storm frequency and river plume, other biological factors such as nutrient concentrations or grazing may also be important. This requires new data collected for sustained periods of time to complement satellite imagery. The use of gliders as observational platforms allowed for shelf waters to be sampled frequently over long periods of time. Therefore, we recommend gliders and satellite observations be focused during the transition season and provide the basis for evaluating the relationship between stratification/destratification and the blooms in the future.

Acknowledgments

We thank the members of the Rutgers University Coastal Ocean Observation Laboratory (RU COOL), who were responsible for the satellite, glider and CODAR operations, with particular gratitude to Jennifer Bosch and Lisa Ojanen, who helped with satellite data collection and processing. ABSTRACT

Results of Office of Naval Research (ONR)- and National Science Foundation (NSF)-sponsored collaborative coastal science experiments using underwater gliders were reported at the E.U./U.S. Baltic Sea conference in 2006. The National Oceanic and Atmospheric Administration (NOAA) recognized the parallel educational potential and issued a trans-Atlantic challenge—modify one of the coastal gliders and fly it across the Atlantic, entraining and inspiring students along the way. Leveraging the experience of the NSF Centers for Ocean Sciences Education Excellence, a needs assessment process guided the development of a new undergraduate research program based on the cognitive apprenticeship model. The generalized model was applied to the specific opportunities provided by the trans-Atlantic challenge, involving students in every aspect of the missions. Students participated in the modifications and testing required to increase glider endurance and in the development of the mission planning tools. Scientist and student teams conducted three long-duration missions: (1) RU15's flight from New Jersey to Nova Scotia to test the lithium batteries and ruggedized fin technology in storms, (2) RU17's first attempt at the Atlantic crossing that provided the lessons learned, and (3) RU27's successful trans-Atlantic flight a year later. Post-flight activities included development of new intuitive glider data visualization software that enabled students to analyze the glider data and compare it with ocean forecast models, enabling students to create their own new knowledge. Lessons learned include the significant gains achieved by engaging students early, encouraging them to work as teams, giving them the tools to make their own discoveries, and developing a near-peer mentoring community for increasing retention and diversity. The success has inspired an even broader vision for international glider missions, that of a glider-enabled global classroom to repeat the track of the HMS *Challenger* and its first scientific circumnavigation of the globe.

Introduction

The field of oceanography is shaped by a rich history of expeditionary science. The inspiration provided by our short times at sea has spurred the imagination and creativity of ocean scientists for centuries, prompting us to imagine and implement new approaches for exploring, observing, understanding, and utilizing the world's oceans. One vision from 22 years ago (Stommel, 1989) was that of a global ocean patrolled by Slocum underwater gliders guided by satellite data and numerical model forecasts. In Hank Stommel's futuristic world, support for the network was galvanized by a 198-day trans-Atlantic flight of the glider *Sentinel 1* from Bermuda to northwest Africa. The mission was flown by researchers working from an attic control room in the Woods Hole Oceanographic Institution's Bigelow Building. At that time in Woods Hole's history, the attic of Bigelow was occupied by oceanography students.

Since that inspirational vision was published, ocean glider technology has matured and now routinely anchors scientific experiments, enabling scientists to conduct sustained and adaptively adjusted science missions (Davis et al., 2003; Schofield et al., 2007). The adaptive sampling capabilities of the gliders are enabled by their ability to navigate relative to the flow and the two-way communications provided by the global Iridium network, allowing glider data to be sent to control centers on shore and new sampling commands to be sent back to the gliders at sea. As ocean observatories continue to mature, coordinated fleets of gliders are growing contributors to the National Oceanic and Atmospheric Administration (NOAA)-led U.S. Integrated Ocean Observing System (IOOS®) (Schofield et al., 2010a), the National Science Foundation (NSF) Ocean Observing Initiative (OOI) (Schofield et al., 2010b), and the Navy's Littoral Battlespace Sensing-Glider (LBS-G) initiative. These initiatives and others are implementing what Walter Munk termed the 1 + 1 = 3 scenario for ocean sampling (Munk, 2000), where a new ocean omnipresence is enabled by satellites in space combined with vast in-water arrays of drifting profilers, gliders, and time series stations. The approach not only offers researchers new opportunities for ocean science but also provides a potential mechanism to share the real-time excitement of exploration and scientific discovery with students and the public.

The educational value of the gliders was recognized by NOAA leadership in May of 2006 at the E.U./U.S. sponsored conference promoting international collaborations in the Baltic Sea. NOAA responded to the growing number of glider presentations with a challenge to take one of the existing gliders, modify it, and fly it across the Atlantic, entraining and inspiring students along the way. It was presented as a response to the *Rising Above the Gathering Storm* (2007) report's observation that while the vitality of the U.S. economy depends on the scientific and technological innovations of a well-educated workforce, U.S. economic leadership was eroding partly because of the decreasing number of students choosing science, math, and engineering careers. The trans-Atlantic glider mission was viewed as an opportunity to re-spark interest in science and technology, invigorate student involvement, and influence their career path. It was considered high risk but, with the proper visibility, capable of producing high rewards.

Rutgers scientists attending the Baltic Sea conference viewed NOAA's trans-Atlantic challenge as an opportunity to develop a new educational program enabled by the gliders. Participation in high-risk ocean-scale glider expeditions would provide opportunities for students to directly experience the many difficulties of operating at sea, the value of perseverance and teamwork, and the feeling of accomplishment when successful. Students would experience the excitement of discovery through the analysis of data they helped collect from harsh environment, and they would gain a more global cultural perspective by communicating with scientists and students from around the world.

This led Rutgers, Teledyne Webb Research, and their international partners to conduct three long-duration glider missions in 2008–2009. The first extended-duration mission of the series, glider RU15's flight from Tuckerton, New Jersey to Halifax, Nova Scotia, crossed international borders and tested the new technologies that would be required on future trans-Atlantic missions. Glider RU17's first attempt at the Atlantic crossing started off the coast of New Jersey and ended in what may have been a biologically induced leak offshore the Azores and the always heartbreaking loss of a glider at sea. One year later, glider RU27, a second trans-Atlantic Slocum glider christened *Scarlet Knight* by U.S. IOOS, was launched off New Jersey. Visited by divers in the Azores for a visual inspection, it was freed of barnacles while still in the water and continued traveling its 7,400-km course. After spending 221 days at sea, it was recovered in Spanish waters by the Puertos del Estado buoy tender *Investigador,* making it the first underwater robot to cross an ocean basin. It now resides in the Smithsonian's National Museum of Natural History. What was unique about these three missions is that they were conducted with undergraduate students as part of their classroom experience, beginning in the construction phase, throughout the three ocean journeys, and into the post-mission data analysis phase, providing a unique opportunity for participatory science learning.

This manuscript provides an overview of the education programs developed, how they were applied to the trans-Atlantic missions, and the educational lessons learned. It concludes with a perspective on how this educational effort provides the foundation for an international partnership to explore the world ocean on a second NOAA challenge, a repeat of the 1870 Challenger Mission, the first scientific circumnavigation of the globe.

New Approaches to Undergraduate Education

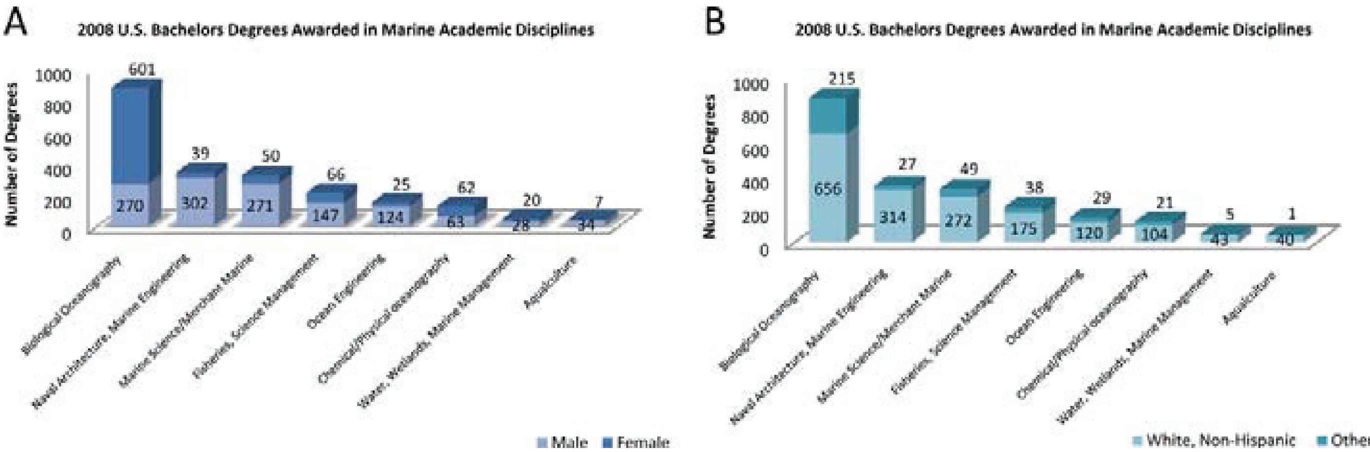
Rising Above the Gathering Storm noted that while 30% of students entering U.S. colleges intend to major in science and engineering; less than half complete their bachelor's degrees in these subjects. Even qualified students grow discouraged before reaching the workforce. The report recommends providing undergraduate research experiences that extend beyond the classroom and across the summer as early as possible and emphasizes the need for near-peer mentorship to augment engaged faculty. Since the envisioned trans-Atlantic glider mission would require a workforce for construction, prelaunch testing, and post-launch path planning and data analysis with limited support for technician time, student participation was necessary. But how could the required long-term student involvement fit within an already busy undergraduate schedule, and how would it help the students in their future job searches?

Our approach was informed through a needs assessment process facilitated by the NSF Centers for Ocean Sciences Education Excellence-Networked Ocean World (COSEE-NOW). The needs assessment confirmed that oceanographic graduate education programs are still looking for Ph.D. students with strong basic science and math backgrounds, but it also revealed that federal agencies, companies, and even some university research laboratories are also looking for oceanographers with bachelor's and master's degrees. Other requirements include people to operate new observing technologies, to run and interpret forecast models, and to communicate scientific information. The assessment indicated that government agencies are willing to support undergraduate internships as a cost-effective way to both engage and evaluate students as potential new employees, with opportunities for earning of a master's degree once hired. Support for certification of oceanographic professionals was found to be greatest at the bachelor's degree level (Rosenfeld et al., 2009). Employers are looking for individuals with a cross-disciplinary education (oceanography plus a minor), a range of technical abilities that could adapt to different jobs, strong written and verbal communication skills, and hands-on real-world working-team experiences. An educational environment that developed the student's ability to work as part of a larger team was especially well received by companies. If a student receives a bad grade in a class, the bad grade can be hidden, since it only affects the individual. But workplace activities are often team efforts, where the failure of one team member publicly impacts the entire team. In addition, federal agencies emphasized that the desired workforce should be more diverse and more reflective of the U.S. general population. U.S. census bureau estimates for 2008 indicate that the 22-year-old resident population is 62% White, non-Hispanic. NSF graduation statistics for 2008 indicate that the existing undergraduate marine science pool is extremely small, with only 2,109 bachelor's degrees awarded nationally (Figure 1). In these marine academic disciplines, 82% of the bachelor's degrees were awarded to White, non-Hispanic students, and 59% were male.

In response to *Rising Above the Gathering Storm* and guided by the COSEE-NOW needs assessment, the NOAA trans-Atlantic glider challenge has become the catalyst for transforming our approach to undergraduate education in marine sciences. To move students beyond the marine science classroom into a team project environment and to increase diversity, an undergraduate education program was established based on the cognitive apprenticeship model restated more simply as "watch one, do one, teach one". (See education break-out box in Glenn and Schofield, 2009). The three phases start with the initial engagement, move on to team research, and culminate with veteran students in leadership roles mentoring the new students. Students from diverse disciplines across the campus are engaged as early as their freshman year, with opportunities to continue with the program through graduation. Initial engagement occurs by (a) recruiting from several traditional 100-level science-distribution Introduction to

FIGURE 1

Distribution of the 2,109 U.S. bachelor's degrees awarded in marine academic disciplines for 2008 by sex (A) and ethnicity (B). Source: *National Science Foundation*.



Oceanography lecture courses, to which we have added (b) faculty participation in a university-wide series of one-credit freshman seminars where small groups of 20 students are introduced to senior level faculty, (c) the establishment of the Oceanography House as an on-campus living-and-learning community for incoming freshmen with an interest in the ocean, and (d) through near-peer university-sponsored events and an active Oceanography Club where students already involved discuss their involvement with other Rutgers undergraduates or with students back at their high schools.

At the middle level, while students are completing their usual content courses for their major/minor, a new team research track that runs in parallel with their coursework was developed. Undergraduate marine science degrees, as do several other sciences at Rutgers, require at least six credits of research to graduate. To help students fulfill this requirement, the one-credit *Atlantic Crossing* research course was established. The team-taught course runs every semester, and as a research course, students can sign up for it multiple times, potentially taking it every semester of their undergraduate career. The class typically is divided into small working teams of two to three students. Team projects initially focused on the glider rebuilds for long duration, the testing of new systems, and the development of path planning tools to understand the uncertainty associated with the constantly evolving ocean currents used as a roadmap. The product at the end of each semester is a poster session by each working team similar to those conducted at science conferences.

Finally, three capstone opportunities are offered. First, as students become more experienced, they become team leaders, responsible for organizing and reporting their team's progress and acting as a mentor to younger students. Many students have found the long-term progression from a rookie to a veteran team member an achievable goal and a confidence-building experience. Second, the glider datasets provide senior thesis topics for those who want to expand their formal research skills through the preparation and defense of an honors thesis. Often senior theses begin through summer internships available after the student's junior year. Third, the NSF-sponsored nationally coordinated course *Communicating Ocean Sciences to Informal Audiences (COSIA)* is offered for those desiring an introduction to learning theory with participatory opportunities to develop their communication and teaching skills. In *COSIA*, the gliders are a proven magnet, providing a vehicle for engaging informal audiences outside the classroom in more interactive learning activities.

The above approach—needs assessment followed by implementation of a cognitive apprenticeship learning model—can be applied to develop a wide variety of undergraduate education opportunities. It does not require a fleet of gliders to implement.

Application to the Trans-Atlantic Glider Missions

Vehicle Construction. When the trans-Atlantic challenge was issued, Rutgers had completed 66 glider missions, ¾ being in shallow shelf waters and ¼ being in the surface layers of the deep ocean. Mission durations depend on the number of sensors on board, the water depth of operations (deeper water being more power efficient), and the amount of time spent communicating. The longest mission in May of 2006 was 27 days. Since then, many deeper missions were completed with standard alkaline battery packs and only Conductivity, Temperature and Depth (CTD) sensors in the 30- to 40-day range, with a theoretical value of 34 days. A trans-Atlantic mission would require an estimated 300 days, a factor of 10 increase in mission duration. This would not only require more power but also ruggedizing mechanical systems for surviving the longer durations at sea and protection from corrosion and biofouling that do not normally plague a mission of 1-month duration.

Students worked alongside Rutgers technicians in the laboratory to adapt gliders for long-duration missions. Some of these students were on work-study plans with their pay already supported as part of their financial aid package. Others worked for hourly pay or for course credit. This phase was especially well suited for entraining engineering undergraduates. The students learned to take gliders apart, reassemble them with new test parts, reballast, and prepare them for launch. Software changes were tested on simulators. When class schedules permitted, students would accompany technicians on the launch and recovery cruises. The required factor of 10 increase in power was achieved by switching from alkaline to lithium batteries that had four times the energy, building and test flying an extended payload bay that increased the number of batteries from 230 C-cells to 453 C-cells and by reducing the daily average power usage from 2 to 1.5 W by removing the altimeter, the payload bay computer, and lowering the amount of data transferred over Iridium. Corrosion protection was monitored and evaluated by students weighing all parts before and after each deployment. A variety of paints and coatings were tested as student projects to limit biofouling.

Mission Planning Tools. A flight across the Atlantic would require mission planning capabilities well beyond those available in May of 2006. Rutgers had coordinated several month-long Office of Naval Research (ONR) Coastal Predictive Skill Experiments from a collaboratory located at a remote field station (Glenn et al., 2000a, 2000b; Glenn and Schofield, 2003) and recently completed a series of NSF studies of the Hudson River plume with an on-campus collaboratory (Chant et al., 2008). But these studies were relatively short in duration compared with a trans-Atlantic mission that would require sustained operations for many months. Some of these capabilities were developed during the ONR Shallow Water 2006 Joint Experiment on the New Jersey outer shelf (Tang et al., 2007). In this experiment, a distributed team of collaborators was provided an online coordination portal where scientists posted environmental data updates that could be accessed over the Internet on shore or via HiSeasNet on board the fleet of ships. The portal provided a mission planning capability for a coordinated fleet of gliders and ships by sharing daily updates of the environmental conditions.

The trans-Atlantic glider missions required development of a similar collaborative workspace to coordinate the activities of a distributed team of scientists and students located on both sides of the Atlantic and living in different time zones. The international team would require (1) common access to the variety of datasets acquired and forecasts generated on both continents, (2) the ability to overlay the datasets and forecasts in a common operational environment to create new composite analyses for mission planning, and (3) the ability to share our analyses, results, and interpretations so flight decisions could be made. The collaborative portal also had to be constructed and operated with considerably fewer resources than were available to the Shallow Water 2006 Joint Experiment. To accomplish this, the expertise of COSEE-NOW was again tapped to establish an online learning community. The IOOS Mid-Atlantic region was chosen as our testbed, and our students became the beta testers.

To accomplish the first task above, a collaborative Web portal was designed that access points to all existing analyses products and programs could be posted and shared. Rather than build a dedicated set of software tools for overlaying the wide variety of available data and forecasts, Google Earth was chosen as our mission planning tool for the second task. Many of the required datasets (coastlines, bathymetry, weather) were already in Google Earth, and new datasets could be added relatively easily. The full capabilities provided by Google Earth were used to overlay and compare spatial maps, to zoom and pan, to pull off latitudes and longitudes, and to measure distances and bearings. Major data layers added to Google Earth include global ocean forecasts, satellite maps of sea surface height and the resulting geostrophic currents, satellite-derived sea surface temperature and ocean color maps, and the glider tracks with depth-averaged currents. Students

FIGURE 2

were quick to learn the many features of Google Earth and soon developed their ability to create their own analyses and interpretations. The third piece was the ability to post the new analyses products along with an explanation in an open forum. A blog space was established using open-source software. The blog was used not only as our own mission log but also as a means to share interpretations and comment on others. Students posted their weekly assignments to the blog and used the blog to discuss their results each week in class. The blog evolved into the students' textbook, written by the professors and students themselves, and quality controlled through weekly discussions of the postings.

RU15—New Jersey to Nova Scotia. Glider RU15's test flight to Halifax was our first long-duration test mission. It was run on a standard size glider, one of the first equipped with the new ruggedized tailfin designed for the Navy (Figure 2). ONR needed long-term tests of the new fin, especially to determine if the shorter tail would maintain communications during storms. NOAA needed a test of lithium batteries on the coastal gliders to see if they could provide the additional energy for power hungry biological sensors. RU15, modified by Rutgers glider technicians and students to fly off of lithium batteries, was deployed on the New Jersey coast in March of 2008 (Figure 2A). It flew for nearly 2 months on a track that took it out on the Tuckerton Endurance line (Castelao et al., 2008) across the shelf and slope and into the Gulf Stream. Weekly class activities included discussions of the best locations and methodologies for crossing the heavily fished shelf break. Students learned the commands for flying deep below the fishing nets and aiming for locations between the canyons that were focal points for fishing activity. Following the Gulf Stream downstream and exiting about 62.5 W, RU15 headed for a newly formed warm core ring for a boost of momentum to the north. In the process, students were introduced to the many satellite products for locating the meandering Gulf Stream, the ring formation, propagation and absorption process, and the history of ocean forecasting that developed from this region. Exiting the ring proved difficult, requiring a second lap around rather than a slow flight against the strong head current. Scientists and students learned the value of simple path planning tools to decide where to enter a ring and when to start leaving. After exiting the warm core ring on the second lap, RU15 flew from small eddy to small eddy across the Slope Sea, flying back up onto the continental shelf near 63 W and continuing east over the more wind-driven outer shelf until it reached the historic Halifax Line. From there, RU15 flew into shore where it was recovered by our collaborators at Satlantic, Inc., offshore Halifax Harbor. Along the way, RU15 encountered a large winter storm with significant wave heights exceeding 25 feet recorded by a nearby NOAA weather buoy (Figures 2B–2D). Even during the height of the storm, no Iridium satellite communication calls were missed by the antenna in RU15's shortened tail fin. But tests of the lithium batteries after recovery indicated that power was used faster than we expected. Our estimate of battery power available, the power draw of the vehicle, or both were in error.

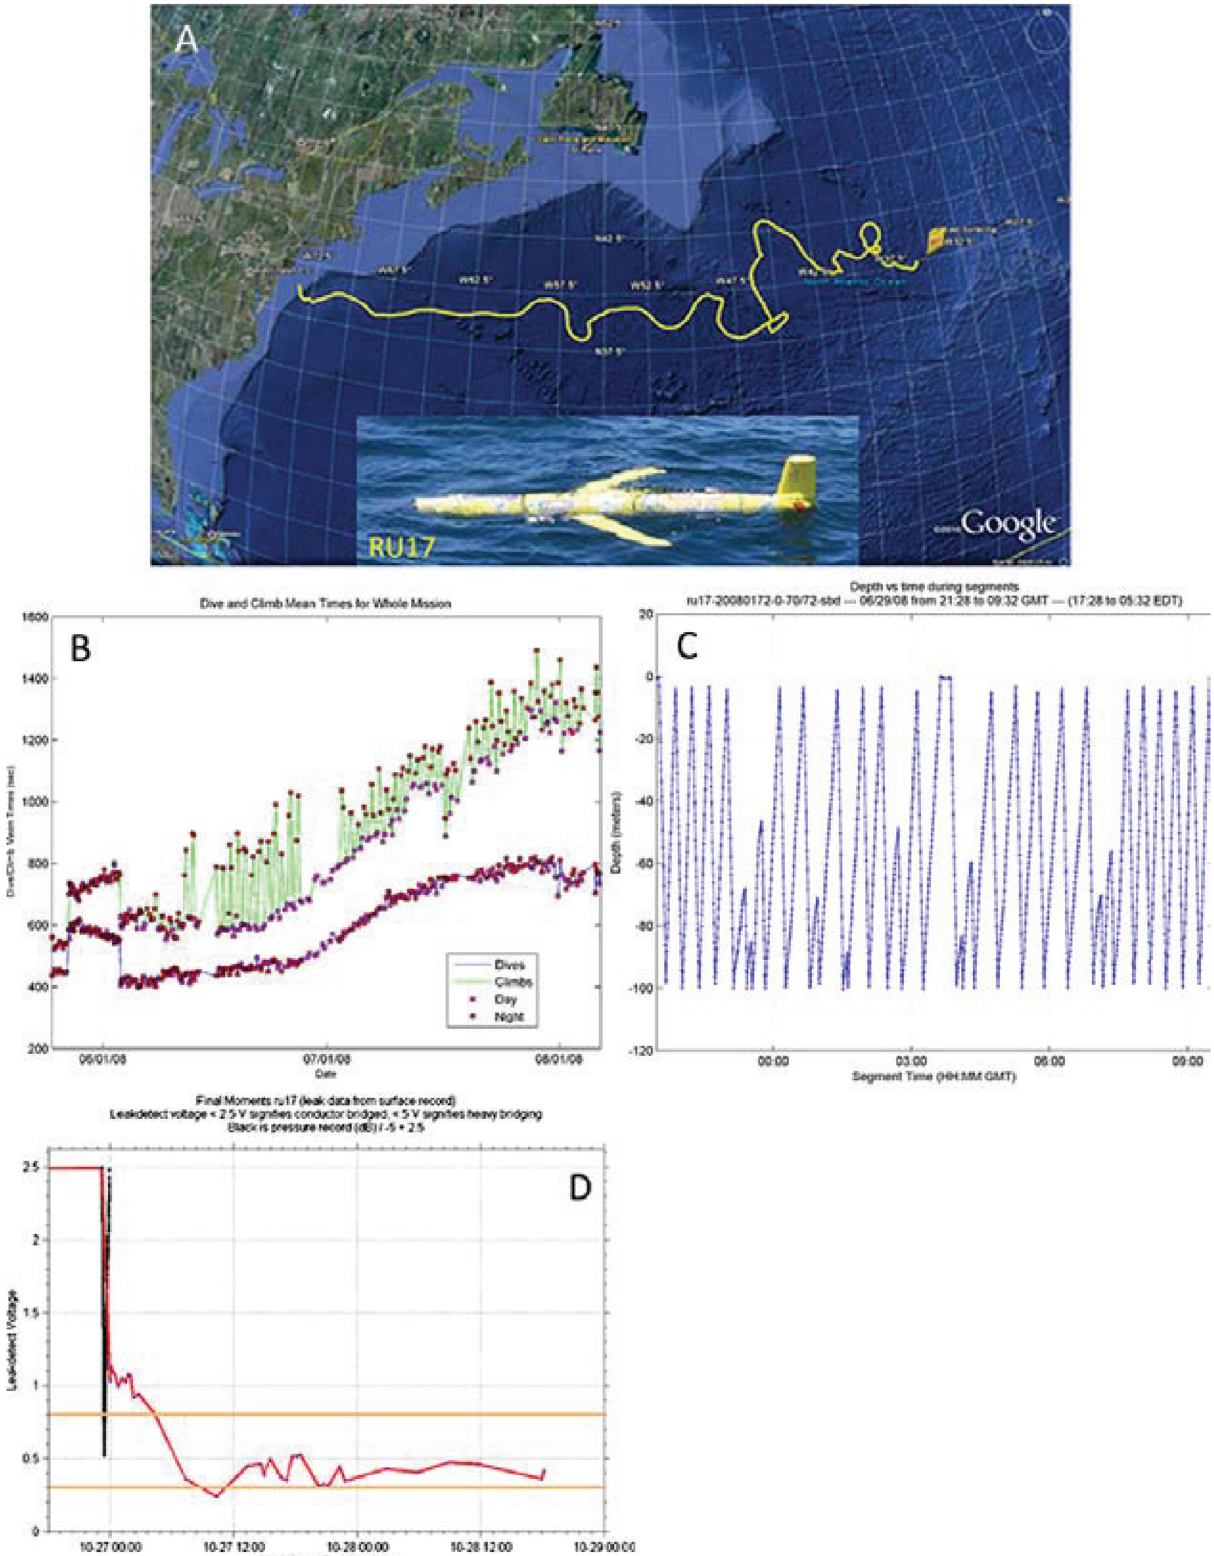
RU17—New Jersey to the Azores (almost). With RU15's recovery on April 28, work on outfitting RU17 proceeded in earnest. There was little time to deal with the power uncertainty if we were to make the spring 2008 launch window. RU17 was launched on May 21 from an offshore location on the outer shelf to save power. RU17 would follow the same general path as RU15, crossing the shelf break between seafloor canyons to avoid the fishing activity. But getting into the Gulf Stream presented problems. There were no warm core rings to catch, and RU27 was on the western side of a Gulf Stream meander crest. It was shedding shingles of warm water that RU17 had to fly against, requiring a full month to get into the Gulf Stream. But the Gulf Stream was relatively straight that spring, and RU17 quickly flew down its length past the Grand Banks of Newfoundland (Figure 3A). The first third of the mission, New Jersey to the Grand Banks, was accomplished during the spring semester with a seasoned crew of students repeating what they had just learned from the RU15 test deployment.

The next task, passed from the *Atlantic Crossing* class onto our summer student interns in the NSF Research Internships in Ocean Sciences (RIOS) program, was to cover the middle third of the mission, flying RU17 from the Grand Banks to the Azores. After passing the Grand Banks, the Gulf Stream splits and filaments, taking several routes east. The region is characterized by an energetic mesoscale eddy field, with eddies that can speed the glider's progress east or totally halt it, sending it back west. This is precisely what occurred at 45 W where RU17 encountered a strong eddy that stopped eastward progress. Summer students running simulations with virtual gliders flying through the Navy's model forecast currents determined that our only alternative was to backtrack with the current to the west, then turn north to a zone of more favorable currents much farther north. The 5° of latitude excursion, with path decisions informed through model simulations, required a full month to complete. RU17 then turned east until about 38 W. During this segment of the flight, engineering students monitoring the flight parameters noted that the biological interactions intensified. Three types of interactions were discovered. One was a behavior that slowed down the glider's vertical motion during the night, and then let it speed up again during the day (Figure 3B). A second behavior included times that the glider's upward motion would nearly or completely stop (Figure 3C). Similar behaviors had been observed in the Gulf of Mexico when negatively buoyant Remora attach to a glider and hold the vehicle down until it triggers an emergency ascent. The third behavior student engineers discovered was the spinning of the glider caused by drag on one side. Hypothesizing that something may have been snagged by one of the wings, technicians and students developed a procedure to fly backwards that they tested on simulators. By deflating the tail floatation bag, pulling the pitch battery all the way back to lower the tail as if it is ascending and simultaneously pulling the pump in to reduce the volume, the glider sinks tail first, flying backwards. Repeated attempts could not clear whatever was causing the drag, and the spinning persisted. Over time, the engineers noted that the spinning was tied to the cycle of the moon. The spinning was worse during the new moon, when the biologists suspected that bioluminescence made the glider one of the brightest objects in the region. During the full moon, the spinning would cease, and the glider was able to fly a steady course again. Given this, our plan was to conserve power and use flight time during the new moon to reach the Azores so that an observation vessel could be launched for a visit.

That plan changed suddenly on October 26, when just before midnight GMT, RU17 scrambled to the surface to report a leak. Leak detection sensors are located in the nose and the tail of each glider. If even a drop of water crosses the leak sensor, a voltage drop is detected and the glider does an emergency ascent. We had seen leak detects with small voltage drops in gliders before, and upon recovery, a failure in an O-ring was detected by visual inspection. This leak detect was different, with an immediate and

FIGURE 3

(A) Track of RU17 on the flight towards the Azores. (B) Average duration of full excursion dives (bottom line) and climbs (top line) showing the day-night variation in climb performance. (C) Sample segment showing normal climbs (100–2 m) and numerous aborted climbs during the local night. (D) Time series of leak detect voltage (red) from the time of the last dive (black dots) on October 27 until the loss of communications on October 28, 2008. Yellow bars show the range of leak detect voltages in laboratory tests for water touching the leak detect sensor (top) to full immersion (bottom).



much larger voltage drop than we had ever seen. From the engineering data, the leak detect was triggered as RU17 was ascending toward the surface at a depth of about 50 m. The large voltage drop on the leak detect indicated that this was unlikely to be a similar O-ring failure. If it was corrosion, it is expected that the hole would break open on the way down as the pressure was increasing, not on the way up as pressure was decreasing. A leak in the air bladder would also result in a significant change in the vacuum inside the pressure hull. There was no change in vacuum, and an air bladder leak would be expected to occur at the surface when the bladder is being inflated, not at depth. Moving to the front, the seams on the movable piston on the buoyancy pump are a possibility, but the design cycles had not been exceeded, and a piston leak would be expected when it is moving at the top or bottom inflection points, not in the middle of a glide. We concluded that the most likely location for a leak of this size that could not be ruled out by the engineering data would be associated with the hull fittings of the CTD. In deployments off Hawaii, we have seen the CTDs damaged by big fish, including sharks, that can bend the sensor by bumping into it, presumably while they are chasing smaller preys that use the glider for cover.

RU17 remained at the surface for 2 days, transmitting its position and engineering data. While preparations were being made for recovery, the leak detect voltage continued to drop (Figure 3D). Students measured the reaction of the leak detect sensors to different amounts of seawater in the laboratory, discovering that the leak detect voltage was already suggesting that the sensors were fully submerged in seawater. Finally, on October 28, we received the last transmission from RU17. The flight of RU17 resulted in the loss glider and heartbreak but also the accumulation of significant knowledge on the long-duration flight requirements for shallow gliders. It reminded everyone of the risk.

RU27—New Jersey to Spain. Lessons learned from the flight of RU17 were used to inform the construction a second long-duration glider with an education mission. RU27 was constructed with an extended payload bay by Teledyne Webb Research as a new product, and as with RU17, the altimeter and payload bay computer were removed. The 100-m buoyancy pump used in RU17 was replaced with a 200-m pump based on the successful repeated deployments by Oregon State University. New pin supports strengthened the CTD. The 435 lithium C-cells on RU17 grew to 453 plus 15 reserve on RU27 by space-saving rearrangements of the internal electronics (Table 1). A Coulomb meter was developed and installed to measure how much energy was being drawn from the batteries. Hull sections and the tail cone were coated with the light rubberized ClearSignal (Lobe et al., 2010) to minimize the need for heavy ablative antifouling paints. Students were involved with all aspects of the build and conducted a test flight from February 18 to March 13, 2009, across the shelfbreak to deepwater to tune the steering and establish the power usage.

RU27 was christened the *Scarlet Knight* by IOOS on March 23, 2009. Placed inside the hull was a NOAA coin, a USB memory stick containing over 100 letters from school children to be printed in Spain and sent back upon arrival, and paper copies of the letters congratulating partners on both sides of the Atlantic, just in case the mission was successful. The *Scarlet Knight* was launched offshore Tuckerton, New Jersey, on April 27, 2009, 10 years after the first Slocum glider was flown at sea in the same location by Doug Webb and a Rutgers student and 20 years after the publication of *The Slocum Mission* (Stommel, 1989).

Continuous monitoring of the flight was coordinated by professors (S. Glenn, O. Schofield, and J. Kohut) working with teams of undergraduate students in the Rutgers *Atlantic Crossing* research course during the spring and fall semesters and with teams of undergraduate interns participating in the pilot for the Summer Research Institute sponsored by the DHS Center of Excellence for Port Security between semesters. Typically, 10 teams of two to three students were working in parallel on different aspects of the mission,

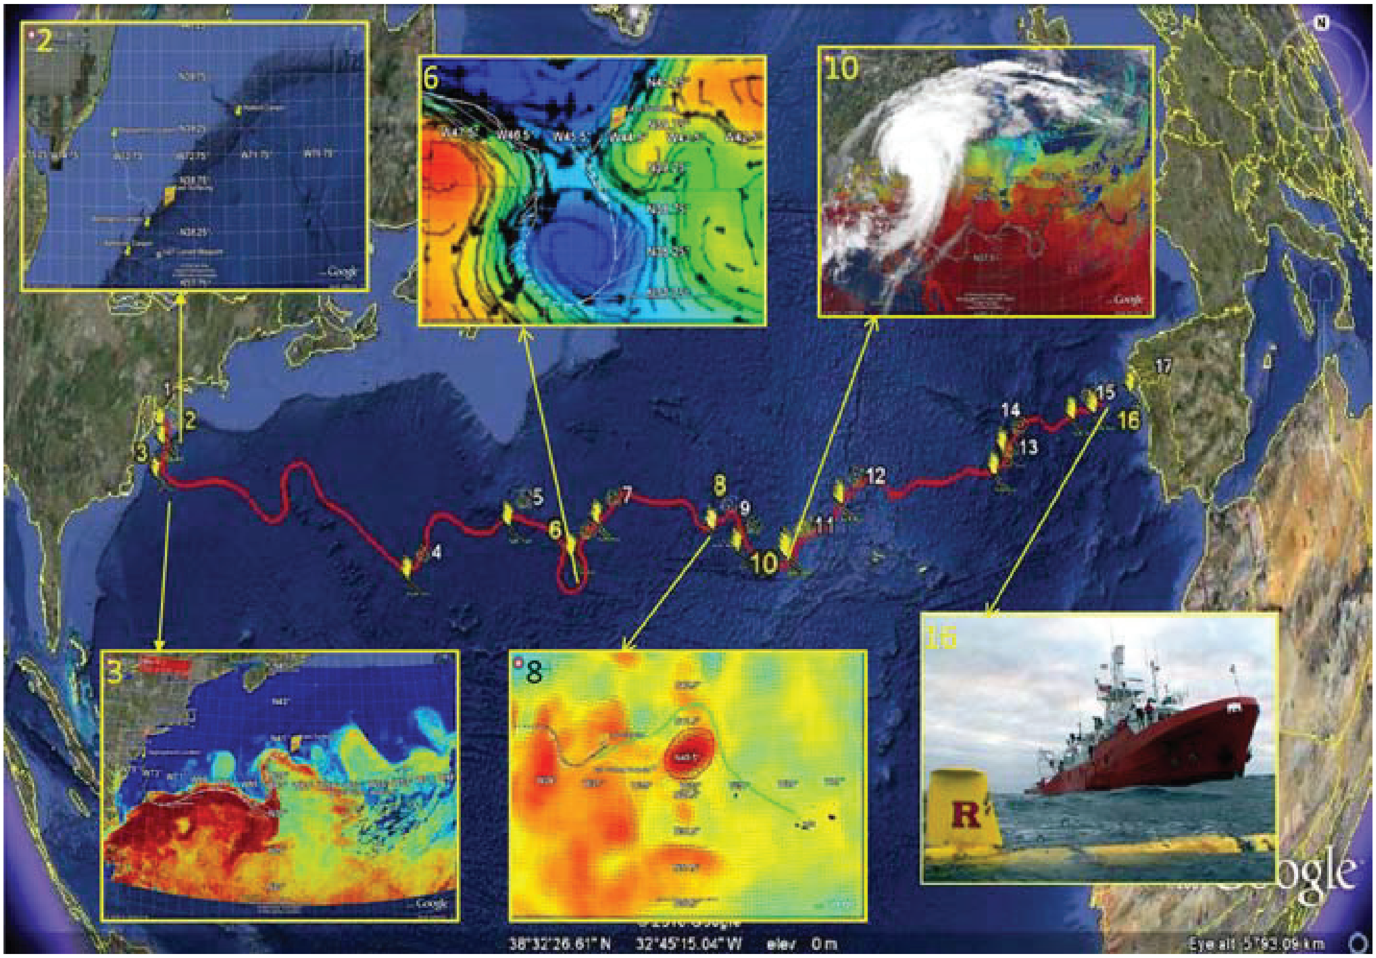
TABLE 1

Battery pack comparison for a standard alkaline-powered coastal glider and the RU27 lithium-powered trans-Atlantic glider (not including 15 batteries reserved for emergency power).

	Number of C-Cells	Energy per C-Cell	Daily Average Power Use	Theoretical Duration	Cost per C-Cell	Total Battery Cost
Alkaline Slocum	230	21.6 kJ	2 W	34 days	$5.22	$1,200
RU27	453	88.5 kJ	1.5 W	371 days	$50.60	$22,922
Factor	1.9	4.1	1.33	10.9	9.7	19.1

FIGURE 4

Insets: (2) RU27 leaves the shallow water and fishing activity of the Mid-Atlantic Bight continental shelf; (3) RU27 navigates the meandering warm jet of the Gulf Stream flowing from Cape Hatteras to the Grand Banks; (6) RU27, after encountering a strong head-current, flies around the southern side of a large cyclonic cold-eddy; (8) RU27 approaches the Phantom Eddy in the HyCOM forecast, an artifact generated by the data assimilation scheme; (10) Hurricane Bill leaves the U.S. East Coast and turns east toward RU27; (16) RU27 is approached by the Spanish *R/V Investigador* for recovery (photo by diver Dan Crowell).



from watching the weather for winds and waves, validating the ocean current models, monitoring the glider flight performance and its ability to communicate, analyzing the glider data, definition of a safe landing zone, and logistics for recovery. The students blogged their results and met weekly as a group to discus new information and define strategies for the next week.

The flight track of RU27 across the Atlantic is shown in Figure 4, where the flight blog highlights labeled by number in the figure are described in Table 2. By May 2, RU27 had completed the dangerous trip across the continental shelf, where it encountered fishing fleets and shallow water without an altimeter. From there, the glider would be in deepwater, where it would remain for the rest of the mission. By May 7, RU27 had made it into the Gulf Stream. The strategy was different from before, with RU27 instead approaching an eastward propagating Gulf Stream meander from the downstream side. As the meander crest propagated forward, RU27 was entrained after only 10 days at sea and a full 10 days ahead of the projected schedule. With May being one of the historically best months for viewing satellite sea surface temperature (SST) images of the Gulf Stream, RU27 easily traversed the Gulf Stream's entire length in less than a month, with only a short delay caused by a quick encounter with a cold core ring near May 23. The first half of June was spent circling around the southern side of a large cyclonic eddy that

TABLE 2

RU27 Blog Highlights from 2009.

No.	Date	Event Description
1	Apr 27	Deployed from Tuckerton, NJ.
2	May 2	Leave the continental shelf and enter deepwater where it will remain for the entire deployment. Successfully made it through the fishing activity and did not collide with the bottom without an altimeter. First look at the deepwater power usage.
3	May 7	Into the Gulf Stream. Only 10 days at sea and already 10 days ahead of schedule.
4	May 23	Spun out of the southern side of the Gulf Stream and into a cold eddy. Turn north to fly back into the Stream.
5	Jun 5	Leave the Gulf Stream region, passing south of the Grand Banks of Newfoundland. Encounter a head current along the northern side of the largest cold eddy of the trip, requiring RU27 to loop around its southern side.
6	Jun 18	Finally pull out of the cold eddy on its eastern side, just before being swept around for a second loop.
7	Jun 29	Break through a countercurrent after a week-long struggle to fly just 125 km. This was RU27's first persistent countercurrent not associated with a strong eddy structure.
8	Jul 19	After navigating the eddy field with excellent ocean forecasts, RU27 encounters a forecast eddy that is clearly incorrect. RU27 focuses our attention on a series of sensitivity studies as to why this anticyclonic warm eddy incorrectly appears in the forecast.
9	Aug 2	Enter European waters for the first time. These are the Portuguese waters surrounding the Azores. The steering difficulties attributed to an unknown biological interaction begin.
10	Aug 25	Hurricane Bill passes to the north, generating large waves. The glider team prepares to depart the Azores on the sailboat *Nevertheless*.
11	Aug 28	Glider team completes its mission to document the biological activity on RU27, clean off the barnacles they found, and let it resume its mission without taking the glider out of the water.
12	Sep 8	RU27 breaks the along-track distance record of 5,700 km set by RU17 in 2008.
13	Oct 12	RU27 hits the half-power point on the theoretical power curve.
14	Oct 22	RU27 breaks free of the second persistent countercurrent. Like the first encounter, a full week of careful navigation was required.
15	Nov 14	RU27 crosses into European waters for the second time. This time it crosses into Spanish waters off of the Spanish mainland.
16	Dec 4	Recovery aboard the Spanish Research Vessel *Investigador*. RU27 exactly on target. Just north of the maritime border between Spain and Portugal and just west of the 12 W line, safe from the shipping traffic and fishing activity.
17	Dec 11	Landfall in Baiona, Spain

seemed to be parked just to the east of the Grand Banks. The rest of June and July was spent navigating the North Atlantic mesoscale eddy field, flying from eddy to eddy based on guidance from satellite altimeters and ocean forecast models. It was during July that RU27 focused attention on the largest forecast model error encountered on the trip, a mesoscale anticyclonic circulation that came to be known as the Phantom Eddy generated through the incorrect treatment of the combined drifter and satellite altimetry ingested by the data assimilation component of the forecast system.

In August, RU27 entered the European waters surrounding the Azores. This is where steering problems attributed to an unknown biological interaction began. At times, RU27 would fly straight, and at other times, it would spin in a tight circle, with no apparent day-night or moon phase cycling as observed for RU17. On August 25, Hurricane Bill passed to the north of RU27, leaving large waves in its wake. As Bill dissipated over the United Kingdom, a glider team left the Azores on the sailboat *Nevertheless* to document the cause of the steering problems. On August 27, the glider team rendezvoused with RU27, discovering that barnacles had attached themselves to the narrow uncoated seams between the five glider hull sections, forming four rings of barnacles that circled the glider. The barnacles could fan out or retract, creating significant and variable drag on RU27. The uneven growth resulted in uneven drag and steering offsets. The barnacles were photographically documented and then removed by hand by divers, while RU27 remained in the water.

Once cleaned and flight characteristics were verified, RU27 resumed its mission to fly east the next day on August 28. September and October continued the process of navigating the North Atlantic eddy field based on satellite altimetry and forecast model guidance. On November 14, RU27 crossed into European waters surrounding the coast of Spain and Portugal. Inspired by discussions with their student collaborators in the Azores and Canaries, the undergraduates chose Baiona, Spain, for RU27's potential landfall because of its historical significance. Baiona is the Spanish port where the caravel *Pinta,* the fastest of Columbus' three ships (the first to sight the New World and the first to return to Europe in 1493), made landfall. RU27 proceeded to the chosen pick-up point, a safe spot just north of the maritime Spanish-Portuguese border and just west of the high traffic north-south shipping lanes. It was recovered by Puertos del Estado using the *R/V Investigador* on December 4, 2009, the first underwater glider to be deployed on the western side of the Atlantic and recovered on the eastern side. The trans-Atlantic flight of RU27 required 221 days to cover the 7,400 km along-track distance, completing over 22,000 undulations and making over 1,000 satellite phone calls to report data and receive new commands. Total power used was 7,750 Wh, equivalent to a 100-W light bulb turned on for 77.5 h or just under 3.25 days.

On December 9, 2009, still aboard the recovery vessel *R/V Investigador,* RU27 made landfall in Baiona. It was here in Baiona that Spain's Minister of Development officially returned RU27 to the U.S. delegation, lead by representatives of the U.S. White House Office of Science and Technology Policy, NOAA, and Rutgers. A congratulatory video from the U.S. Secretary of Commerce was played, and the Mayor of Baiona unveiled a new RU27 plaque permanently placed on the seawall next to the plaque commemorating the voyage and crew of the *Pinta*.

Over 25 multiauthored student research posters were constructed from the flight and presented at research meetings, including one summary student poster representing the entire team that was presented at the 2010 Ocean Sciences meeting. The Dean of Undergraduate Education sponsored events for the students to tell their stories and inspire other undergraduates to get involved. Our class size doubled each semester, from 3 to 7, to 13, to 26 over the 2 years covering the flights of RU17 and RU27, leveled off near its present range of 50–60. The opportunity for undergraduate students to gain hands-on experience with the latest technology, to take risks with a robot at sea while remaining in a safe on-shore environment, and to experience the international collaborative teamwork required to successfully complete this mission are reasons cited by the students in their own recruiting video.

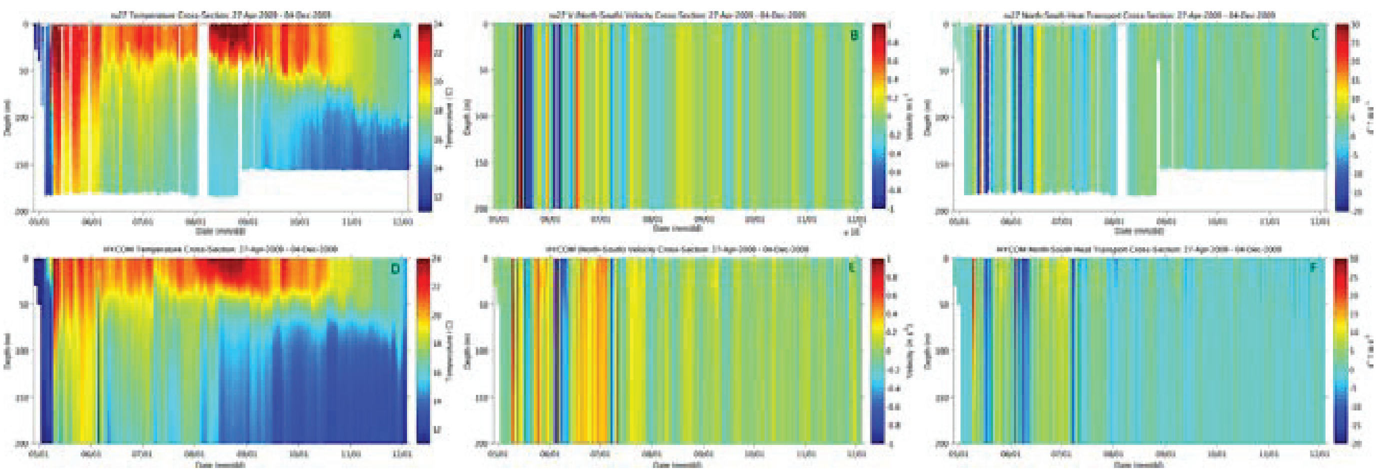
In addition to oceanography classes, the trans-Atlantic flight was used as the subject of a documentary filmed, edited, and produced by a collaborating English professor (D. Seidel) and her undergraduate students in a series of English courses, including *Documentary Filmmaking* and *Digital Storytelling*. The documentary *Atlantic Crossing: A Robot's Daring Journey* has now won eight film festival awards. English students in the class not only learned documentary film making but also learned about ocean science by working alongside oceanography undergraduates for 1.5 years. RU27 also was the inspirational centerpiece for the *Communicating Ocean Sciences* course (J. McDonnell) in the spring of 2009, using climate change as the science theme and gliders as the new enabling technology. Undergraduate designed and tested hands-on glider activities designed to demonstrate new technologies for monitoring climate change at informal education institutions are now in place at New Jersey's Liberty Science Center as a permanent docent-led activity and have also been demonstrated by students on the floor of the Smithsonian National Museum of Natural History.

RU27—Post-Flight Data Analysis. The datasets collected by RU27 were analyzed by a team of summer student interns in the 2010 NSF RIOS program. The three-person undergraduate team consisted of a physics major, a biology major, and an engineering major. The interdisciplinary team results on heat transport calculated from RU27 and compared with the Navy forecast model used in the crossing is shown in Figure 5. For RU27, temperature (Figure 5A) and the northward depth-averaged velocity (Figure 5B) were combined to provide a proxy for heat transport (Figure 5C). The same variables generated from an ocean numerical model (the Navy's Hybrid Coordinate Ocean Model, HyCOM) are plotted in Figures 5D–5F.

Starting on the Mid-Atlantic Bight shelf in late April and continuing into early May as RU27 crossed the Slope Sea, temperatures in the glider data and the model are cold, around 11°C. Currents are generally slow to the south for both glider and model. From May 7 through June 5, RU27 navigated the warm water of the Gulf Stream. The glider data indicates, as expected, that the warm water of the Gulf Stream is above 18°C in the

FIGURE 5

Comparison of measured (Glider RU27; A, B, C) and modeled (HyCOM; D, E, F) trans-Atlantic cross sections of temperature (A, D), north-south component of the current (B, E) and north-south component of the heat transport (C, F) along the track shown in Figure 4.



upper 200 m along the entire length of the Gulf Stream. Temperature differences between the model and data in this region, specifically the cold bands below 100 m, are due to imperfect forecasts of the Gulf Stream position. The banding in the north-south velocity time series is apparent in both the glider data and the model. Both have a strong band of northward velocity (red) as RU27 moves north with the Gulf Stream near 64 W, both exhibit southward velocity (blue) as RU27 travels the length of the Gulf Stream from 64 to 55 W, and both turn to positive northward velocities as RU27 turns north with the Gulf Stream on May 23 near 54 W. Small differences between the model and the data can be attributed to incorrect placement of the Gulf Stream in the model, but the general trends are reproduced. Most strikingly, the depth average current returned by RU27 is not that different in structure from the actual current profile in the model. This is important, since the resulting heat transport is dominated by the variability in the currents. In this region, the water is nearly uniformly warm in the upper 200 m, and the heat transport depends on the proper location of the Gulf Stream meander crests and troughs.

Leaving the Gulf Stream region on June 5, RU27 encounters a strong anti-cyclonic eddy on the southeast side of the Grand Banks. The warm water above 18°C is shallower than 50 m in both the glider data and the model. North-south currents in both abruptly switch from southward (blue) to northward (red) as the southern side of the cold eddy is crossed, remaining in place until mid-June when RU27 breaks free of this eddy and heads east. As in the Gulf Stream, the currents dominated heat transport in the eddy, and therefore, the location of this eddy in the forecast is critical. For the next month and a half, RU27 navigated the North Atlantic eddy field. On July 29, RU27 encounters the largest forecast error observed in the model. During this time, the warmest waters above 18°C are observed and forecast to be in the upper 40 m of the temperature field. Less variability is observed in the glider data than the model, which might indicate that the model may be overestimating the intensity of eddies and their impact on the surface layer temperature field. Currents in both the model and the data show alternating bands of ± 20 cm/s north-south currents, depending on the side of the eddy. Calculating the correct heat transport from model results becomes a challenge for placing the eddies in the proper locations. At the beginning of August, RU27 turns southeast towards Portuguese waters, and a warming trend is observed in the upper 30 m of the data and the model. This warming is abruptly halted by the passage of Hurricane Bill on August 25 and the resulting mixing in both the model and the data. Continuing east from the Azores, the process of flying eddy to eddy continues as the magnitude of the variability in the eddy currents remaining relatively constant, with only occasional currents exceeding 20 cm/s in the north or south direction. The surface layer of the ocean is observed to cool as winter approaches. Water less than 14°C rises above the 100 m depth. By December, the water column is nearly uniformly cool near 14°C. Heat transport is small compared with the western side of the basin earlier in the year.

Evolving the Undergraduate Education Experience—Lessons Learned

Traditional university marine science programs are often structured around a classical model of classroom learning in the first 2–3 years, after which a small minority of the students gain field experience by working in research laboratories and gaining prized access to research cruises. This has been an effective model for developing future Ph.D. students over the last 50 years. Given the challenges facing society today, there is a greater need for science education than only grooming future Ph.D. students. It is critical that the undergraduate experience expands ocean literacy across all of the sciences and humanities. This is especially important since the observed changes occurring throughout the world's ocean will have profound economic, cultural, and security consequences. Based on our experience, oceanography provides a level of adventure that is a vehicle to inspire students to begin and continue pursuing degrees in science and engineering. Given our positive experience of entraining undergraduates into the sciences via ocean exploration, we believe it provides a blueprint for redesigning the undergraduate education curriculum. In fact, it is now being reapplied at Rutgers with a larger and even more distributed group to engage students in environmental sciences issues associated with the Raritan River and Estuary. The Raritan Initiative utilizes Rutgers location on the banks of the Raritan River to involve students from across campuses in interdisciplinary studies that use the river and estuary as a natural laboratory. The natural environment provides motivation, and the co-location provides access. The course work includes freshman year seminars to entrain students, an interdisciplinary team taught sophomore year field course, and the support of senior thesis studies involving data from the Raritan.

The new approach has several characteristics that are important:

It is critical to engage students as early as their freshmen year in research. The Web-based nature of ocean observatories allows students to take part with ongoing experiments, which lets them live the excitement of doing research. They experience the uncertainty, adventure, and creativity required to conduct an experiment, which provides an effective counterbalance to classroom learning that often portrays science as a very linear process. Taking part in the ocean experiments, they experience the numerous stumbling blocks, such as the loss of RU17 after months of work. These hurdles, while emotionally draining, generally engage students to see the adventure through until the end. Many of the students who joined the Atlantic crossing effort of RU17 were freshmen and sophomores. The RU17 attempt, failure, engineering analysis, construction of RU27, and eventually successful Atlantic crossing was a 3-year process. For the students to experience the full adventure, they need to be engaged early in their academic career to realize the fruits of their labor. Designing strategies to entrain the students as they enter the university is critical.This realization led us to establish Oceanography House as a dedicated freshman dormitory for students interested in the oceans regardless of their major. The living and learning community is advertised during the university open house for incoming students and provides them with a direct link to marine science from their first day on campus. Undergraduates involved in the observatory work also visit their high schools to provide science talks and act as ambassadors. The students of Oceanography House meet weekly with professors and upper class students to focus ongoing scientific efforts.

Developing a near-peer community is important for expanding diversity. A critical component to the oceanography living learning community is that incoming students are provided guidance by upper class advanced oceanography students. These oceanography mentors provide assistance in transitioning the freshmen into the ocean exploration classes. This is critical as the students entering the classes as freshmen have a wide range of expertise, represent a wide range of disciplinary interests spanning from oceanography to English, and mirror the ethnic and cultural diversity of the Rutgers student body, one of the most diverse research universities in the U.S. For the upperclassmen, they are put in a position of mentorship that requires them to understand key concepts with sufficient detail to keep the new students on track, providing teaching experience. Many of the students who do not pursue graduate school often become science teachers. This is particularly important since there is a critical need to improve science education at the K-12 education level. To assist in this process, the students are provided the *COSIA* opportunity for developing the skills required to be an inspirational science teacher by providing a firm foundation in communication techniques and pedagogy.

Allow the students to work as teams. Given the goal of increasing the diversity of disciplines, the teacher is often confronted with a wide range of student skills/science knowledge. To help address these gaps and to facilitate the near-peer relationships, student are often given specific projects as a team of three to four students. The team consists of at least one advanced upperclassmen. Teams are coordinated in a systems engineering model, where initially individual projects are iterated over a period for a few months and then the individual parts are combined to provide an overall system to help coordinate glider activities. For example, during the RU27 journey, the undergraduate teams focused on a successful recovery off the coast of Spain. The teams documented the major shipping lanes, provided weather and wave forecasts, provided logistical planning for the ship crew, and researched the history of the Spanish port cities to help a develop a RU27 recovery plan.

Give students intuitive tools to analyze data and make their own discoveries. The analysis of the RU27 data and comparisons to ocean forecasts by undergraduate summer interns was enabled by a new toolkit of interactive glider software developed specifically for education. As students gain experience with program languages and complex file formats, they could do these same analyses on their own. But developing a working knowledge of these software skills is a barrier to many students. Simple intuitive interfaces, such as Google Earth, were used by students at any level to visualize and compare datasets, allowing them to draw their own conclusions. The glider data analysis interfaces developed here and tested by the undergraduates in the 2010 NSF RIOS program enabled the students to visualize and interpret vertical glider data as easily as they did with the horizontal data in Google Earth. The result of the software test was three research posters, one on the heat transport of RU27 discussed above, a second on the flight characteristics of a new Slocum Thermal Glider, and a third on optimizing the flight profiles for heat transport calculations along 26.5 N, a standard trans-Atlantic sampling line for monitoring the maximum in the north-south heat transport caused by the Meridional Overturning Circulation.

A Future Vision—The Challenger Mission and a Global Classroom

In Baiona, Spain, Rick Spinrad reflected on his initial 2006 challenge to modify one of our gliders and fly it across the Atlantic. With this challenge complete, Dr. Spinrad issued a second challenge, to send an internationally coordinated fleet of gliders on a circumnavigation that revisited the track of the HMS *Challenger*. The original *Challenger* mission (Cornfield, 2003) was the first dedicated scientific circumnavigation of the globe. It took 3.5 years, leaving England in December 1872, returning in May 1876, and traversing 111,000 km, exactly 15 times the distance covered by RU27.

As with the trans-Atlantic glider mission, a circumnavigation will require the development of new technologies, and it will require the development of new international teams. The range of technologies potentially includes not only the full suite of electric gliders available to the international community from both the U.S. and China but also the Slocum Thermal Glider, part of the original vision of Doug Webb and Hank Stommel. The fleet will likely include a mix of gliders or even hybrids of the thermal and lithium battery technology. Our own experience has shown that flexibility in glider design is again a desired trait. Thermal gliders work best when there is a large temperature difference between the surface and the bottom of the undulation, typically about 15°C. Winter and summer forecasts from the HyCOM model indicate that thermal gliders can be tuned to cover much of the subtropical ocean basins and the tropics. Our own student calculations have demonstrated that in some cases, for example, the calculation of heat transport in the subtropical ocean basins, that flying to the deepest allowable depth on every undulation may not be the optimal dive profile. Again, flexibility in the mix of dive profiles is going to be desired, with deep profiles interspersed with shallow.

As with the trans-Atlantic mission, the Challenger Mission will require new technologies, but it will also require people. We have found that many of those people already exist—they are already in our classrooms. Our students have already developed a prospectus and approach for the Challenger Mission, starting with an expansion from the North Atlantic to the South Atlantic, followed by a circling of the globe. Moving to the South Atlantic and eventually the globe will require a transformation from a Rutgers classroom to a globally distributed classroom, facilitated by on-line virtual learning communities, entraining an even more diverse range of partners and disciplines, and providing an even broader global perspective to the generation that must deal with climate change over their lifetimes. We hope that the perspectives gained through the local *Atlantic Crossing* course and the envisioned global *Challenger Mission* course will provide our students with the scientific perspective and the global cultural experience to meet the challenges of their generation.

Acknowledgments

Slocum gliders were developed through the vision and support of the Office of Naval Research, transitioning from an engineering demonstration on its first deployment at sea, to a research tool used by many federal agencies, to an operational Naval asset in less than a decade. NOAA provided the challenge for the first trans-Atlantic missions. Rutgers alumni, Teledyne Webb Research, NOAA, and U.S. IOOS provided support for the build and the launch. Educational support was provided by the National Science Foundation and the Department of Homeland Security. Our partners in Spain at Puertos del Estado and Universidad de Las Palmas de Gran Canaria provided support for the recovery. These and future missions would not be possible without the direct participation and continuing interest of the *Atlantic Crossing* students and their international collaborators.

Mid-Atlantic Bight

ABSTRACT

Mixing has long been recognized as having an important role in influencing underwater light and nutrient budgets and thus regulating phytoplankton bloom. Mixing related to stratification and de-stratification is a key parameter of the physical environment that can control the timing and magnitude of blooms. Here we use a high-resolution three-dimensional biogeochemical model in the Mid-Atlantic Bight (MAB) to study phytoplankton bloom dynamics for the years 2004–2007. We present a simulated fall-winter bloom in the shelf region and spring bloom in the shelf-break front region. The ratio of light over mixed layer depth (MLD) was used to determine the trade-off effects of mixing (increase mixing will increase nutrients availability but decrease light availability). We find that the critical light value ($I'_{chl\ \mathrm{mas}}$) is around 60 (W m^{-2}) for the shelf region and 150 (W m^{-2}) for the shelf-break front region. There is a predictable linear regression relationship between $I'_{chl\ \mathrm{mas}}$ and depth. A sensitivity run with no wind forcing was used to test the role of wind-induced mixing on the balance between light and nutrient terms and its influence on timing and magnitude of the bloom. The phytoplankton dynamics in the shelf-break front region are found to be more sensitive to the wind-induced mixing.

1. Introduction

Broad continental shelves are highly productive systems that are globally significant zones for the biogeochemical cycling of elements (Longhurst, 1998). This is especially true for the Mid-Atlantic Bight (MAB), which has an extremely productive ecosystem that is fueled by large seasonal phytoplankton blooms (O'Reilly and Busch, 1984; O'Reilly et al., 1987). This has motivated numerous observational studies on the physical forcing of phytoplankton blooms in the MAB. These studies have documented the spatial and temporal variability in phytoplankton biomass in the MAB and have hypothesized about the key physical processes that underlie the observed variability. The 12 yr (1977–1988) NOAA NMFS Marine Resource Monitoring and Prediction (MARMAP) survey of the Northeast of US continental shelf found the highest phytoplankton concentrations during the winter-spring (O'Reilly and Zetlin, 1998). This was consistent with previous results from the Coastal Zone Color Scanner (CZCS) and Sea-viewing Wide Field of view Sensor (SeaWiFS) imagery that showed a fall-winter maximum of chlorophyll concentration in the middle and outer shelf waters and a spring maximum in the shelf-break/slope waters (Ryan et al., 1999; Xu et al., 2011; Yoder et al., 2001). Despite these large data sets, the observational studies did not have the spatial and temporal data required to link the environmental factors that underlie the phytoplankton dynamics. This has prompted the development of coupled ecosystem models to test hypotheses about the physical regulation of the MAB phytoplankton communities (Fennel et al., 2006).

Models describing phytoplankton dynamics must reconcile a phytoplankton's need for light and nutrients, both of which are related to the overall mixing in the water column. The limitation of light to support phytoplankton growth builds on the (Sverdrup, 1953) "critical depth" model which predicts the initiation of phytoplankton blooms only after cells reside at a the critical depth where photosynthesis is larger than respiration allowing for the build-up of biomass. The maximum depth suitable for phytoplankton photosynthesis is most often defined as the depth where photosynthetic available radiation (PAR) is 1% of its surface value. While the absolute lower limit of light capable of supporting photosynthesis is still a subject of debate (Dubinsky and Schofield, 2010), estimates of the compensation depth irradiance based on Sverdrup's theory suggest it is relatively uniform throughout many regions of the ocean (Siegel et al., 2002). If light is present in sufficient quantities, the magnitude and duration of the bloom is then a complex function of mixing, nutrient availability (Tilman, 1982) and grazing pressure (Fasham et al., 1990; Gentleman et al., 2003; Martin, 1965; Turner and Tester, 1997). The flux of nutrients to the euphotic zone is determined by mixing across the nutricline, which can happen with mixed layer depth (MLD) increase if it is associated with

entrainment. MLD thus has been demonstrated to be a key factor in determining phytoplankton abundance (Behrenfeld et al., 2002; Field et al., 1998); however while vertical mixing in the upper-ocean boundary layer can increase productivity in the surface waters through enhanced nutrient supply from deep waters it can also decrease productivity due to mixing phytoplankton below the critical depth and therefore introducing the possibility of light limitation (Dutkiewicz et al., 2001). To parameterize the relative roles of mixing and light availability the ratio of Z_{mld} (mixing layer depth) to Z_{eu} (euphotic depth) has been used to describe the regulating primary production (Huisman et al., 1999; Irigoien and Castel, 1997); however, this ratio only reflects the relationship between surface light condition and MLD. Therefore, the ratio of integral of light in the euphotic zone and MLD ($\int_{-Z_{\mathrm{eu}}}^{0} I(z)dz/z_{\mathrm{mld}}$) might be a preferred value to compare the balance between light limitation and nutrient limitation.

We use time series of satellite chlorophyll and 3-D biophysical model simulations to investigate the relative importance of mixing rates and light availability for phytoplankton populations in the MAB.

2. Methods

For this project we utilized data collected by the Mid-Atlantic Regional Coastal Ocean Observing System (MARCOOS) that is part of the United States Integrated Ocean Observing System (IOOS) (Schofield et al., 2010). MARCOOS provided an extensive data set to validate biological model simulations. In this effort we used surface data provided by ocean color satellite imagery and in situ data collected by Webb Slocum gliders (Schofield et al., 2007).

2.1. The biogeochemical model

In this study we used the Regional Ocean Modeling System (ROMS, http://www.myroms.org) (Haidvogel and Beckmann, 1999; Wilkin et al., 2005) which was configured to the continental shelf of the Middle Atlantic Bight (MAB) (the model domain is shown in Fig. 1). The model has a horizontal grid resolution of approximately 5 km, and uses 36 vertical layers in a terrain-following s-coordinate system. The biogeochemical model was developed and described in Fennel et al. (2006). The model here assumes nitrogen is the major limiting nutrient, which is a reasonable assumption as nutrient budgets indicate nitrogen limitation is frequently observed in the MAB (Ryther and Dunstan, 1971; Sharp and Church, 1981). Also nitrogen availability in the MAB is found the key nutrient to accurately simulating primary production (Fennel et al., 2006). The basic structure of this model follows a classical Fasham model (Fasham et al., 1990) and is constructed using seven state variables: phytoplankton, zooplankton, nitrate, ammonium, small and large detritus, and chlorophyll. The time rate change of phytoplankton is influenced by the growth rate of phytoplankton, grazing by zooplankton, mortality, aggregation of phytoplankton to small and large detritus, and vertical sinking of the aggregates. This model drives phytoplankton growth (μ) through variations in temperature (T) (Eppley, 1972), incident light intensity (I) (Evans and Parslow, 1985), and the availability of nutrients (Parker, 1993), following:

$$\mu = \mu_{\max} f(I)(L_{\mathrm{NO_3}} + L_{\mathrm{NH_4}}) \tag{1}$$

μ_{max} is the maximum growth rate which depends on temperature. I is the photosynthetically available radiation and decreases with water depth due to absorption by seawater (assumed constant) and the time and spatially varying chlorophyll computed by the model.

$$I = I(z) = I_0 par \exp\{-z(K_w + K_{chl} \int_z^0 Chl(\zeta)d\zeta)\} \tag{2}$$

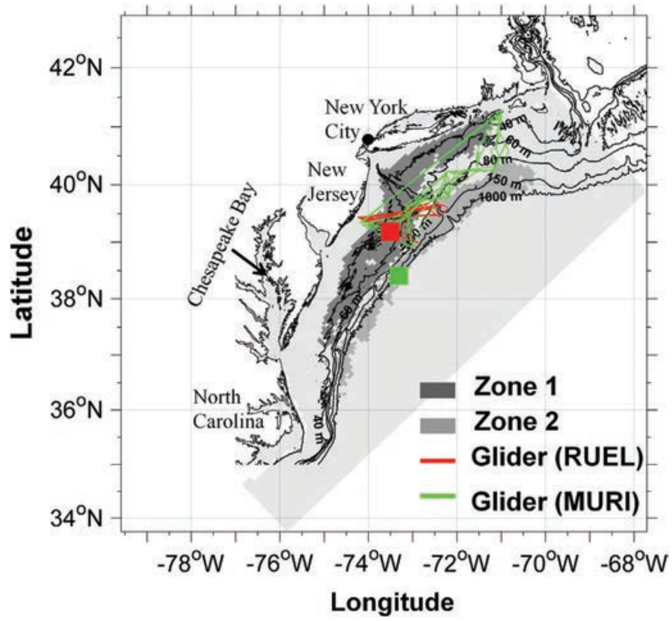

Fig. 1. Model domain (light gray). Dark gray and gray highlight the Zone 1 and Zone 2 region identified by Xu et al. (2011). Red and green lines show the glider transects. Red and green square symbols represent the grid point used for calculation in Zone 1 and Zone 2. The black lines with number show the bathymetry. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

where I_0 is the surface incoming light and is the shortwave radiation flux from NCEP reanalysis data, par is the fraction of light that is available for photosynthesis and equals 0.43. $K_w$and K_{chl} are the light attenuation coefficients for water and chlorophyll, and are set to 0.04 m^{-1} and 0.025 (mg Chl)$^{-1}$ m^{-2} respectively (Fennel et al., 2006). The$f(I)$ represents the photosynthesis-light (P–I) relationship. The parameter α is the initial slope of the P–I curve. The terms $L_{\mathrm{NO_3}}$and $L_{\mathrm{NH_4}}$ represents the nutrients limitation.

$$f(I) = \frac{\alpha I}{\sqrt{\mu_{\max}^2 + \alpha^2 I^2}}, \tag{3}$$

$$L_{\mathrm{NO_3}} = \frac{\mathrm{NO_3}}{K_{\mathrm{NO_3}} + \mathrm{NO_3}} \frac{1}{1 + \mathrm{NH_4}/K_{\mathrm{NH_4}}}, \tag{4}$$

$$L_{\mathrm{NH_4}} = \frac{\mathrm{NH_4}}{K_{\mathrm{NH_4}} + \mathrm{NH_4}} \tag{5}$$

The rate of grazing by zooplankton is represented by a Holling type s-shaped curve (Gentleman et al., 2003). The mortality loss term has linear relationship with phytoplankton. The aggregation rate is assumed to scale with the square of small particle abundance for more details see Fennel et al., 2006. The model was driven by atmospheric forcing provided by the North American R (NAM) forecast regional Reanalysis (NARR) from the National Centers for Environmental Prediction (NCEP). We used a 3-hourly re-analysis of surface air temperature, pressure, relative humidity, 10 m vector winds, precipitation, downward long-wave radiation, and net shortwave radiation to specify the surface fluxes of momentum and buoyancy using bulk formulae (Fairall et al., 2003). In the open boundary, we specified temperature, salinity, nitrate ($\mathrm{NO_3}$), total inorganic carbon (TIC), alkalinity, and oxygen. Because the focus of this study is the influence of wind forcing on phytoplankton dynamics, the open boundary inputs are specified by the climatology input based on the Fennel ROMS model simulation of the Northeast North American (NENA) shelf (Fennel et al., 2006). We included the inputs of seven rivers

(Hudson, Connecticut, Delaware, Susquehanna, Potomac, Choptank, and James River) on the boundary. River outflow was provided by the daily mean outflow from the United States Geological Survey (USGS) gauges (available online at http://waterdata.usgs.gov/nwis/). The riverine inputs of temperature, salinity, dissolved and particulate biological constituent concentrations were derived from the total nitrogen in the nitrate pool after Howarth et al., (1996). Here the inputs were multiplied by the freshwater transport to give discharge rates, which for our simulations was treated as time invariant. The model is initialized with model output in this domain described in Hofmann et al. (2011). The 4 yr (2004–2008) duration simulations were conducted with the first year used as a spin-up period; results presented here are from the analysis of the final three-years of simulation.

2.2. Satellite imagery

Seasonal cycles in MAB phytoplankton were characterized using four-day averaged nine-year time series of surface chlorophyll concentration derived from Sea-viewing Wide Field of view Sensor (SeaWiFS) ocean color imagery from January 1998 to December 2006. Images with more than 20% cloud coverage were excluded. Therefore we utilized the 4-day composite, which was the minimum time interval that minimized cloud contamination and provided a reasonable time series that could define seasonal phytoplankton dynamics on the shelf. Even using the 4-day average 43% of imagery was eliminated from the data set. The missing data was largest in the fall-winter in each year. The monthly SeaWiFS Level 3 photosynthetically available radiation (PAR) data from 1998 to 2006 were downloaded from http://oceancolor.gsfc.nasa.gov. We used the spatial mean for both chlorophyll-a and PAR for the shelf and shelf-break front regions (Zone 1 and Zone 2, as showed in Fig. 1 dark gray and gray area respectively) identified in Xu et al. (2011). The two zones were defined by a decadal Empirical Orthogonal Function analysis of ocean color imagery, which identified two major modes of variability. The first mode (Zone 1) was associated with the inner continental shelf of the MAB spanning the 20–60 m isobaths. Zone 1 was defined by the fall-winter bloom of phytoplankton (Xu et al., 2011). Zone 2 was located in the 80–150 m isobaths located at the edge of the MAB continental slope and was associated with the spring phytoplankton bloom.

2.3. Glider Observations

We utilized Webb Slocum gliders for this study (Schofield et al., 2007). The data was collected as part of local and regional glider time series in the MAB (Schofield et al., 2010, Fig. 1). The time series is not formally funded and thus is not a complete monthly time series; however the time series is a large data base providing vertical profiles of temperature and salinity. A smaller subset of chlorophyll data was available, however it should be noted that not every glider is equipped with a fluorometer. The data base used for this study spans from 2006 to 2008. During the periods, there are three missions (June 2006, July 2006, and July 2007) along Rutgers University Glider Endurance Line (RUEL) and three missions (March 2007, April 2007, and March 2008) along Multidisciplinary University Research Initiative Line (MURI). For the RUEL transect, it takes approximately 5–10 days to be completed, while for the MURI transect, it takes 12–25 days to be completed. The majority of the glider observations provide data for spring and summer time. These efforts provide over 8257 vertical profiles with temperature, salinity and chlorophyll data that were included in this study. All gliders are equipped with a Sea-Bird conductivity-temperature-depth (CTD) sensor. The MLDis based on the measurement of temperature and salinity and is defined using the criterion of a 0.125 kg m^{-3} density increase from the surface.

3. Results

3.1. Model simulation and observations of MAB phytoplankton

We have focused our analysis of the seasonal variability in phytoplankton in Zone 1 and Zone 2 as identified in Xu et al. (2011). Time series of the 4-day average spatial mean SeaWiFS

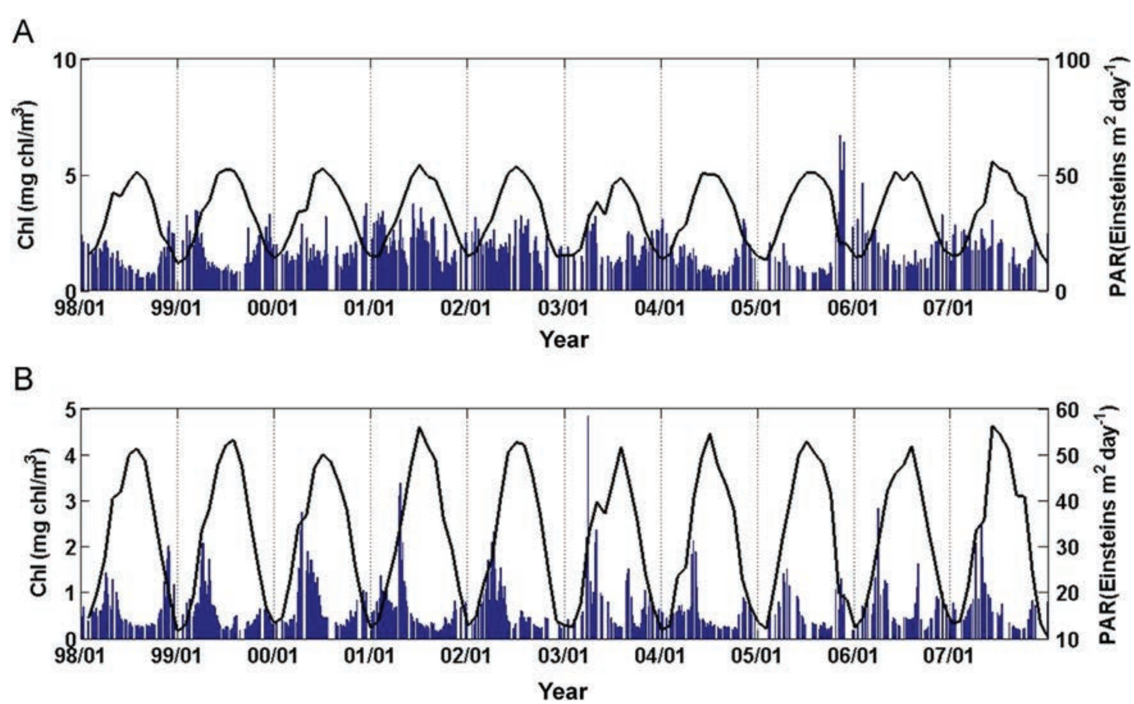

Fig. 2. The 9-year record of SeaWiFS chlorophyll (bar) compared to photosynthetically active radiation (PAR, black line) from the spatial mean in (A) Zone 1 and (B) Zone 2.

chlorophyll for both zones is shown in Fig. 2. Generally, the chlorophyll in Zone 1 showed a persistent phytoplankton bloom in the late fall and winter that typically lasted several weeks despite the solar illumination being lowest during this time of year. The timing of this bloom has been related to the seasonal destratification of the MAB, which replenishes nutrients to the surface waters. The magnitude of bloom has been related to the overall wind-induced mixing with the frequency of winter storms determining the overall seasonal light-limitation of the phytoplankton (Xu et al., 2011). In contrast, the phytoplankton blooms in Zone 2 occur in the spring and are associated with the onset of stratification in the deeper waters of the outer shelf (Fig. 2B). The spring bloom is shorter and has lower concentrations of chlorophyll than the fall-winter bloom. These seasonal cycles of chlorophyll are consistent with the *in situ* MARMAP data (Yoder et al., 2001, shown in Fig. 6), that show peak chlorophyll values occur during fall-winter in middle and outer shelf water and a distinct spring maximum in shelf-break slope waters (Yoder et al., 2001).

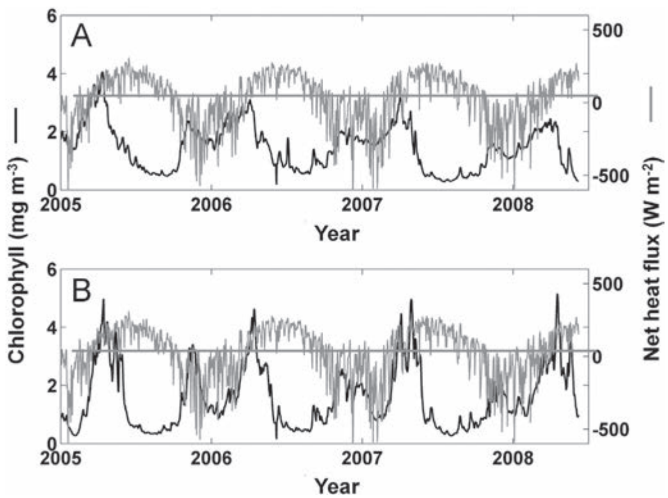

Fig. 3. Time series of surface chlorophyll concentration (black line) and net heat flux (gray line) of spatial mean in Zone 1 and Zone 2 calculated from model output.

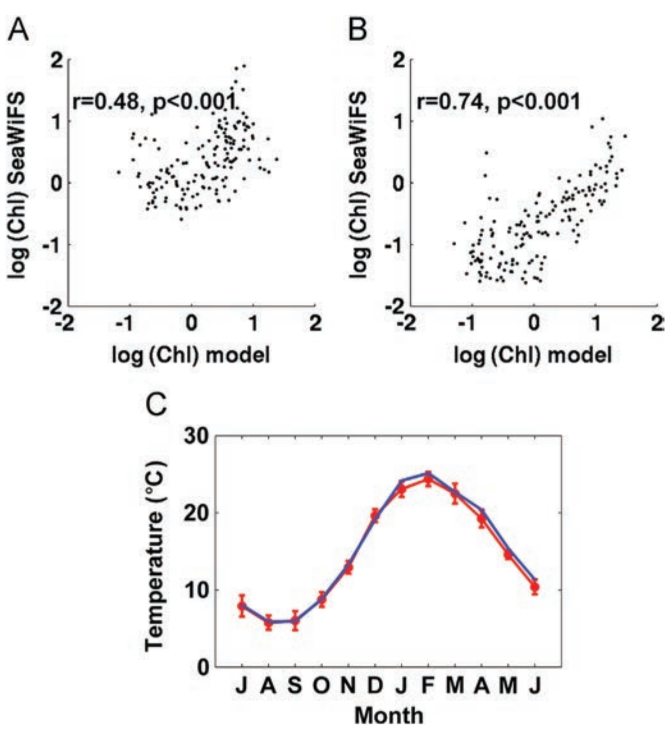

Fig. 4. Comparison between the log-transformed surface chlorophyll concentrations provide by SeaWiFS and mode output from spatial mean of Zone 1 and Zone 2. The linear correlation of the chlorophyll before log-transformed is 0.42 and 0.75 (P value < 0.001) for Zone 1 and Zone 2 respectively. The climatology of surface water temperature from the NDBC buoy 44009 (the red line with error bar) was used to compare with the simulated SST at the same location (blue line) in Fig. 4C. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The satellite measured chlorophyll dynamics were successfully reproduced by the biological model (Fig. 3). The simulated sea surface temperature was also in the standard deviation range when compare with the climatology measurement from NDBC buoy 44009 (Fig. 4C). The simulated chlorophyll in Zone 1 increased in late fall and lasted through the winter. The correlation found between simulated chlorophyll and SeaWiFS chlorophyll was 0.48 ($p < 0.001$, Fig. 4A) which was mainly due to the winter bloom. The bloom showed a bimodal peak with lower concentrations found during the darkest periods of winter which was not readily evident in the satellite data that perhaps reflect the relatively low availability of ocean color images during the cloudy winter (Xu et al., 2011). The model also successfully simulated the timing and magnitude of spring bloom in Zone 2, which could explain ~74% of the log-transformed variance of the observed chlorophyll ($p < 0.001$, Fig. 4B).

The model overestimated observed chlorophyll and likely reflects the poor prediction of zooplankton grazing for the following reasons. During the SEEP II experiments in this area (Flagg et al., 1994), zooplankton concentrations ranged from 0.4–28.6 mmol N m^{-3}. Our modeled zooplankton concentrations varied from 0 to 2 mmol N m^{-3}, which is within the range observed during SEEP II (Flagg et al., 1994) but at the lower end the observations. If grazing pressures were too low, then major factor regulating the termination of the spring bloom in the model would be the depletion of nutrients. This would result in the modeled spring bloom lasting longer than the satellite observations if zooplankton is significant in driving bloom senescence. The spring bloom based on the 4-day average SeaWiFS data typically lasted 12–20 days over a 10-year data set (Fig. 2B). The spring bloom in the model simulations typically lasted for 30–40 days (Fig. 3B), which would be consistent with the model that underestimating grazing pressure.

3.2. Environmental regulation of phytoplankton

Accepting that the model describes the general variability observed for chlorophyll (Fig. 4), we used the model simulations to analyze the physical factors regulating phytoplankton biomass on the MAB. Time series of the modeled chlorophyll and key environmental variables (temperature, upper mixed layer, light, nutrients, and zooplankton) for both zones are shown in Figs. 5 and 6. In Zone 1(Fig. 5), water column cooling resulted in destratification, which was reflected as an increase in the upper mixed layer depth from 10 m at the beginning of October to 30 m deep at the end of February. The deepening of the upper mixed layer depth was associated with an increase of nitrate within the euphotic zone. Nitrate exhibited considerable variability within the upper 20 m showing that convective overturn and entrainment processes were effective increasing nutrients in surface waters. Nitrate within the mixed layer was consumed rapidly by phytoplankton from December to March. Phytoplankton growth was significant even during the dim winter months as >50% of the water column was above the 1% light level depth. Phytoplankton biomass remained high until the upper mixed layer depth began to shallow and nitrate was rapidly depleted and grazing pressure increased. After surface

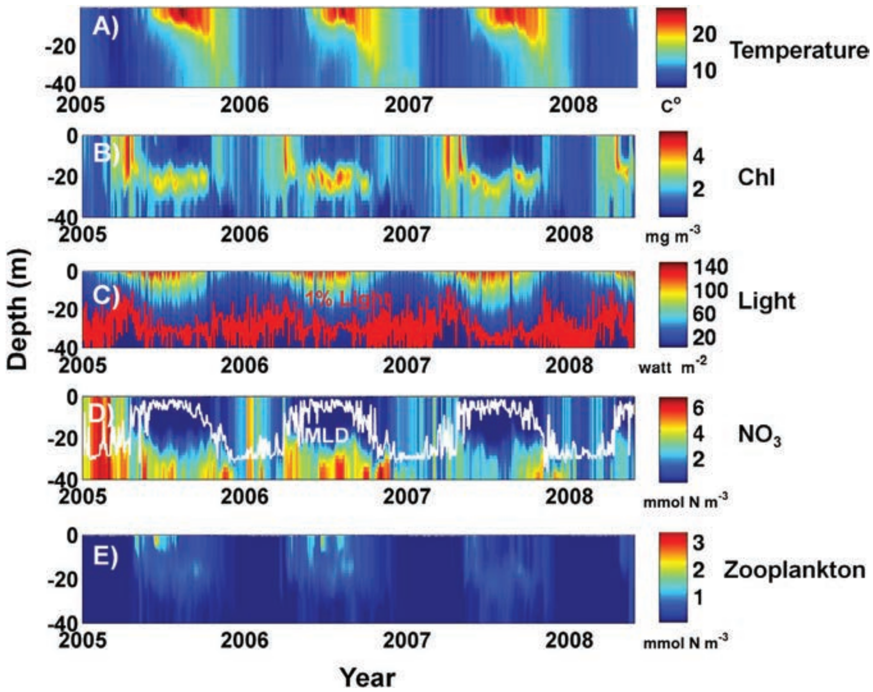

Fig. 5. Model simulated vertical distribution of temperature (A) chlorophyll concentration (B), light (C), NO_3 (D) and zooplankton (E) at a point located in Zone 1 (dot shown in Fig. 1). The 1% light level depth is plotted with light (in C, red line) and the MLD is plotted with NO_3 (in (D), white line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

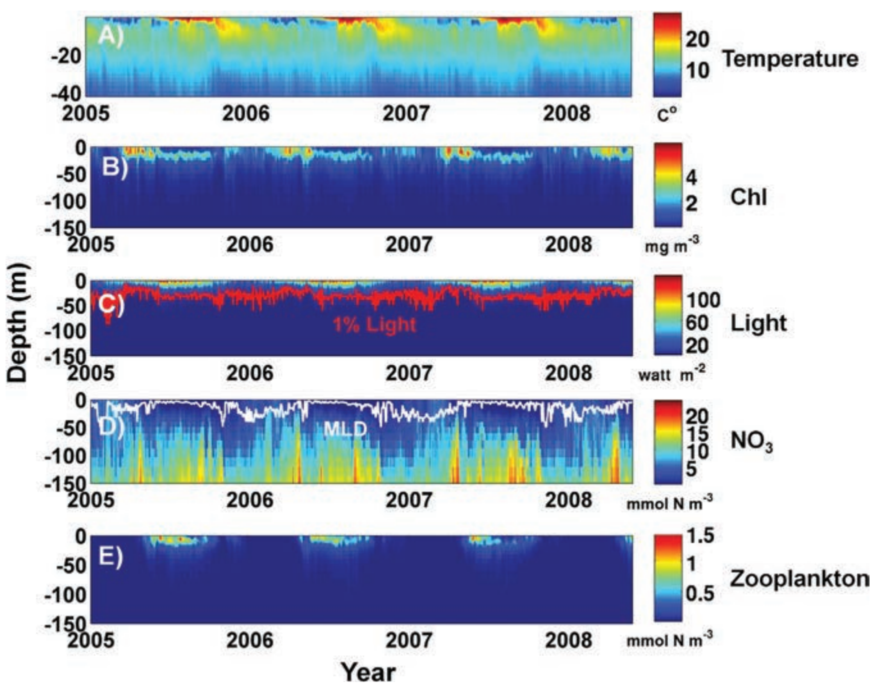

Fig. 6. Model simulated vertical distribution of temperature (A) chlorophyll concentration (B), light (C), NO_3 (D) and zooplankton (E) at a point located in Zone 2 (square shown in Fig. 1). The 1% light level depth is plotted with light (in C red line) and the MLD is plotted with NO_3 (in D, white line). (Here, we only show the upper 150 m of the water column). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

nitrate was depleted, a significant subsurface phytoplankton peak was maintained at the nutricline throughout the year.

In contrast, phytoplankton blooms in Zone 2 were found primarily in the spring with a smaller secondary bloom in the fall when stratification began to weaken (Fig. 6). No winter phytoplankton bloom was observed as the upper mixed layer was deep and the majority of the water column was below the 1% light level (Xu et al., 2011). The spring phytoplankton bloom formed in March every year during the simulation as the upper mixed layer depth decreased and nitrate concentrations were high. The nutrients were consumed in several weeks and nutrient depletion resulted in the termination of the bloom. As observed in Zone 1, a subsurface phytoplankton bloom formed, however the nutricline was deep and the subsurface concentrations of chlorophyll were less than half then observed on the inner continental shelf.

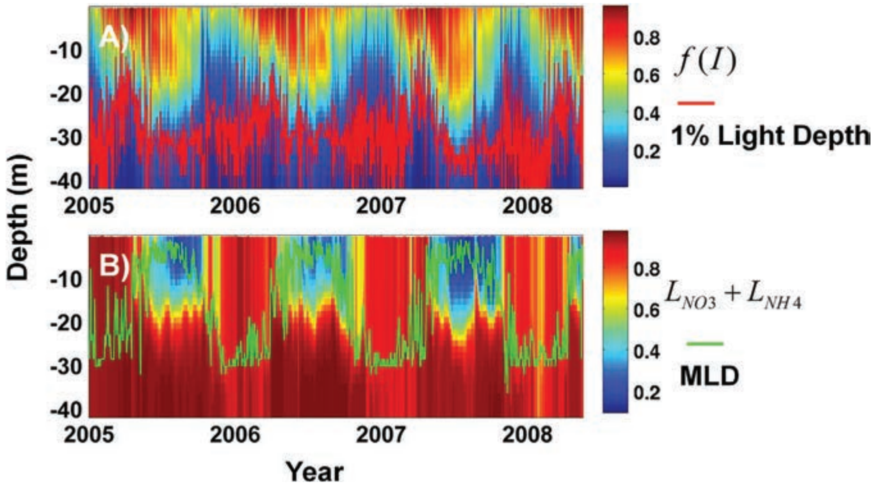

Fig. 7. Vertical distribution of limitation function of light (A) and nutrient (B) at a point located in Zone 1 (dot shown in Fig. 1). The 1% light level depth is plotted with function of light (in A, red line) and the MLD is plotted with nutrient limitation function (in (B), white line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The relative limitation of phytoplankton by light and nutrients is tightly coupled to the depth of the upper mixed layer as is illustrated in Fig. 7. The threshold for light limitation is described as Eq. (3). The threshold for nutrient limitation in the model is calculated as Eqs. (4) and (5). Value of 1 indicates no limitation. During winter months, when the upper mixed layer is deep, the majority of the phytoplankton in the water column are light limited (<0.8, Fig. 7A). During this period, nutrient limitation is low (>0.8, Fig. 7B). As solar illumination increases in spring, the mixed layer depth shallows and light limitation is decreased; however the entrainment of nutrients to surface waters is decreased and nitrate limitation begins to increase as the phytoplankton grow rapidly. In the euphotic zone, where there is sufficient light for photosynthesis, the reduction of CO_2 to organic carbon fuels the rate of cell doubling and population growth. Thus, the availability light drives the flux of carbon, and other elements, into cells and thereby determines the rate at which nutrients are utilized by photoautotroph for growth (Dubinsky and Schofield, 2010).

To test the role of mixing in regulating phytoplankton bloom dynamics we conducted a series of model simulations where we compared the models driven by measured wind (as above) to hypothetical simulations where no wind was applied to the ocean. Comparisons of the simulations for both Zone 1 and Zone 2 are shown in Fig. 8. In Zone 1, the "no wind" condition resulted in fall blooms later in the season, which reflects the importance of wind-induced mixing combined with seasonal cooling to drive the convective overturn on the MAB. The "no wind" condition does not show convective overturn and replenishment of nutrients to the surface waters until several weeks later in the season (Fig. 9D). The mid-winter depression in the winter bloom is not present in the "no wind" simulation. The magnitude and timing of the winter bloom is strongly tied to storms, which induce mixing during the dim winter months leading to increased light limitation of the phytoplankton (Xu et al., 2011); therefore the "no wind" condition diminishes mixing and light limitation and allows for larger winter blooms. The decline in the winter light limitation is also visible in the "no wind" plot (Fig. 10A, black line). Finally, as the spring transition begins and the water column begins to stratify due to increased radiant heating, the phytoplankton in the "no wind" experiment showed a more rapid biomass decrease reflecting an earlier onset of nutrient limitation (Fig. 10A). For Zone 2, the "no wind" condition resulted in an earlier spring bloom (Fig. 8B) reflecting the earlier onset of stratification of the offshore waters. This is consistent with satellite analyses that suggested pre-spring storms strongly influenced the timing and magnitude of the spring bloom in the MAB (Xu et al., 2011). The other major differences in Zone 2, is that the spring phytoplankton activities were higher under the normal windy conditions (Fig. 8B), which alleviated the early onset of nutrient limitation as the MLD became shallower (Fig. 10B). Finally the fall bloom observed in Zone 2 was not present (Fig. 8B), as the convective overturn on the MAB was delayed and cells were nutrient limited (Fig. 10B).

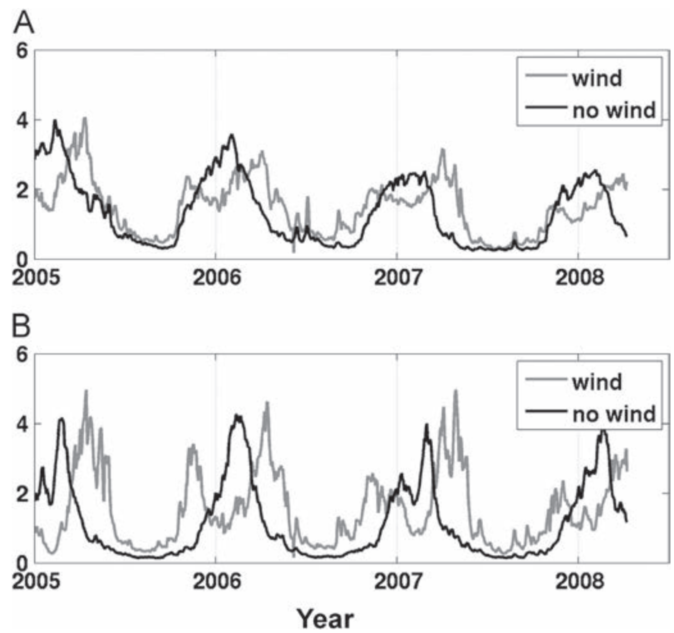

Fig. 8. Simulated time series of spatial mean surface chlorophyll concentration in Zone 1(A) and Zone 2(B). Black line represents the result under normal wind conditions; gray line represents the "no wind" forcing result.

3.3. Light, upper mixed layer depth, and chlorophyll

There is an inverse relationship between the MLD and the average light levels within the MLD (Fig. 11). Deeper mixed layers are associated with lower irradiance ($r=-0.84$, $p<0.001$; $r=0.72$, $p<0.001$ for Zone 1 and Zone 2 respectively). This relationship

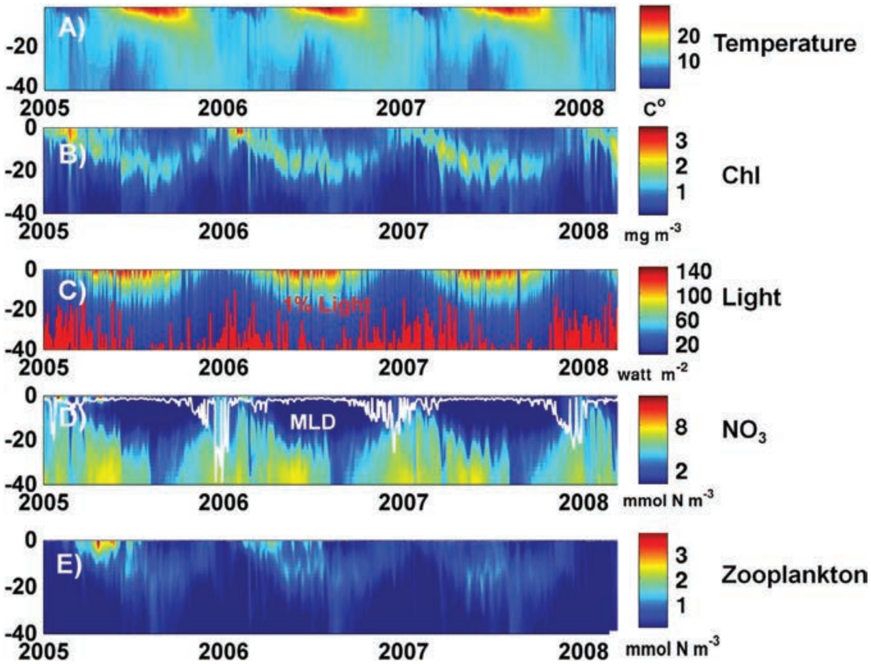

Fig. 9. Without wind forcing, the simulated vertical distribution of temperature (A) chlorophyll concentration (B), light (C), NO_3 (D) and zooplankton (E) in a dot located in Zone 1(dot shown in Fig. 1). The 1% light level depth is plotted with light (in C, red line) and the MLD is plotted with NO_3 (in (D), white line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

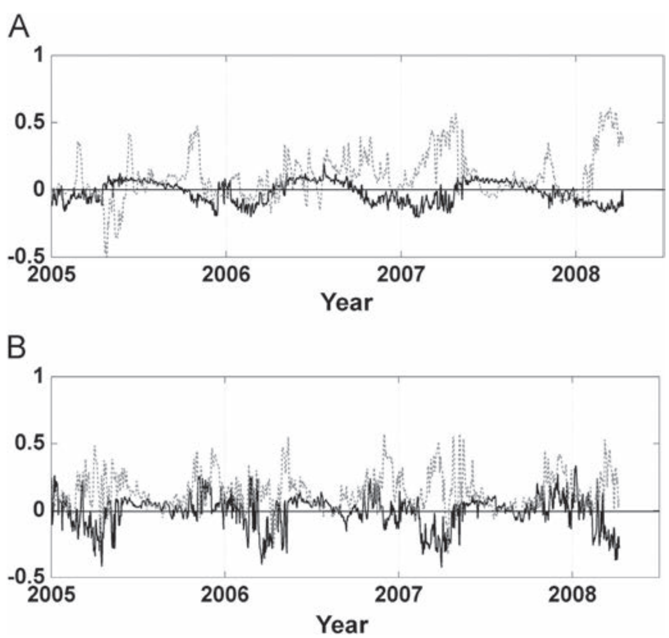

Fig. 10. Difference in light (black line) and nutrient (gray dashed line) limitation function between normal wind and no wind forcing condition in (A) Zone 1 and (B) Zone 2.

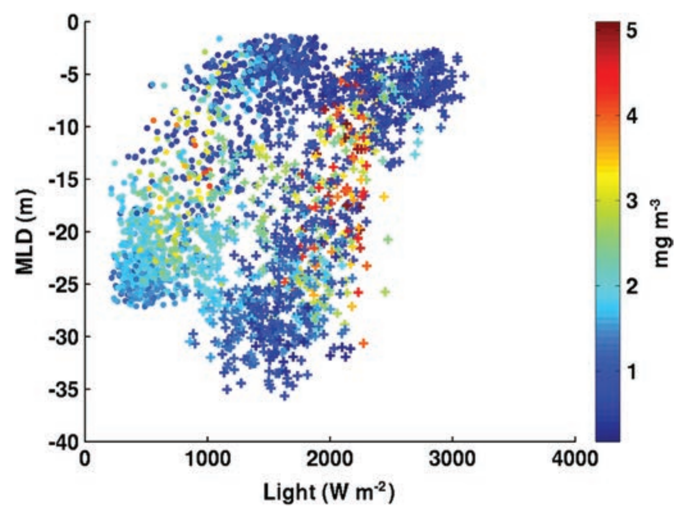

Fig. 11. Scatter plot of modeled mean light value in the mixed layer with MLD. The color represents the chlorophyll concentration in Zone 1 (dots) and Zone 2 (plus sign).

varies between Zone 1 and Zone 2, with offshore waters having a higher mean irradiance in the MLD. This reflects that the waters on the continental shelf are more turbid due to the enhanced attenuation of light by chlorophyll, colored dissolved organic matter and non-algal particles found in the shelf waters of the MAB (Schofield et al., 2004). While peak phytoplankton biomass ($> 4\ \mathrm{mg\ m^{-3}}$) is found over a 5-fold range of MLDs, there is a narrow range (50%) of mean irradiances associated with peak phytoplankton concentrations (Fig. 8). Peak chlorophyll values in Zone 1 were associated with lower mean light intensities compared to Zone 2. In order to parameterize both the MLD and light critical threshold of light to induce phytoplankton blooms we calculated mixing-light value (I') as the ratio of integral of light (I) in the euphotic zone (Z_{eu}) divided by the MLD (Z_{mld}) as

$$I' = \int_{-Z_{\mathrm{eu}}}^{0} I(z)dz / Z_{\mathrm{mld}} \tag{6}$$

The I' term incorporates both the incident light and the mixing environment through the depth of the MLD. The MLD also contains information on the probability of nutrient availability. We assessed if there is a critical I' value associated with both the observed and simulated chlorophyll maximum ($I'_{chl\mathrm{max}}$). The I' values derived from the model were integrated into $20\ \mathrm{W\ m^{-2}}$ bins for Zone 1 and Zone 2 (Fig. 12). There is an increase in chlorophyll with increasing I' up until 60 and $160\ \mathrm{W\ m^{-2}}$ ($I'_{chl\mathrm{max}}$) for Zones 1 and Zone 2 respectively. Under these conditions,

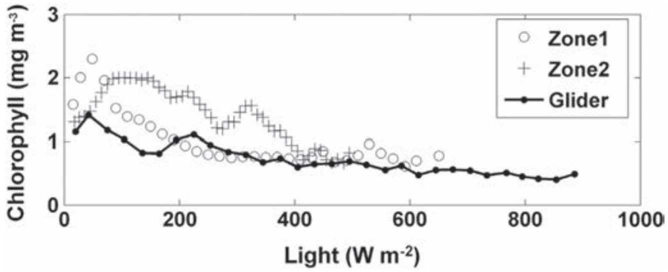

Fig. 12. Simulated mixed depth mean chlorophyll concentration and I' in every 20 W m^{-2}. I' value bins in Zone 1 (gray circle line) and Zone 2 (gray plus line), chlorophyll and I' based on glider observation are shown in black line with dots.

deeply mixed layers limited phytoplankton growth as overall light levels were low. For the waters of Zone 1 with shallow water depths, the mixed layer only need to decrease slightly to ensure that the majority of the water column is within the euphotic zone and phytoplankton have sufficient light to grow. In Zone 2, the deeper water depths require the MLD to decrease significantly in order to overcome light limitation. After this threshold has been reached, increasing I' is associated with declining chlorophyll. Here cells are maintained under high light but a shallow MLD does not allow for replenishment of the nutrients from depth. These chlorophyll and I' relationships were compared to chlorophyll data measured with Slocum gliders outfitted with fluorometers (Fig. 12, black line with dots). Despite that the glider data set is smaller and does not include many transects during the winter months, the relationship between I' and chlorophyll is similar showing an increase at low I' values to a value of 50 W m^{-2} and then decreasing values as I' increases. The glider chlorophyll values are lower than model estimates which is not surprising as the data set does not include many transects during the winter bloom. Calculations of I' for the "no wind" simulation show similar patterns except that it takes a high magnitude of I' to reach the peak chlorophyll values for Zone 2 (Fig. 15 plus line).

Is $I'_{chl\max}$ predictable? Spatial maps of $I'_{chl\max}$ associated with the chlorophyll maximum for the MAB are shown in Fig. 13. Generally, $I'_{chl\max}$ is low and relatively constant on the continental shelf and increases in magnitude out over the continental slope and deep sea. The one shallow water exception was associated with the Hudson River plume, which is extremely turbid and mixing rates in the buoyant plume water must be high enough to overcome chronic light limitation for phytoplankton bloom Schofield et al., submitted for publication. Excluding this river zone, the relationship between $I'_{chl\max}$ and bottom depth were robust (Fig. 14). Bottom depth could explain 70% of the variability in $I'_{chl\max}$ ($p < 0.001$).

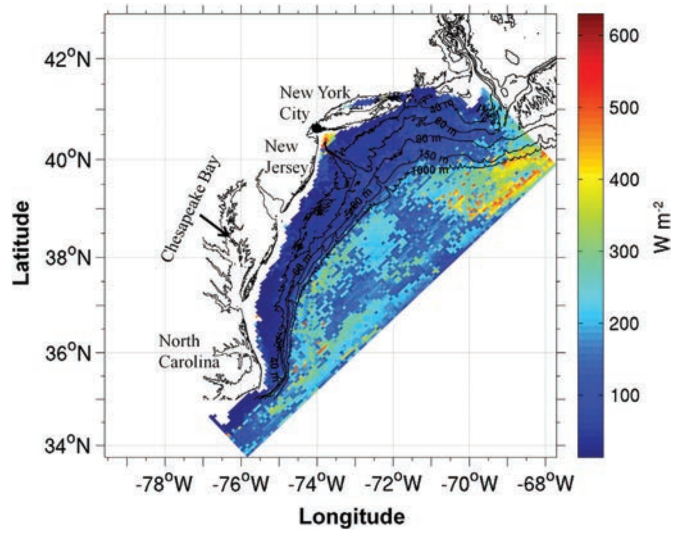

Fig. 13. The critical light value ($I'_{chl\max}$) in each grid of model domain.

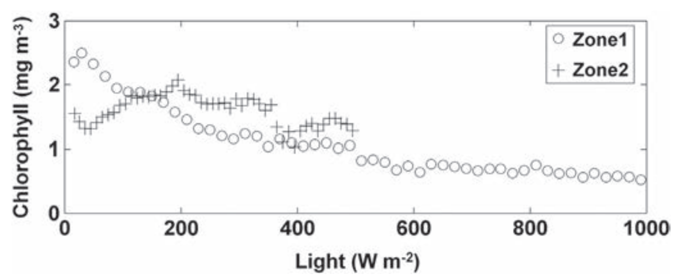

Fig. 15. Under no wind forcing, simulated mixed depth mean chlorophyll concentration and I' in every 20 W m^{-2} I' value bins in Zone 1 (red circle line) and Zone 2 (blue circle line), chlorophyll and I' based on glider observations are shown in black line with dots. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

4. Discussion

The late fall-winter bloom is the most recurrent and largest phytoplankton bloom in the MAB (Xu et al., 2011; Yoder et al., 2001). The fall-winter bloom is fueled by the replenishment of nutrients to the euphotic zone once the summer thermal stratification has been disrupted. This thermal stratification is dramatic (summer thermoclines on the MAB exhibit a temperature gradient of over 15 °C in only 5 m water depth, cf. Castelao et al., 2010) and this stratification deprives the surface phytoplankton of macro and micronutrients throughout the late spring, summer and early autumn. Observational studies have documented there is a great deal of inter-annual variability in the timing of the late fall-winter bloom (Yoder et al., 2001). The variability in the timing of the bloom has been related to the timing of destratification, which is driven by seasonal cooling of the surface waters and the passage of large storms that induce mixing (Beardsley et al., 1985; Glenn et al., 2008; Lentz et al., 2003). The magnitude of the fall-winter bloom is thought to be regulated by factors that stabilize the water column (Xu et al., 2011). In the MAB, these processes include the frequency of winter storms and the presence of low salinity buoyant plumes (Xu et al., 2011). While the observational data is compelling it has been insufficient to confirm the hypothesized forcing of the late fall-winter phytoplankton bloom.

To test the hypothesized physical forcing of the MAB phytoplankton we utilized the physical–biological ROMS model to conduct a series of simulations where we varied the physical forcing and analyzed the source and sinks of the phytoplankton.

The model which used realistic forcing was able to simulate the timing and spatial extent of the phytoplankton dynamics observed in SeaWiFS data. The model did a quantitatively good job of predicting the winter bloom; however the model had a more difficult time in reproducing the magnitude of the spring bloom. For the spring bloom region, there are large horizontal and vertical gradients in water properties and are associated with the shelf-break front, a feature susceptible to nonlinear instabilities and strong interactions with Gulf Stream warm-core rings (Gawarkiewicz et al., 2001, 2004). As a result, this region has complicated physical background that the mixing by wind cannot really be isolated. The discrepancy for the spring bloom likely reflected both by underestimated in chlorophyll by satellite-derived chlorophyll in this region (Fennel et al., 2006) and underestimated zooplankton grazing (Flagg et al., 1994). For the late fall-winter bloom, our numerical experiments explicitly demonstrated the role of wind-induced mixing in winter phytoplankton dynamics when all the other forcing factors were held constant. For the initiation of the late fall-winter bloom the no wind-induced mixing simulation demonstrated that wind was a secondary factor; therefore seasonal cooling and the corresponding convective overturn on the MAB is the dominant feature initiating the phytoplankton bloom. This is consistent with observations that tropical storms on the MAB can only induce water column turnover if the summer thermocline had been previously weakened by seasonal cooling (Glenn et al., 2008). After destratification, the frequency of high wind regulates the size of the phytoplankton bloom. Strong winds result in high mixing rates or less solar radiation because of cloudy weather, which results in the light limitation of the phytoplankton (Xu et al., 2011), which is confirmed by the model as an increased wind forcing resulted in smaller phytoplankton blooms.

Wind forcing also has a significant role on the timing and magnitude of the offshore spring bloom. Observational efforts have related the size and timing of the spring phytoplankton to the amount of wind-induced mixing present in the late winter (Xu et al., 2011). Wind-induced mixing in the late winter delays the thermal stratification of the MAB, which influences the spring bloom as cells require water column stabilization to overcome light limitation. During the no wind simulation, the spring bloom was dominated by a single event that occurred earlier in the season compared to normal wind conditions. This bloom was short lived as the cells rapidly consumed available nutrients. In contrast, the model simulation that used natural wind forcing resulted in a spring bloom that lasted longer throughout the season compared to the no wind condition as wind-induced mixing replenished the supply of nutrients and enhanced the overall amount of chlorophyll on the MAB. The SeaWiFS observed bloom in the shelf-break front region commenced in late March and lasted up to late April. In our simulated case with wind, the spring bloom in the shelf-break front region initiated in early March and lasted up to early April. It looks like that although the model simulated spring bloom start a little bit earlier under normal wind condition, it can better capture the both spring and fall bloom in this region compare with no wind forcing condition.

Is there a relatively predictable light condition that promotes a maximum chlorophyll concentration? Photosynthetic activity is confined to the euphotic zone, which is nominally defined as the depth where the light levels are 1% of the surface light intensity.

The depth of the euphotic zone is poor at predicting the initiation of phytoplankton blooms as any mixing to depth limits phytoplankton biomass accumulation in the upper mixed layer. This is due to the high respiratory costs to build cells (Falkowski and Raven, 2007). This discrepancy is accounted by Sverdrup's (1953) "critical depth" for bloom initiation (Obate et al., (1996); Smetacek and Passow, 1990). This framework has been highly effective for the open ocean where the compensation depth for phytoplankton growth appears to be relatively constant (Siegel et al., 2002). In MAB, the light regime is tied closely to mixing regime as light is rapidly attenuated by high phytoplankton biomass and significant inputs from buoyant turbid plumes (Cahill et al., 2008; Castelao et al., 2008). As mixing determines not only the light but also the nutrient availability, there is need to parameterize the relative impacts of both. To parameterize the relative tradeoffs of mixing and light availability the ratio of Z_{mld} to Z_{eu} has been used to describe the regulating primary production (Huisman et al., 1999; Irigoien and Castel, 1997); however, this ratio only reflects the relationship between surface light condition and MLD. We suggest that it is more appropriate to use I' which is the ratio of integral of light in the euphotic zone and MLD to compare the balance between light limitation and nutrient limitation. When I' is low, phytoplankton are light-limited due to low surface irradiance and deep mixed layer. The variability shows a single peak in both the offshore and nearshore conditions. At high values ofI', the mixed layer is shallow, coincident with the seasonal increase in solar illumination, which allowed the photosynthetic activity to consume the available nutrients. This in turn results in low biomass. We used the model to define this integral and then assess when it results in the maximum chlorophyll biomass ($I'_{chl\max}$). Model simulations suggest that on MAB, $I'_{chl\max}$ varied by a factor of three and were spatially variable. The spatial variability was positively correlated with water depth, suggesting that this term can be parameterized.

Our results based on numerical simulation and glider observations confirm the SeaWiFS observation of seasonal phytoplankton bloom in the MAB. The modified light values are used to describe the balance between light and nutrients limitation and so as the influence the timing and magnitude of bloom. Sensitivity study of no wind forcing simulation proves that the mixing plays a significant role in regulating the nutrient and light field and thus influences the phytoplankton dynamics.

Mid-Atlantic Bight

ABSTRACT

A recently implemented real-time ocean prediction system for the western North Atlantic based on the physical circulation model component of the Harvard Ocean Prediction System (HOPS) was used during an observation simulation experiment (OSE) in November 2009. The modeling system was built to capture the mesoscale dynamics of the Gulf Stream (GS), its meanders and rings, and its interaction with the shelf circulation. To accomplish this, the multiscale velocity-based feature models for the GS region are melded with the water-mass-based feature model for the Gulf of Maine and shelf climatology across the shelf/slope front for synoptic initialization. The feature-based initialization scheme was utilized for 4 short-term forecasts of varying lengths during the first two weeks of November 2009 in an ensemble mode with other forecasts to guide glider control.

A reanalysis was then carried out by sequentially assimilating the data from three gliders (RU05, RU21 and RU23) for the two-week period. This two-week-long reanalysis framework was used to (i) study model sensitivity to SST and glider data assimilation; and (ii) analyze the impact of assimilation in space and time with patchy glider data. The temporal decay of salinity assimilation is found to be different than that of temperature. The spatial footprint of assimilated temperature appears to be more defined than that of salinity. A strategy for assimilating temperature and salinity in an SST-glider phased manner is then offered. The reanalysis results point to a number of new research directions for future sensitivity and quantitative studies in modeling and data assimilation.

1. Introduction

Ocean observing has advanced in the last decade from a ship-based expeditionary science to a distributed and observatory-based approach. This transition, which has been occurring over last decade (Glenn and Schofield, 2003, 2009), reflects the maturation of a wide range of observation platforms, data assimilative numerical models, and improved global communications (Schofield et al., 2012). The expanding suite of observational assets include remote sensing (satellite: Halpern, 2000, aircraft: Lomax et al., 2005, HF Radar: Crombie, 1955; Barrick, 1972; Barrick et al., 1977), fixed location assets (moorings: Hayes et al., 1991, Weller et al., 2000, seafloor cables: Schofield et al., 2002, Kunze et al., 2006), and Lagrangian platforms (AUVs: Blackwell et al., 2008, gliders: Sherman et al., 2001, Eriksen et al., 2001, Webb et al., 2001, drifters: Niiler et al., 2003, floats: Davis et al., 1992, Gould et al., 2004). As the number of deployed platforms increases there is a growing need to aggregate the data and coordinate the sampling among the individual systems in order to create a system-of-systems. This will require the development of coherent software networks that allow a distributed group of sensors and/or scientists to operate as a group.

The integration of software systems is currently under development. For example, the U.S. National Science Foundation's Ocean Observatory Initiative (OOI, http://www.oceanleadership.org/programs-and-partnerships/ocean-observing/ooi/) has focused a significant effort on developing a sophisticated cyberinfrastructure (CI) that binds the physical observatory, computation, storage and network infrastructure into a coherent system-of-systems. This CI is also being designed to provide a web-based social network, enabled by real-time visualization and access to numerical models, to provide the foundation for adaptive sampling science. The OOI cyber-development has chosen to utilize a spiral design strategy, allowing the oceanographic community to provide input during the construction phase with the strategy of utilizing existing ocean observing networks. For this effort, the OOI utilized an existing

ocean observing network in the Mid-Atlantic Bight (MAB) as part of the National Oceanographic and Atmospheric Administration's (NOAA) Integrated Ocean Observing System (IOOS) in November 2009. The goal was to use this network to conduct an observation simulation experiment (OSE). The objective was to use the oceanographic testbed to support field operations of ships and mobile platforms aggregate data from fixed platforms, shore-based radars, and satellites; and offer these data streams to data-assimilative forecast models. Additional goals were to use multi-model forecasts to guide glider missions and coordinate satellite observing, and to demonstrate the ability to conduct two-way interactions between the sensor web and predictive models. While previous studies have focused on the phytoplankton dynamics during spring and/or spring transition (Ryan et al., 1999a, 1999b, 2001), this field effort was conducted to collect data on the status of the Mid-Atlantic shelf in early winter, when the winter phytoplankton bloom occurs (Schofield et al., 2010).

This paper uses data collected during the OSE to investigate the forecast sensitivity to glider data assimilation. One goal of this study is to understand and develop a protocol for future similar test experiments based on a careful reanalysis during the OSE period. An interesting new result from the assimilation analysis is the apparent difference of spatial and temporal scales of impact between temperature and salinity. These behavioral differences might lead to future areas of research in modeling and assimilation.

This paper is organized as follows. The methodology is presented in Section 2 and the analysis of the real-time forecasts made during the OSE period is presented in Section 3. A reanalysis based on systematic glider data assimilation is presented in Section 4, followed by a summary and discussion in Section 5.

2. Approach and methods

A distributed community of ocean scientists provided the CI team with regional surface datasets, a surface current mapping network, a constellation of fixed and taskable satellites, a fleet of autonomous Slocum gliders, a multi-vehicle network of autonomous underwater vehicles, and five different data-assimilative forecast ocean models that tested the OOI software. An overview of the OSE effort is described by Schofield et al. (2010). The OSE was a multi-institutional, multi-investigator effort. Various OSE groups coordinated satellites, multiple gliders, and an AUV during the OSE period of October 26 through November 17, 2009. A data and model portal was assembled (http://ourocean.jpl.nasa.gov/CI) (Wang et al., in this issue) for multi-model ensemble forecasting and glider guidance decision-making efforts.

2.1. Regional data streams

A large suite of satellites were used during this study. The satellites provided multiple passes of sea surface temperature and ocean color observations. The data was downloaded and processed at both the NASA Jet Propulsion Lab and the Rutgers Coastal Ocean Observation Lab. Data was processed in near real-time (hours) and posted to the data portal.

The surface currents on the MAB are measured by an extensive network of high frequency CODAR networks array. The CODAR network consists of twelve 5 MHz systems located along the northeast of the United States. The HF Radar uses the Doppler Shift of a radio signal backscattered off the ocean surface to measure the component of the flow in the direction of the antenna. The network provides surface current estimates to a depth of 2.4 m (Stewart and Joy, 1974).

2.2. Gliders

Slocum gliders are an autonomous underwater scientific platform (Webb et al., 2001) manufactured by the Teledyne-Webb Research Corporation. They are 1.8-m long, torpedo-shaped, buoyancy-driven vehicles with wings that enable them to maneuver through the ocean at a forward speed of 20–30 cm s^{-1} in a sawtooth-shaped gliding trajectory. Each Slocum glider has a payload bay that houses a SeaBird conductivity–temperature–depth sensor and includes space for a range of additional sensors. The glider acquires its global positioning system (GPS) location every time it surfaces, which is programmable and was set to call-in every 3 h for the purposes of this study. By dead reckoning along a compass bearing while flying underwater, estimates of depth averaged current can be calculated based on the difference between the glider's expected surfacing location and the actual new GPS position. Depth averaged current measurements obtained in this manner have been validated against stationary Acoustic Doppler Current Profiler data (Glenn and Schofield, 2003).

During this experiment, four Webb gliders were deployed by Rutgers University and the University of Delaware. The gliders were deployed prior to the start of the experiment on Nov 1 2009 and operated for two weeks. During that period the gliders traversed 1673 km underwater collecting 23,332 vertical profiles. The data collected were analyzed for various process studies including phytoplankton productivity (Schofield et al., 2012) and sediment re-suspension during fall storms (Miles et al., in this issue).

2.3. Numerical model

One of the five numerical models employed during the OSE is the SMAST-HOPS (School for Marine Science and Technology—Harvard Ocean Prediction System) real-time forecast system, which has been operational since March 9, 2009, providing a 7-day ocean forecast for the large-scale Gulf Stream region from Cape Hatteras to 55°W, including the Gulf of Maine and the Mid-Atlantic shelf region. The other four models were: (i) the New York Harbor Ocean Prediction System (NYHOPS) for MARACOOS (Bhushan et al., 2009; Georgas and Blumberg, 2009); (ii) the regional ocean modeling system for MARACOOS (Wilkin et al., 2005); (iii) the regional ocean modeling system from USGS (Warner et al., 2008); and (iv) the MIT multidisciplinary simulation, estimation and assimilation system (MSEAS) (Lam et al., 2009; Haley and Lermusiaux, 2010). The SMAST-HOPS operational system (described by Schmidt and Gangopadhyay, 2012, in this issue, SG12 henceforth; Brown et al., 2007a, b; Robinson et al., 2001) regularly assimilates satellite SST and, when available, MARACOOS glider-measured 4-D water properties to produce weekly 3-D nowcast and forecast MARACOOS regional temperature maps (see http://www.smast.umassd.edu/modeling/RTF/index.php). Four forecasts were provided during the OSE period, assimilating all available data from SST and the four gliders.

The horizontal structure of the SMAST-HOPS operational model domain consists of 131×83 grid points with 15 km resolution, extending from 30.5°N to 47.93°N in the meridional and from 80.54°W to 54.23°W in the zonal direction. The vertical structure of the model is resolved by 16 levels that are distributed according to a topography-following "double sigma" transformation described by Lozano et al. (1996) and Sloan (1996). The open boundary conditions for tracers and velocity are based on Orlanski (1976); and the horizontal subgridscale processes are parameterized using a set of scale-selective Shapiro filters: 4-1-1 (fourth order, one time, every time step) for velocity and tracers, a 2-2-1 for vorticity and 2-1-1 for streamfunction. The time step

Table 1
Objective analysis parameters for glider data initialization and assimilation with a 12-h time window.

	Initialization		Assimilation	
	Synoptic	Mean	Synoptic	Mean
Decay (km)	60	180	30	90
Zero crossing (km)	120	360	60	180
Time decay (day)	90	1000	10	80

used in all runs was 225 s. Some of the important numerical model parameters and their values are given in Table 1 of SG12. Note that this model system has yet to incorporate a real-time river runoff input.

The operational forecasting system is built on the feature-oriented initialization scheme developed by Gangopadhyay et al. (1997) for the Gulf stream meander and ring (GSMR) region and for the Gulf of Maine and Georges Bank (GOMGB) region (Gangopadhyay et al., 2003). The feature-oriented methodology is explained in detail for the GSMR–GOMGB region by SG12, and has now been developed for many other regions of the world ocean including the South Atlantic (Calado et al., 2008), the Trinidad North Brazil current (Schmidt et al., 2011) and the California current system (Gangopadhyay et al., 2011). Briefly, FORMS methodology (Gangopadhyay and Robinson, 2002) requires (i) the development of analytical–empirical formulation of the synoptic-dynamic characters of features such as fronts, eddies, gyres and currents etc. called 'feature models,' and then (ii) implementation of a multiscale melding using objective analysis of calibrated synoptic feature models (with available satellite and in-situ data) with background mean state to create the "most knowledgeable" nowcast. For the MARACOOS implementation, the deep-water feature model set for GSMR (Gulf Stream, Deep western boundary current, warm and cold core rings, southern and northern recirculation gyres; see Gangopadhyay et al. (1997) for details) is melded with the shallow-water feature model set in the GOMGB region (Maine coastal current, Georges Bank tidal front, Wilkinson–Jordan–Georges basin gyres, northeast channel inflow and great south channel outflow; see Gangopadhyay et al. (2003) for details), and further supplemented with the Levitus climatology as the background in a multiscale objective analysis framework. The initialization field is dynamically adjusted with wind forcing and used in an SST-assimilative forecast model using the methodology described by Brown et al. (2007b). The model is forced with atmospheric fields (surface momentum flux, surface heat flux, surface water flux and shortwave radiation) from the global forecast system (GFS) at 0.5-degree resolution for 7 days. Several products are used for assimilated SST, including 3-day composite products from the Johns Hopkins University/Applied Physics Laboratory, AVHRR passes processed by the MARACOOS group at the University of Delaware College of Marine and Earth Studies, and daily and multi-day blended products from remote sensing systems. See SG12 for full details of this implementation and the model skill validation using drifters and GS axis locations from satellite observation.

While the OSE period was a test of the development and implementation of the cyberinfrastructure, the data collected during this period provided a valuable opportunity to reanalyze and understand various aspects of underlying processes and methodologies, which depend on data, models and model-data synthesis exercises. One of them is the focus of this paper, in which we assess the impact of glider data assimilation on the SMAST-HOPS model simulation. Such an exercise would make possible the design of better and more effective schemes for real-time assimilation utilizing satellite, glider and other in-situ observations in future OSEs.

Assimilation of data in numerical ocean models has been in practice for over couple of decades now (Carter and Robinson, 1987; Robinson et al., 1989; Derber and Rosati, 1992; Ezer and Mellor, 1992; Fukumori and Malanotte-Rizzoli, 1995). A comprehensive set of studies on the different approaches to data assimilation in ocean modeling for the early nineties were compiled by Malanotte-Rizzoli (1996). More recent advances in data assimilation include, among many, the works with the regional ocean modeling system (3DVAR and 4DVAR) (Li et al., 2008a, 2008b; Chao et al., 2009; Broquet et al., 2009; Veneziani et al., 2009), with the navy's coastal ocean model (Barron et al., 2007; Shulman et al., 2007, 2009), and with the Harvard Ocean Prediction System (Lozano et al., 1996; Lermusiaux, 1999, 2002; SG12) and the MIT multidisciplinary simulation, estimation and assimilation aystem (MSEAS) (Lam et al., 2009; Haley and Lermusiaux, 2010). With increasing computing power, more mathematically elegant and computationally demanding methods such as extended Kalman Filters, ensemble Kalman Filters (EnKF) are being adapted to ocean and atmosphere modeling at a rapid pace (Kalnay, 2003; Ott et al., 2004; Hunt et al., 2004; Kalnay et al., 2007; Evensen, 2009). However, while the techniques are improving, the availability of data for assimilation in the ocean models still remains sparse and infrequent. This necessitates generating suitable initialization and assimilation fields from a set of irregularly occurring observations in both space and time. Specifically, a set of decay scales in space and time (based on data auto-correlations) is generally applied to construct the initialization and assimilation fields (Mooers, 1999). It is also expected, that the impact of such patchiness would result in an assimilated field where errors will dominate away from the center of assimilation. In this study, we attempt to understand this impact facilitated by the availability of the patchy glider data set in a selective region in the reanalysis mode.

3. Assimilation of glider data in model forecasts

The sensitivity of the model simulations to glider data assimilation is examined over the two-week period (Nov 2 through Nov 16). This section describes the Gulf Stream system during the OSE period, the glider data and the initialization and assimilation protocols. Section 4 then describes the numerical experiments and the results.

3.1. The gulf stream system during OOI–CI–OSE

The FORMS-based initialization for the SMAST-HOPS operational system requires an ocean analysis. This analysis for the western North Atlantic provides the surface characterizations of the locations, shapes and sizes of various features such the Gulf Stream, its rings, and the shelf-slope front. The specific product used for the SMAST-HOPS model is Jenifer Clark's Gulfstream (http://users.erols.com/gulfstrm/), which is a typical ocean analysis created primarily from the NOAA polar orbiting thermal infrared satellite imagery. The data are false-colored based on different sea surface temperatures. Other sources of data include altimetry, drifting and fixed buoys, model output, and sea surface isotherm analyses. The analyses extend from 80°W to 45°W and from 50°N to 30°N. The images are then subjectively analyzed by an oceanographic expert. They are generated once a week and have been analyzed since 1980. The analyses have improved over the years due to inputs and feedback from various stakeholders such as sailboat racers, coast guard search and rescue, fishermen,

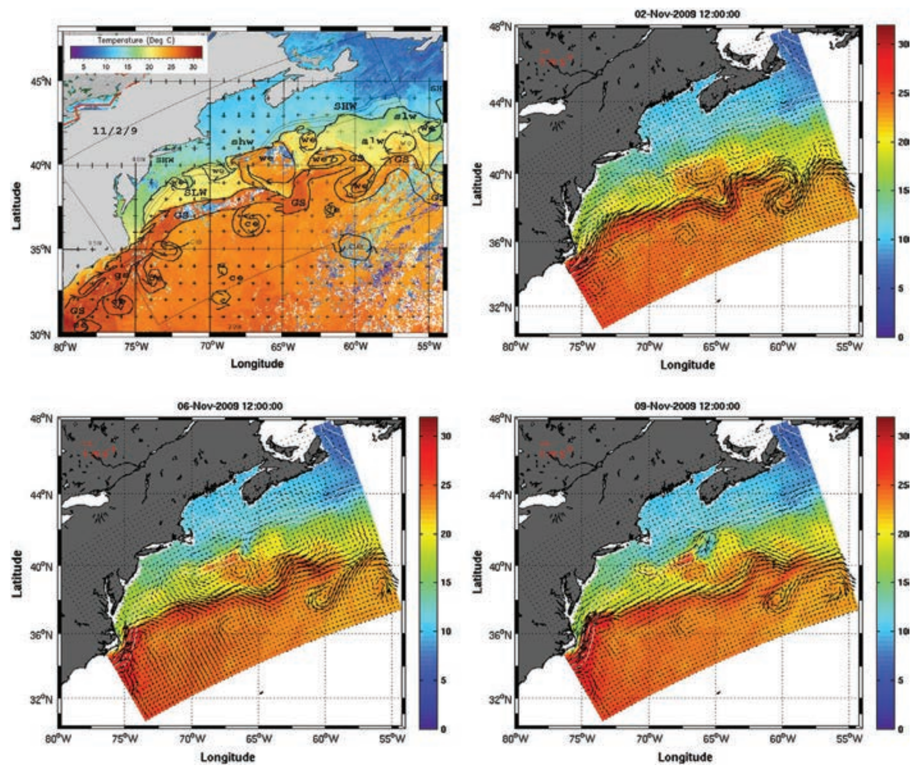

Fig. 1. Weekly Jenifer Clark analysis of Gulf Stream ring and eddy positions, with cold core rings and eddies noted as "ce" and warm core rings and eddies noted as "we" (top-left) for Nov 02, 2009.The SMAST-HOPS forecasts for Nov 2nd, Nov 6th and Nov 9th are shown in the other three panels.

scientists, forecast modelers, yacht deliveries, ocean rowers, swimmers, etc.

The week-long forecasts are issued generally by wednesday morning; monday 0-h is a typical model initialization state, with SST assimilation carried out on monday afternoon or on Tuesday morning. The forecast fields (temperature, salinity, currents) are available at www.smast.umassd.edu/modeling/RTF/MARCOOS for different levels at 6-hourly intervals for the full domain, and for zoom domains of the Mid-Atlantic shelf and the Gulf of Maine. To provide high-resolution, nested forecasts for the mission control of the AUV and glider fleets, the forecast data in netCDF format (CF-compliant) were made available from the OPeNDAP-enabled THREDDS server http://aqua.smast.umassd.edu:8080/thredds/catalog/models/catalog.html.

The configuration of the Gulf Stream system on November 02, 2009, as the study period begins, is shown in Fig. 1. The left panel shows the Jenifer Clark analysis, with outlines of the Gulf Stream and its filaments spreading out to the recirculation gyres and each independent ring. During the OOI–CI–OSE, the Gulf Stream system north of 32°N and west of 55°W includes 6–7 warm and 6–7 cold eddies, and a large meander from 65°W to 55°W. The meander shifts and changes shape over the 2-week period as it absorbs a large warm core ring and casts off a cold-core ring. The SMAST-HOPS forecasts for Nov 2, 6 and 9 are shown in Fig. 1 b–d. During these forecasts the SST and Glider data were assimilated in a strategic reanalysis to understand the behavior of assimilated fields after glider data assimilation.

3.2. Description of the glider sampling

The tracks of the gliders, showing the coverage area, are delineated in Fig. 2. The individual tracks for RU05, RU21, RU23 and UD134 are distinguished by color. The three Rutgers gliders

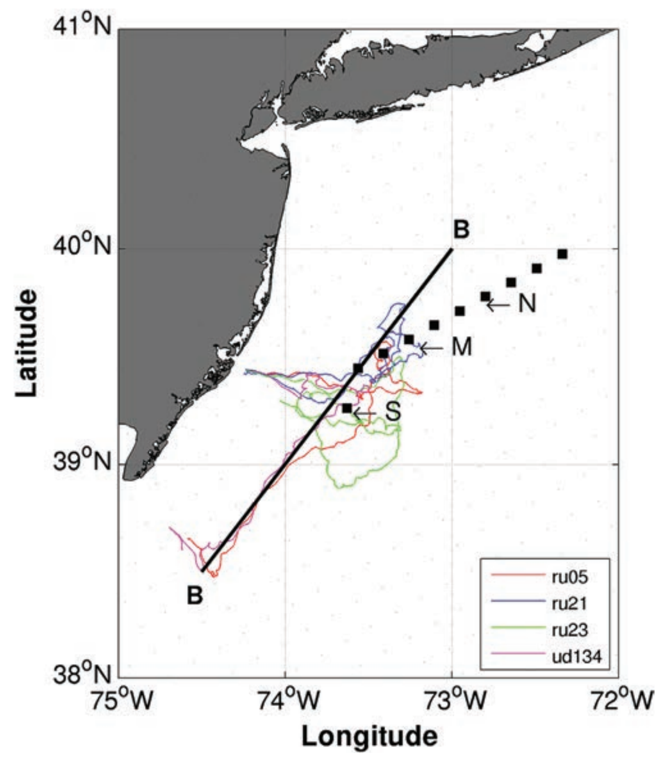

Fig. 2. Tracks of the three gliders (RU05, RU21 and RU23) used for initialization and assimilation of the 02 Nov 2009 SMAST-HOPS run. The tracks span from 30 Oct 2009 to 17 Nov 2009. Glider UD134, not used in the HOPS model, is also shown. The points marked by south (S), middle (M) and north (N), are where the spatio-temporal impact analysis of glider data assimilation is carried out. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

(RU05, RU21 and RU23) were deployed off the New Jersey coast on October 26, and moved across the shelf to near the 50-m isobath within the first 3–4 days. All of them were then used for CI–OSE control experiments (Schofield et al., 2010) and were guided in different directions before recovery. For example, after following the cross-shelf path, RU05 (red) was guided northward during Nov 6–9, then southward in the second week, and finally was recovered near Delaware Bay on Nov 17. RU23 (green) zigzagged during the OSE across the 50-m isobath and was recovered on Nov 17 near its original deployment site. RU21 (blue) started from the same location, moved in a northeastward direction and was engaged in sampling fine-scale features (Schofield et al., 2012, in this issue). UD134 (pink) was deployed later on Nov 6, followed a track similar to that of RU05 (red) for the latter part of the 2-week period, and was also recovered on Nov 17 2009. The sensitivity to assimilation was studied along the line of the black rectangles and is described later.

3.3. Initialization and assimilation methodologies with glider data

For the purpose of initialization, the temperature and salinity data from RU05, RU21 and RU23 between Oct 26 and Nov 2 were melded with the standard operational FORMS-derived initialization field (SG12). The melding was done by carrying out a multiscale objective analysis (OA) in which the synoptic glider data were statistically merged with the FORMS initialization following well-established procedure (Brown et al., 2007a; BG07 henceforth; SG12). The OA parameters, such as the correlation scale and decay scales of choice for the glider data, are summarized in Table 1. The total sampling coverage for Oct 26–Nov 1 is shown in Fig. 3a. This process of melding available glider observations over a week (or less) at initialization of the dynamical model run is also known as 'assimilation at initialization.'

The sequential assimilation protocol for SST is explained in detail by SG12 (see their Section 3.3 and equation 1 therein). Briefly, the OI assimilation is a data-fusion methodology, where the observation (SST or Glider T/S) is assimilated in the model using a time-varying weighting function within each assimilation cycle. Subsequent glider data were assimilated at regular intervals of 12 h. Examples of glider data locations used for assimilation for a selected set of days are shown in Fig. 3b–f for Nov 4, 6, 8, 10, and 12, respectively. Initial fields of salinity and associated error fields are presented in Fig. 4. The contrast between glider salinity and climatology-derived background is much more pronounced than that between the corresponding temperature fields (not shown). This is because the assimilation of glider temperature is smoothed by the SST-assimilation from satellite observations. The subsurface projection of the satellite-derived SST field also helps reduce such contrast between glider and background temperature.

The weighting assimilation scheme for SST is described by BG07 and SG12 in detail. The weights for assimilating the glider data are presented in Fig. 5. Specifically, to allow for the internal dynamical adjustment of the assimilative variable, our approach is to distribute the field over a temporal window with variable weights. The 12-h Glider data is thus slowly amplified from its 20% value (weight of 0.2) on the 6th hour (prior to the observation hour) to its 90% value (weight of 0.9) on the 12th hour and then decays for next 6 h. This ramp-up and decay-down strategy is cycled every 12 h allowing for continuous and sequential assimilation of glider data within the observation window.

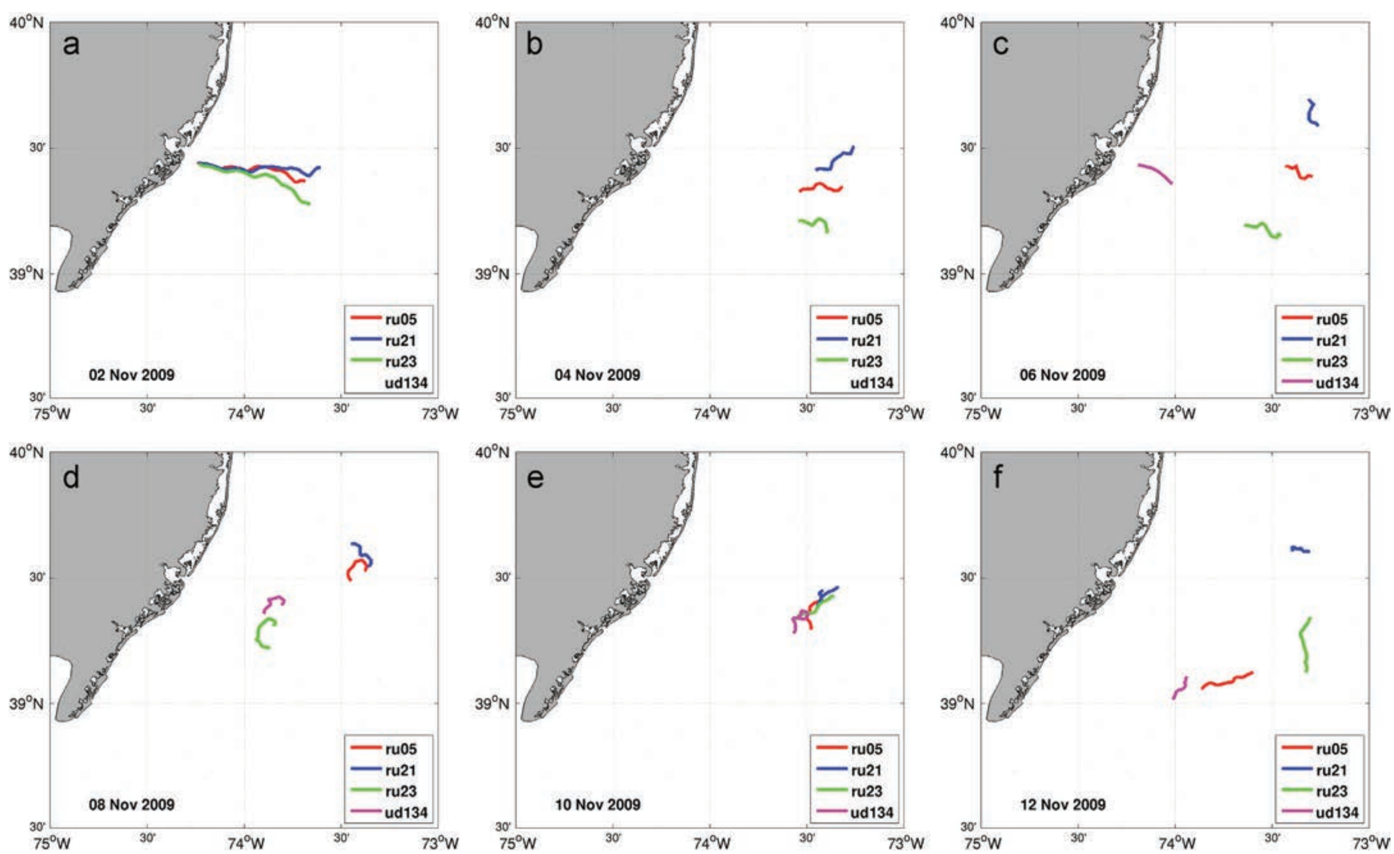

Fig. 3. Position of glider data used in the (a) initialization of the SMAST-HOPS 02 Nov 2009 run, and the assimilation of glider data for (b) 04 Nov 2009, (c) 06 Nov 2009, (d) 08 Nov 2009), (e) 10 Nov 2009, and (f) 12 Nov 2009. The initial field incorporates data collected from 30 Oct 2009 to 02 Nov 2009. The assimilation fields incorporate 12 h of glider data, centered on 0000 UTC.

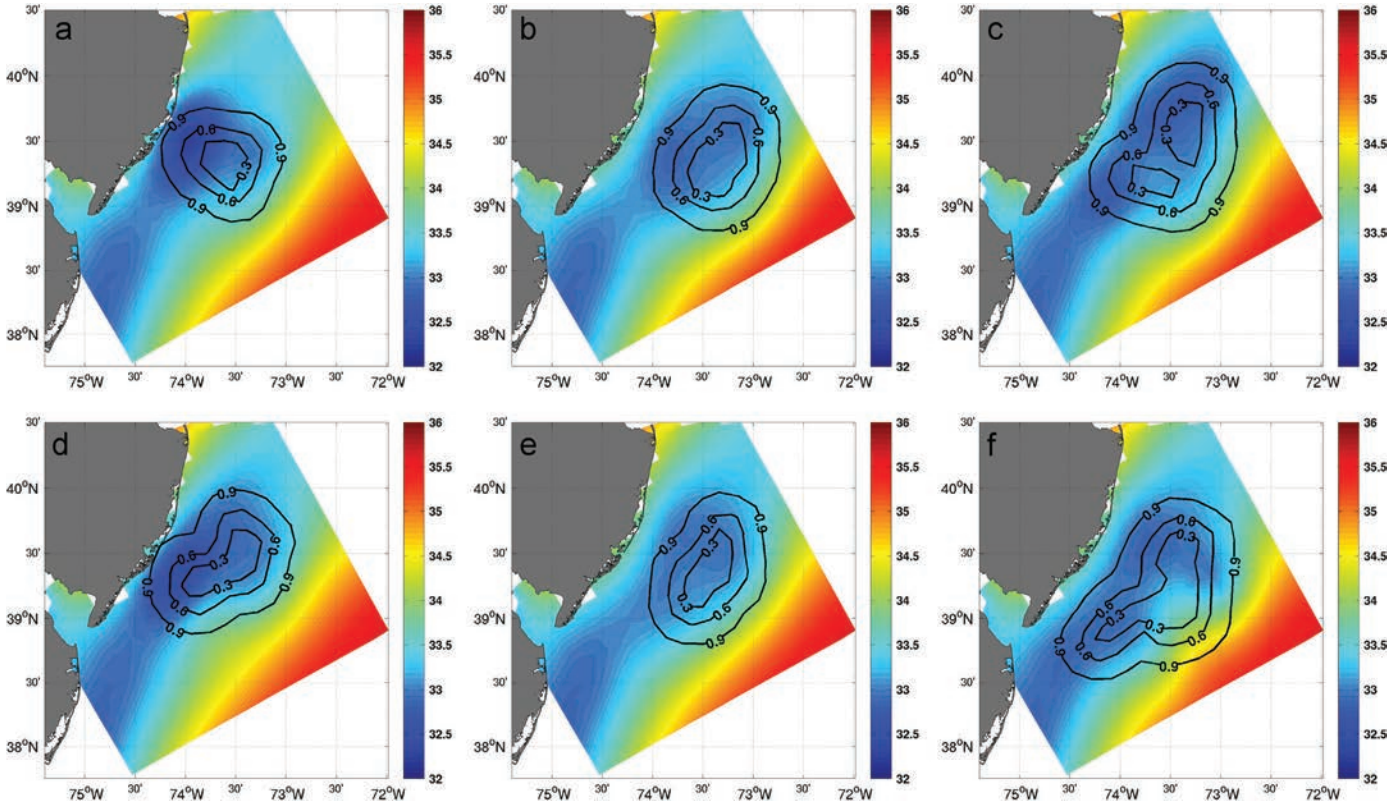

Fig. 4. OA salinity fields assimilated into SMAST-HOPS 02 Nov 2009 run for (a) 02 Nov 2009 (b) 04 Nov 2009 (c) 06 Nov 2009 (d) 08 Nov 2009 (e) 10 Nov 2009, and (f) 12 Nov 2009. Error is shown as contours.

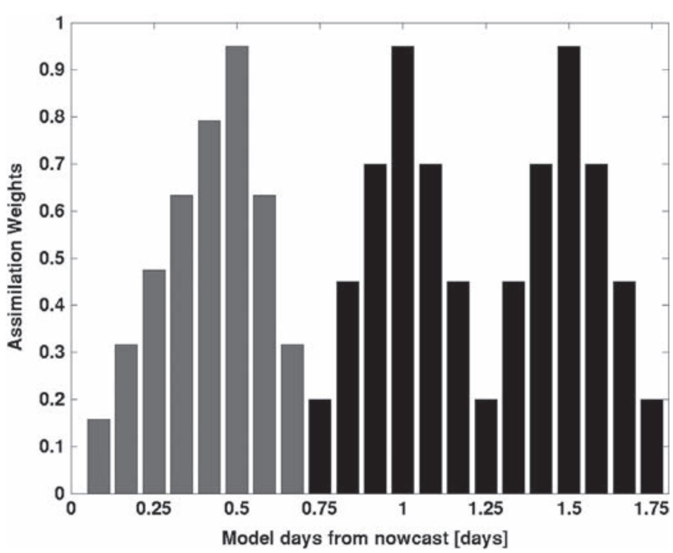

Fig. 5. Assimilation scheme used for SMAST-HOPS 02 Nov 2009 run, showing the weights used for SST (grey), and glider data (black) on the model days. Note that the glider assimilation is repeated with the same cycle as shown here after day 1.75.

It is instructive to analyze the differences between the glider profiles and the objectively analyzed profiles. Overall, the mean rms differences between the OA and glider data for temperature and salinity are comparable for all the gliders at all depths (Fig. 6). The depth-averaged rms difference between OA and the glider for temperature (salinity) at the glider locations for RU05 is 0.275 degree (0.15 psu), for RU21 is 0.22 degree (0.13 psu) and for RU23 is 0.225 degree (0.12 psu). Most of the gliders collected data within 25–30 m depth, while the maximum depth of a particular glider was 63 m.

4. Analysis of post-assimilation fields in forecast mode

This section describes the assimilative forecasts and their analyses in understanding the impact of assimilation from a spatial and temporal footprint perspective.

4.1. Description of assimilative forecasts

The effect of the glider data assimilation on the forecasts is presented next (Figs. 10 –18). In the SMAST-HOPS assimilation strategy, in which glider data is assimilated every 12 h, objectively analyzed fields with appropriate error fields are first computed. The multiscale OA uses the data in the observational window of ± 12 h, and uses the initial field of Nov 2 as the background. This choice of background avoids discontinuities between glider data and climatological background.

Two parallel runs were carried out. Both runs were initialized with the FORMS methodology (SG12). Furthermore, glider data for the initial period of October 26 through Nov 1 were objectively analyzed with the FORMS-derived temperature and salinity fields to produce the reanalysis initial field. The first run was then carried out with satellite-derived SST assimilation only during the first 12 h of simulation for Nov 2 and then continued without further assimilation of glider data (temperature and salinity). This run is designated as "Run1." This run can be described as a run with assimilation of the glider data at initialization.

Another run was done with successive assimilation of temperature and salinity data from gliders RU05, RU21 and RU23.

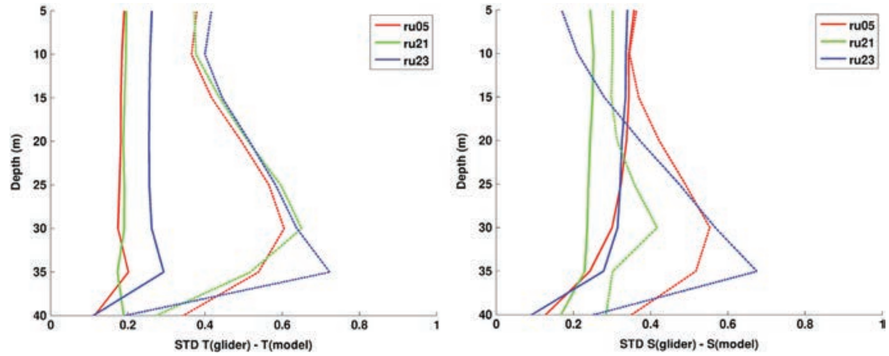

Fig. 6. Glider-OA error at various depths for (left) temperature and (right) salinity. The abscissa is the standard deviation of the difference between the glider data and the OA fields every 12 h.

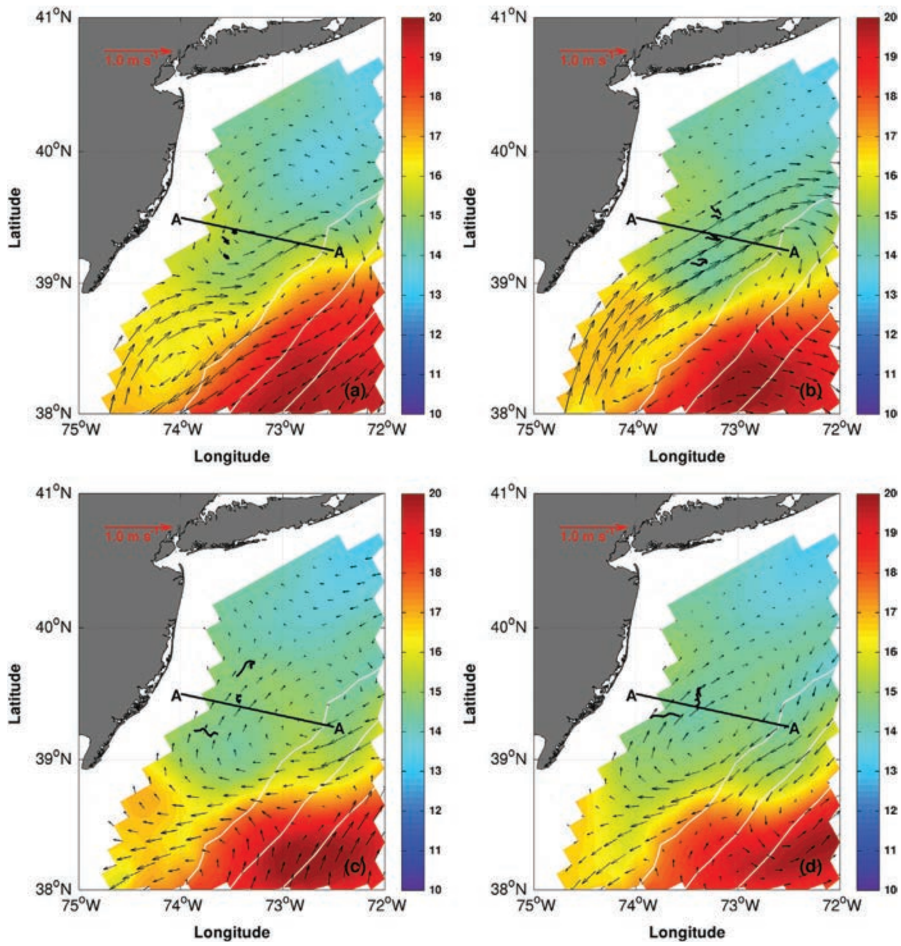

Fig. 7. Twenty-five metre temperature and velocity vectors from 02 Nov 2009 run for (a) 03 Nov 2009, (b) 05 Nov 2009, (c) 07 Nov 2009, and (d) 09 Nov 2009. Solid line A–A shows cross-section region and thick black squiggles show glider positions for data that is assimilated for each day. Temperature in °C.

The satellite-derived SST assimilation methodology is very similar to that described by SG12. Additionally, glider data was assimilated following the methodology described in Section 3. This run is designated as "Run2." Following SG12, the initial field was adjusted for SST assimilation on the first cycle (12 h), which also assimilated the temperature and salinity from the gliders between Oct 26 and Nov 2. The evolution of temperature at 25 m overlaid with velocity for the assimilation run (Run2) for the first week is presented in Fig. 7. The evolution of salinity at 25 m overlaid with velocity for the second week is shown in Fig. 8. The initially weak velocity field develops and adjusts to about 0.1 m s^{-1} of southwestward flow along the shelf between the 50- and 100-m isobaths, while an anticyclonic recirculation develops between 38°N and 39°N (not shown). The weak southward flow to the north of the glider confluence region (Fig. 7) dissipates by Nov 3–5, when a broad northwestward wind-induced flow occurs over the glider region (not shown). During Nov 5–7, the passage of a southwesterly storm was reported. The expansion of glider data assimilation is greatest (in terms of areal coverage) on Nov 7 (Fig. 7). The velocity field adjusts to an

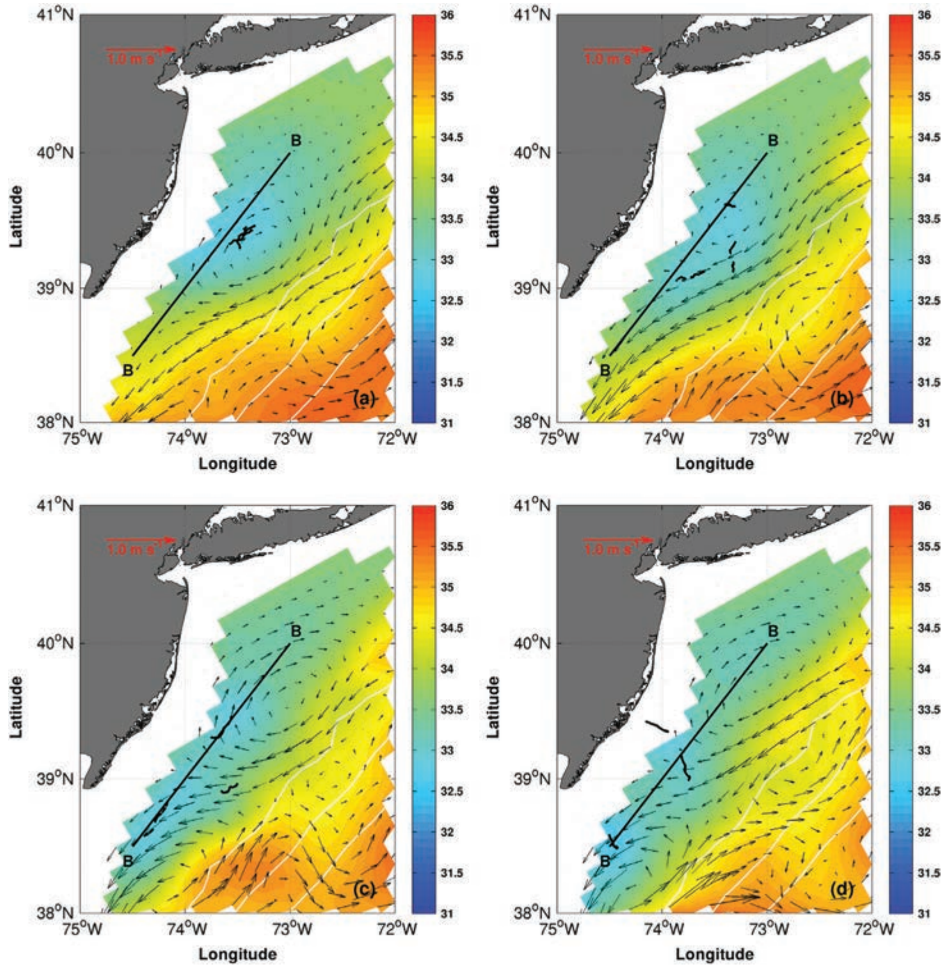

Fig. 8. Twenty-five metre salinity and velocity vectors from 02 Nov 2009 run for (top left) 10 Nov 2009, (top right) 12 Nov 2009, (bottom left) 14 Nov 2009, and (bottom right) 16 Nov 2009. Solid line B–B shows cross-section region, and thick black squiggles show glider positions for data that is assimilated for each day.

anticyclonic eddy-like shelf feature over the glider region (Fig. 7) by Nov 9 to the north of the steady southwestward along-shelf flow.

Fig. 9 shows a sectional view along line AA (Fig. 7) of the evolution of salinity during Nov 3–9. The initial shelf field is dominated by a shallow patch of relatively fresh water (S∼32–33 psu) (Fig. 9a). The contrast between this patch of fresh water and the higher-salinity water from climatological fields creates the salinity front (33–34 psu) between 60 km and 80 km offshore. Most of the glider data assimilated during Nov 3–5 has a uniform vertical profile. As assimilation progressively captures the low-salinity data, the frontal boundary between the near-coastal fresh water and offshore saline water moves gradually offshore and becomes tighter. The salinity front is visible between 80 km and 100 km offshore on Nov 5 and stabilizes at this location (Fig. 9b). The dynamical model shows further relative freshening of the offshore isohalines between 100 km and 150 km offshore during the latter part (Nov 7 through Nov 9) of the simulation (Fig. 9c and d). Note that the Jenifer Clark satellite analysis shows a possible intrusion around an anticyclonic shelf eddy near the glider assimilation region on Nov 6 (Fig. 10). However, in the dynamical model, the eddy was non-existence, as the model was initialized with the canonical shelf-slope front in this region. Thus the climatological signature of the shelf-slope front competes against the freshening and cooling induced by the assimilation of glider observations. Effectively, in the shallow inshore region, the dynamical model develops a weak signature of a fresher and cooler patch on the shelf. Had there been more observations around this area, one would then expect to capture dynamical events like "overrunning" (Kumar et al., 2006), which are deeper and closer to shelf-break.

The evolution of temperature during the week of Nov 2–9 is examined next (Fig. 11a–d) along the cross-shelf section indicated in Fig. 7. Since the SST from satellite images is also assimilated with a vertical projection algorithm, initial contrast between the cooler shelf and warmer offshore water decays rapidly. By day 3 of the assimilation, the temperature range on the shelf (<50 m) reduces to 14–15.3 °C (Fig. 14b and c) from the initial range of 14–16.5 °C (Fig. 11a). The signature of a significant front at about 150–200 km offshore (Fig. 11a) dissipates by day 3.

The weak signature of shelf water intrusion (evident in observation as shown in Fig. 10) across the shelf-break into the slope sea is visible in the temperature field by day 6 and also evident in the day-7 forecast at 60 km offshore (Fig. 11). The center of the simulated anomalous patch is cooler (14.1 °C) than its edges (14.7 °C) (Fig. 11d) at the surface. The patch is also fresher at the core, and the inshore salinity gradient is weaker than its offshore counterpart.

The impact of temperature and salinity assimilation of glider data during the first week is examined next (Figs. 12 and 13) along the north-south section (line *B* of Fig. 8). In the salinity section (Fig. 13a), the far-field impact of assimilation of the three drifters (RU05, RU21 and RU23) is evident in the fresh water signature near the middle of the section, bounded by the

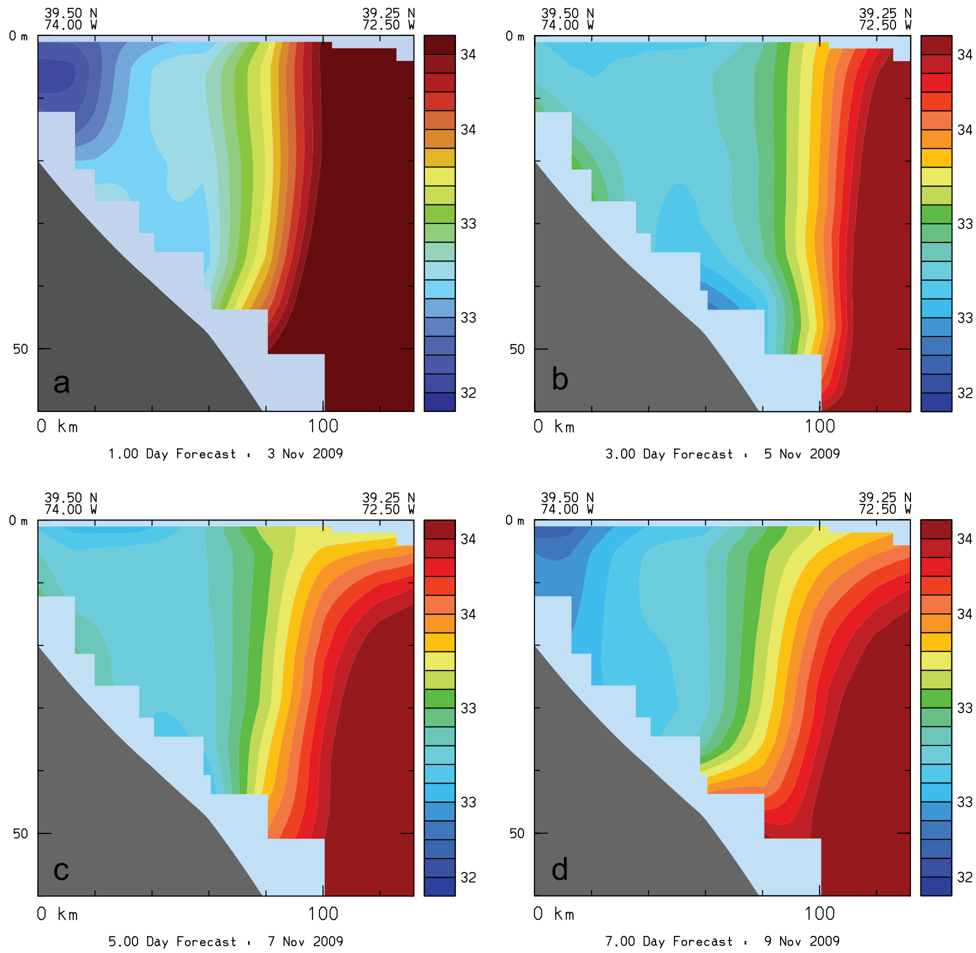

Fig. 9. Salinity cross sectional view of shelf along section line A–A, shown in Fig. 10 for 02 Nov 2009 SMAST-HOPS run with glider assimilation. Panels valid for (a) 03 Nov 2009, (b) 05 Nov 2009, (c) 07 Nov 2009, and (d) 09 Nov 2009.

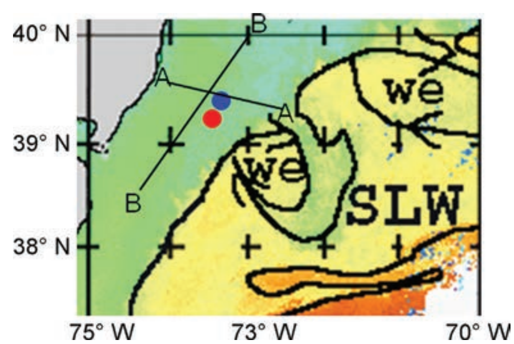

Fig. 10. Possible intrusion of shelf water into the slope during the OSE period. The image analysis is for Nov 6, 2009. Location of glider RU05 (RU23) is shown by the blue (red) dot in upper panel for Nov 6, 2009. The two sectional lines, A–A from Fig. 10, and B–B from Fig. 11, are also shown. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

climatological high-salinity patches. During the first week of the assimilation, the three gliders progressively sample the waters near and along this section, and the waters become fresher and colder due to assimilation. The vertical homogeneity of this assimilated water mass is strikingly different when compared to the unassimilated fields (not shown), which are generally more saline and warmer.

Further evolution of temperature and salinity along the north-south section (shown as B–B in Fig. 8) for the second week is shown in Figs. 14 and 15. This section follows the glider tracks of RU05 and UD134 during the second week of the OSE. Note that while the data from RU05 was assimilated into the model, the data from UD134 was used only for comparing the assimilated model results as an independent validation. The initial high-salinity patches are replaced by realistic fresher water on the shelf through subsequent glider data assimilation within the first week.

The weak signature of the shelf water intrusion across the shelf-break into the slope water, as discussed earlier, is also captured in the forecast fields of temperature (Fig. 14) and salinity (Fig. 15) of day 8 km, 100 km south of the northern end of the section. The subsurface saltier waters to the north and south are due to recirculation generated by the dynamical simulation.

4.2. Time-series comparison of Simulations against glider data

Fig. 16 shows a comparison of time-series of temperature and salinity of the assimilated reanalysis against the three gliders at 25 m. The simulated temperature and salinity profiles of the data-assimilative model are compared with the actual glider profiles at glider locations every half-hour. The assimilation evidently captures the inertial and sub-inertial variability reasonably well (Fig. 16). Difference in the initial 1–2 days between the assimilated simulation and glider data can be attributed to the possible mismatch between the satellite-derived SST (and its extrapolation

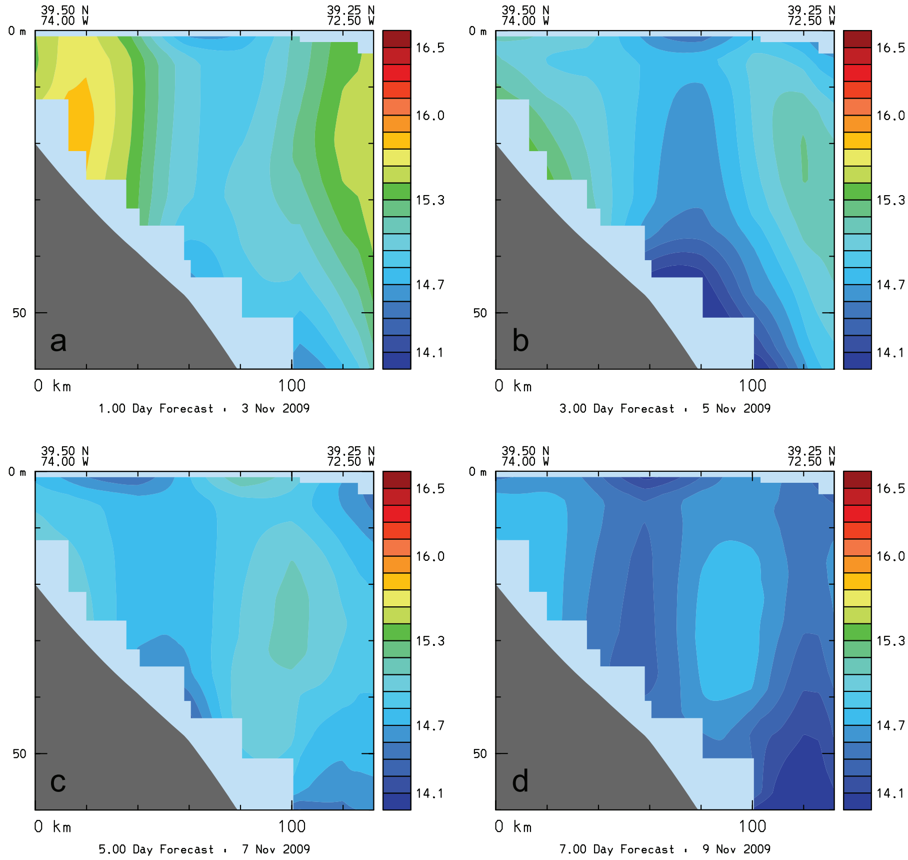

Fig. 11. Temperature cross sectional view of shelf along section line A–A, shown in Fig. 10 for 02 Nov 2009 SMAST-HOPS run with glider assimilation. Panels valid for (a) 03 Nov 2009, (b) 05 Nov 2009, (c) 07 Nov 2009, and (d) 09 Nov 2009.

to depth with a mixed-layer-dependent formulation) and glider temperature (and its vertical uniformity in shallow waters).

Differences between assimilated salinity and glider data can be attributed to the initial mismatch of climatological average salinity with glider data. In all cases, the assimilated temperature and salinity tends to match with glider observations after this initial 1- to 2-day period of internal adjustment (Fig. 16).

Fig. 17 shows a time-series comparison of UD134 data against assimilated forecast at available locations as an independent measure of model skill. The comparison is shown for forecast days 6 and 7. Note that the large biases of the non-assimilated temperature and salinity from the climatology-based shelf initialized run are on the order of 2 °C and 1 psu, respectively. This comparison points to the need for glider assimilation for monitoring the shelf circulation in the Mid-Atlantic Bight region.

The rms differences between the assimilated and non-assimilated runs and the glider data for various depths are shown in Fig. 18. It is apparent that the errors are depth-independent after assimilation. This is probably an artifact of most of the glider data being vertically uniform. However, the depth variation of the unassimilated differences indicates the possibility of assimilation having a bigger impact in the subsurface than at the surface due to glider data. This might be due to the lesser variability at depth than at surface, accentuating the impact of assimilation in the subsurface fields.

However, there are two other ways the glider data could show more impact on the subsurface than on the surface. The first is that SST is being assimilated prior to glider data assimilation, which should make the surface temperature in the model move closer to the glider observation at the surface, leaving the subsurface temperature un-corrected. Thus, the impact of temperature assimilation may seem larger after correction at subsurface (although, not so for salinity correction). Second, the observed Glider profiles for November 2009 depicts a well-mixed, almost-constant profile of temperature and salinity, while the claimtological profiles at these locations, which the model used for initialization had stratification, aka, more subsurface variability. So, after assimilation, the subsurface impact seems larger than that at the surface.

Furthermore, averaged over the two-day (Nov 8–10) time period, the salinity difference between assimilated and non-assimilated runs is about 0.5 psu (Fig. 17b), while the temperature deviation is about 2 °C (Fig. 17a). Since the salinity difference is comparable to the range of assimilation rms (Fig. 18b) of 0.4 ppt, while the SST difference of 2 °C is an order of magnitude higher than the temperature assimilation rms (0.2 °C, Fig. 18a), it is conceivable that salinity assimilation might affect the water column for a longer time period.

4.3. On the temporal and spatial decay of the assimilation footprint

The nature of the decay of the impact of temperature and salinity assimilation is examined next. To determine the temporal decay footprint, we chose two assimilation locations, one offshore (O) and another inshore (I). The OA contours of assimilation errors are presented in Fig. 19a and b, for Nov 6th and 10th, which show the coverage of assimilation for those respective dates. These two locations allowed for tracking the temperature and salinity decay

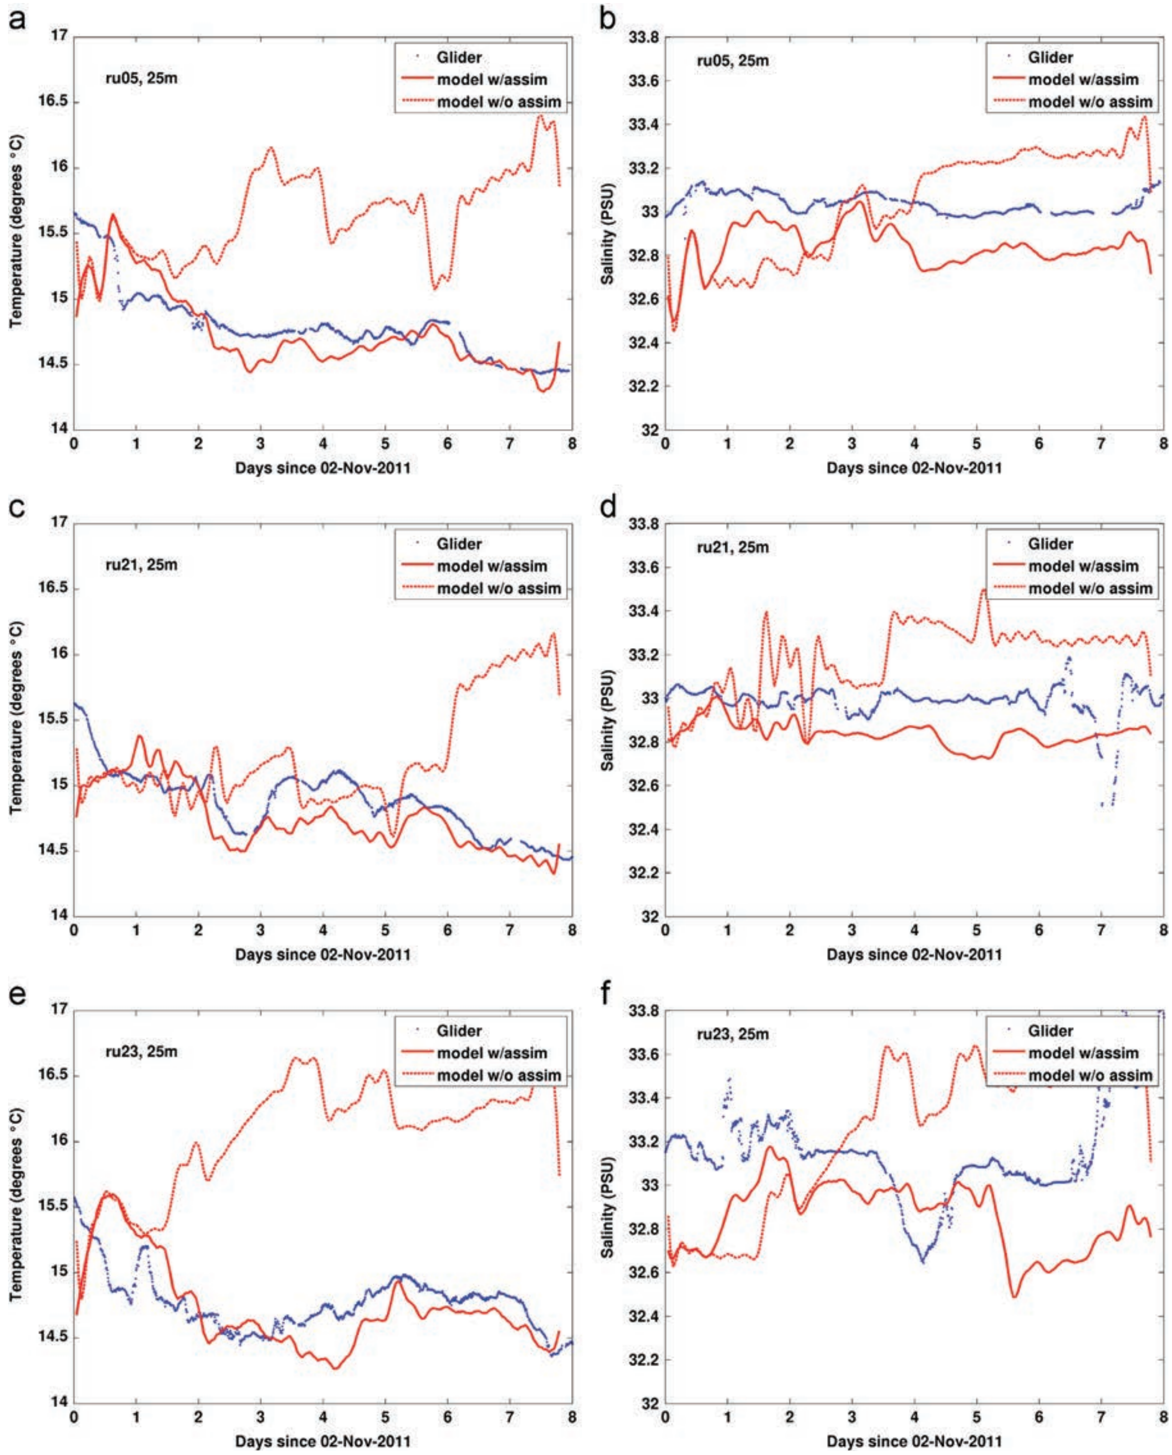

Fig. 16. Twenty-five metre time series of glider (left) temperature and (right) salinity for gliders ((a) and (b)) RU05, ((c) and (d)) RU21, and ((e) and (f)) RU23, compared to the SMAST-HOPS 02 Nov 2009 runs. Glider data are shown with blue dots, the model run with glider assimilation is shown with a solid line, and the model run with no glider assimilation is shown with a dashed line. Temperature in °C, salinity in psu.

scales after the peak of assimilation (marked by arrows in the figures on the error time-series) on Nov 8th for point I (Fig. 19c and e) and after Nov 6th for point O (Fig. 19d and f).

Effectively, there was a single assimilation window of about 2 days for I (Nov 6–8); while for point O, there were two assimilation windows: one for about two days (Nov 4–6) and another also for a different two days (Nov 12–14) at the end of the reanalysis period. The assimilation of satellite-derived SST during the first 12 h, and the ingestion of available glider data at initialization, induced similar impact up to about 0.75 day to both unassimilated and assimilated simulations (Fig. 19c–f). The assimilation during Nov 4–6 then corrects the developing forecast, while the unassimilated forecast behaves differently. After this initial phase, the assimilated temperature takes about

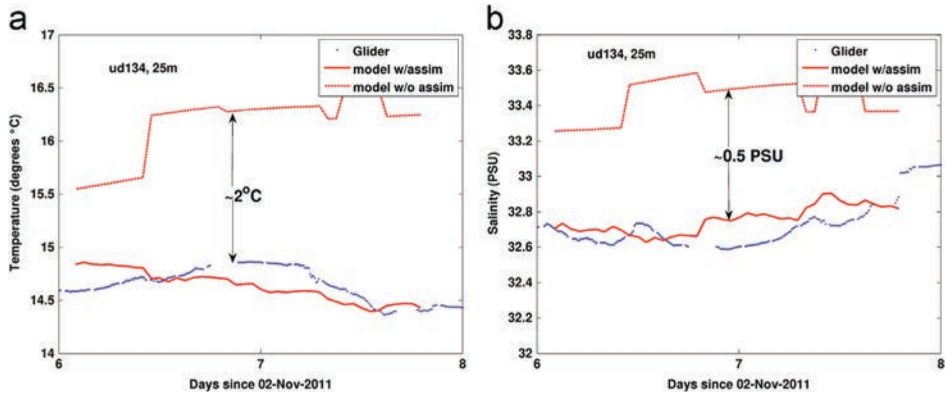

Fig. 17. Twenty-five metre time series of glider UD134 (a) temperature and (b) salinity, compared to the SMAST-HOPS 02 Nov 2009 runs. Glider data are shown with blue dots, the model run with glider assimilation is shown with a solid line, and the model run with no glider assimilation is shown with a dashed line. Temperature in °C, salinity in psu. Note the difference between assimilation and non-assimilation runs for temperature is about 2 °C; while that for salinity is about 0.5 psu.

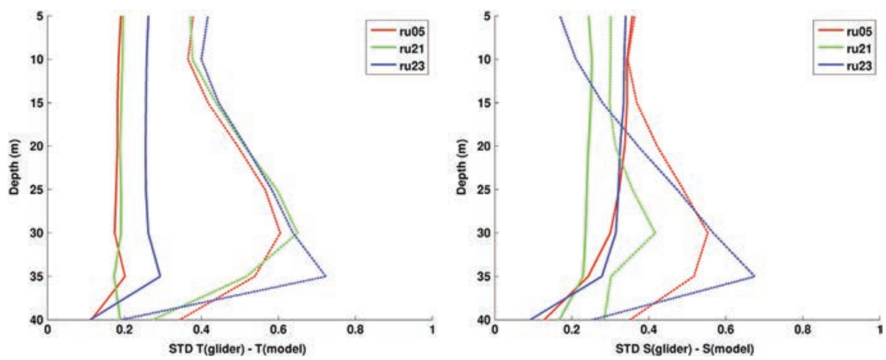

Fig. 18. Glider-model error at various depths for (left) temperature and (right) salinity. The abscissa is the standard deviation of the difference between the glider and the model. The solid lines represent differences between the gliders and the model run with glider assimilation; the dashed lines represent differences between the gliders and the model run with no assimilation. For both types of model runs, the gliders were used for the initial field.

1–2 days to degrade to the levels of non-assimilated run, while salinity takes 3–4 days for point I and about 2 days for point O. The temperature decay time-scales are similar to those (1–1.5 days) obtained for Monterey Bay by Shulman et al. (2009).

Two interesting results are clear from Fig. 19. First, after the assimilation is over, the salinity tends to approach back to the unassimilated value in time, while the temperature settles to a new threshold level and follows the behavior of the unassimilated temperature simulation. Second, the larger the difference between the unassimilated simulation and observation (at the beginning of the assimilation), the longer it takes for the tracer to approach the unassimilated behavior and/or the value itself. Note that we also found these two results to be depth-independent.

The spatial scales of decay for the impact of assimilation are investigated next. Three points (South—S; Middle—M; and North—N) were chosen along one transect through the glider array (Fig. 2) for the spatial decay experiment. The daily difference in temperature field between the runs with and without assimilation is presented in Fig. 20a. Greater difference at the time of assimilation indicates greater impact. Persistence of the initial difference over time beyond the point at which assimilation is discontinued would imply a prolonged impact of assimilation. It is clear from Fig. 20a that the temperature impact decays significantly within the first 2–4 days for all points (S, M, and N), and that the amplitude of the impact decreases with distance from the glider location (point of assimilation). The salinity impact does not show such drastic decay (Fig. 20c) at these locations. The spatial decay scale for the temperature is obtained from Fig. 20a, where the difference in temperature (assimilation vs. non-assimilation) is examined as a function of distance from the assimilation location for two consecutive days (days 3 and 4) after the assimilation is over on day 1.

The exponential nature of the spatial decay of temperature impact from the center of assimilation outward is evident for all days (other days not shown). The e-folding impact scale is determined to be about 100 km for the third day, and about 60 km for the fourth day. In contrast, the salinity signal does not show any preferential decay pattern (Fig. 20d). The salinity difference fluctuates within a narrow range around the initial difference for day 3, and stays almost same for day 4. No consistence spatial-decay pattern for salinity was found in these three locations.

The above differences in the temperature and salinity behavior beget the idea of using different decorrelation parameters for objective analysis of temperature and salt information for assimilation. For example, different decorrelation scales for temperature and salinity error covariance computation were used (Reinicker et al., 2011) by the Global Modeling and Assimilation Office (GMAO) at the NASA/Goddard Space Flight Center for ocean initialization for seasonal-to-interannual climate prediction efforts (http://gmao.gsfc.nasa.gov/research/ocean; Keppenne et al., 2005; Sun et al., 2007). Typically, temperature decorrelation scales (20° zonal, 8° meridional and 100 m in the vertical) are larger than those for salinity (8° zonal, 3° meridional and 40 m in the vertical). Our results indicate similar

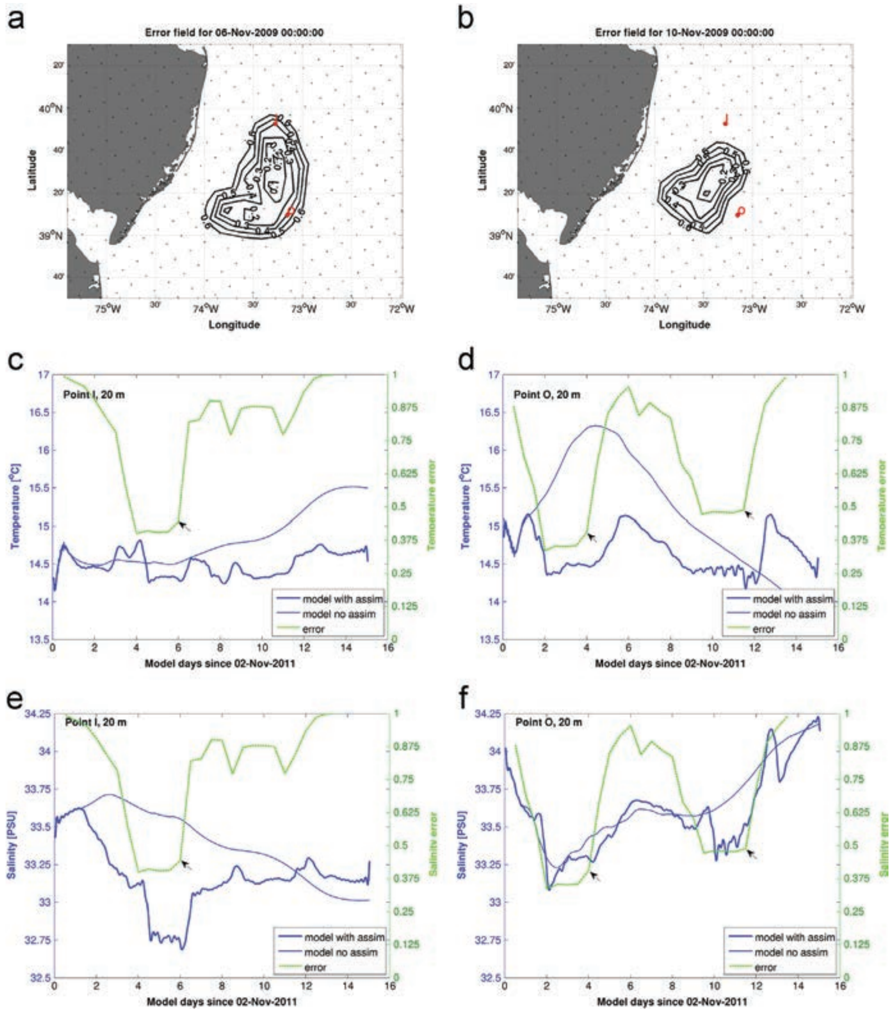

Fig. 19. Temporal behavior of temperature and salinity after assimilation. The error maps of OA fields (T, S) are shown for 4th Nov in (a) and for 10th Nov in (b). The simulation time-series with and without assimilation are shown for temperature at point I and point O are shown in the middle panels ((c) and (d)). Superimposed is the time-series of the error at these locations in dash-line. Similarly, the bottom panels show the salinity fields at these locations. The black arrow in the middle and bottom panels identifies the end of the assimilation period at each location.

qualitative differences in spatial impact of assimilation between temperature and salinity might also exist in the shelf region, albeit at a finer-scale (10s of kilometers for the shelf as opposed to 100s of kilometers for the global models).

5. Summary and discussion

This study presented an application of the SMAST-HOPS real-time forecast system developed for the western North Atlantic during the OOI–CI OSE period (Oct 26–Nov 17, 2009). The ring and front analysis from satellite imagery is used to feed into the feature modeling scheme for generating a three-dimensional initial field. The initialization field is dynamically adjusted with wind-forcing and used in an SST-glider-assimilative (temperature- and salinity-assimilative) forecast model. The model was forced by atmospheric fields from the global forecast system in real time. The forecast fields were made available via a THREDDS data server for easy and efficient extraction by scientists and application developers for glider planning, control and guidance.

The feature-based initialization scheme was utilized for 4 short-term forecasts of varying lengths during the first two weeks of November 2009 in an ensemble mode with other forecasts to guide glider control. A reanalysis was then carried out, assimilating the data from three gliders (RU05, RU21 and RU23) for the two-week period. Results are first compared against data from these three gliders, and then against the independent data from the other glider, UD134. Results from the assimilation are also analyzed to evaluate the impact of glider data and sensitivity of model forecasts to data assimilation. The assimilation of salinity improved the model performance in the area around the data and impacted the subsurface fields. An interesting result was that assimilating (or infusing) the available glider data at initialization enabled the model to smoothly absorb and adjust subsequent cycles of assimilation of patchy glider data.

The glider data assimilation led to a depth-averaged model-data difference of 2 °C for temperature and 0.5 psu for salinity for the upper 25 m of the Mid-Atlantic shelf. A sensitivity analysis was carried out to determine the short-term memory of the simulated ocean. The forecast fields retained assimilated temperature information for about 1–2 days. No coherent pattern for temporal decay of salinity was determined with its range varying from 1–4 days at different locations. However, significant differences in their patterns of behavior after assimilation were clearly observed.

It is interesting to note that the short-term retention period (of temperature and salinity impact) might be increased by

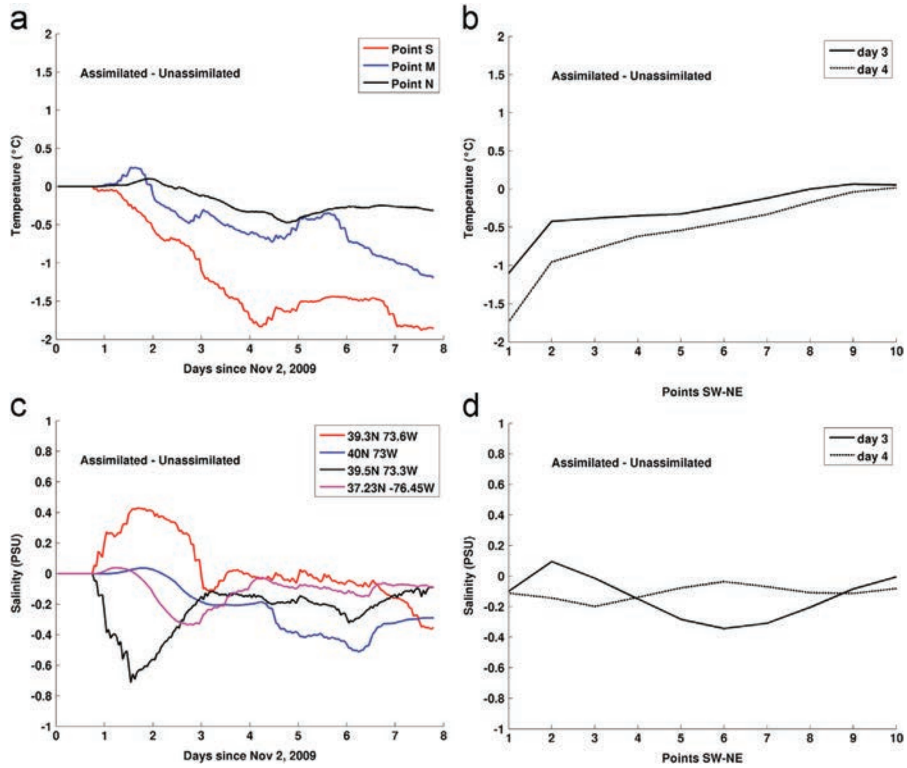

Fig. 20. (a) The temperature difference between the runs with and without assimilation at the three locations (S, M and N) as time progresses after assimilation on Nov 02, 2009 at point S; (b) the temperature difference for days 3 and 4 away from the assimilation point S as shown in Fig. 5; (c) similar to (a), but for salinity; (d) similar to (b), but for salinity.

increasing the model resolution in the horizontal and vertical. While increasing the resolution will result in resolving more features (effectively adding more wave numbers and reducing the de-correlation scales); the underlying OI assimilation scheme brings high-resolution assimilation (correction) fields, because the observations are mapped on the model grid prior to assimilation. Such sensitivity/competition studies would be carried out in future studies. Our results on temporal decay (1–3 days) of temperature after assimilation are consistent with those (1–1.5 days) found by Shulman et al. (2009) for the Monterey Bay region.

It is intriguing to also note that one would expect a sizeable difference in the decay scales of temperature and salinity linked to the underlying real (molecular) diffusivity of the variables. In reality, the short-term temporal memory of the ocean could be thought to be inversely proportional to the diffusivity of the tracer. For example, due to its slower diffusivity, the retention period of assimilated salinity signature may be longer than that of the temperature. Similarly, the spatial footprint of the impact could be directly proportional to the diffusivity. Consequently, the spatial decay scale for assimilated temperature would be larger than that of the assimilated salinity signal (consistent with Reinicker et al. 2010 for GMOA). However, most of the dynamical models (including the present one used here) employ the same numerical diffusivity for the prognostic runs, which might or might not be appropriate for both tracers. More sensitivity experiments would be necessary to further quantify and understand such differences between the temperature and salinity response after assimilation.

The impact analyses presented before clearly shows that there exists certain differences in the spatial and temporal influence windows (scales, footprints) after assimilation for the two tracers, temperature and salinity. These new results open up the possibility of developing new assimilation algorithms which might be similar to the new developments of the EnKF, where variables maintaining two different scales are assimilated in a combined scheme (Ballabrera-Poy et al., 2009). The ideas of scale-preserving assimilation (Lorenc, 2003; Kalnay et al., 2007) and of 'variable localization' for constructing covariance matrix in EnKF (Kang et al., 2011) seem worth investigating in this context of multiple tracers. Specifically, temperature and salinity could be the oceanic proxies for the temperature and carbon (and/or humidity) in the atmospheric models and these new assimilation techniques.

These differences in impact of assimilation of temperature and salinity data and their possible link to the real-ocean diffusion of heat and salt also points to another area of research. Typical large-scale models (Navy's coastal ocean model, hybrid co-ordinate ocean model, regional ocean modeling system, modular ocean model, etc.) use the same diffusivity for both tracers for most applications. Systematic studies with different diffusivities for different tracers in regional modeling exercises in coastal regions such as the Mid-Atlantic shelf might lead to better understanding of processes and better forecasting capabilities for the many operational observing systems.

Based on the sensitivity analysis, a phased-assimilation strategy to assimilate both satellite SST and glider data with different weighting functions for temperature and salinity can probably be developed. For example, while 2-day composite satellite-derived SST fields can be assimilated every two days, individual glider data could be assimilated every day with a 12-h weighting function. However, if salinity data can be retained by the simulated ocean for a longer period of time, independent salinity observations, or satellite-derived chlorophyll-inferred seas surface salinity can be assimilated with different weighting function (yet-to-be-determined) on a different assimilation cycle. Another example would be of designing a phased observation-assimilation scheme, in which XBT observations will be assimilated frequently to supplement SST fields to realize the subsurface thermal structure, while XCTD observations will be sampled and assimilated more sparsely to match and allow for larger retention period of salinity. In the near future, such a system of "phased assimilation" of satellite SST, sea surface color (SSC), glider data and other in-situ observations could be built for monitoring the changes of the water masses in the Mid-Atlantic more efficiently, economically, and knowledgeably.

Acknowledgements

This real-time forecast system has been made possible due to many years of research at Harvard University, UMass Dartmouth, MIT and other institutions by many researchers. We appreciate all of their past efforts and current support. Special thanks are due to our colleagues at MIT who are supporting our efforts with the software and analysis packages. Funding was made available from the Office of Naval Research (ONR) MURI program (N000140610739), the National Aeronautics and Space Administration (NASA), the National Oceanic and Atmospheric Administration (NOAA) and the National Science Foundation (NSF) at different times to different PIs at different institutions. We acknowledge all their efforts and support. Current funding from NOAA under IOOS for MARACOOS and the support of the MACOORA group are gratefully acknowledged. We appreciate the efforts of Applied Science Associates and the Rutgers group for making the glider data available in a format for easy analysis. Our special thanks to Dr. Wendell Brown for his insight in implementing an earlier version of the model system and many discussions in-house on the OSE–Glider-modeling exercises. We appreciate the help, support and guidance of Drs. Scott Glenn, Bill Boicort and the entire MARACOOS group during the OSE. Special thanks to John Kerfoot for his work in making the glider data available in real-time. We thank the other five modeling teams from Rutgers (John Wilkin and his group), Stevens (Alan Blumberg and his group), JPL (Yi Chao and his group), MIT (Pierre Lermusiaux and his group) and USGS (Rich Signell, John Warner and their group), with whom we participated in the OSE real-time ensemble exercises. We wish to acknowledge the invaluable experience gathered during the OOI–CI–OSE on the infrastructure issues of real-time forecasting from the interactions with the JPL, UCSD and the larger CI team. We are appreciative of the help provided by Mr. Frank Smith at SMAST with editing this manuscript.

Our sincere thanks to the reviewers and the editors of this special issue for their comments, patience and support during the revision of this manuscript, which helped clarify many details.

Letting Penguins Lead: Dynamic Modeling of Penguin Locations Guides Autonomous Robotic Sampling

BY MATTHEW J. OLIVER, MARK A. MOLINE, IAN ROBBINS, WILLIAM FRASER, DONNA PATTERSON, AND OSCAR SCHOFIELD

The southwest coast of Anvers Island harbors one of five major populations of Adélie penguins in the West Antarctic Peninsula (WAP; Fraser and Trivelpiece, 1996). This "hotspot" is colocated with a submarine canyon that provides a conduit for warm, nutrient-rich Upper Circumpolar Deep Water to stimulate primary production and support a productive ecosystem (Prézelin et al., 2004). Paleoecological evidence shows Adélie penguins (*Pygoscelis adeliae*) have used this location for hundreds of years (Emslie et al., 1998). Since the mid- to late twentieth century, the Southern Ocean near the WAP has warmed significantly (Gille, 2002) and has lost significant sea ice (Stammerjohn et al., 2008). The maritime climate of the northern WAP has shifted poleward, replacing the cold continental Antarctic climate in the Anvers Island region. During this time period, there has been an 80% decrease in the sea ice dependent Adélie penguin populations and an introduction and increase of Gentoo penguins (*P. papua*; Ducklow et al., 2007). Sympatry of Adélie and Gentoo penguins during the breeding season is new to this coast, and it not known if these species will continue to coexist or if the Gentoos will supplant the Adélies. The stability of this new species interaction depends on how well each species is able to exploit the coastal ecosystem. It may be that while submarine canyons offer predictable prey populations, different foraging strategies may allow Gentoos better access to existing prey (krill and fish) populations relative to Adélies. This situation is difficult to assess because penguins are dynamic predators that rapidly forage for krill and fish across a heterogeneous and complex coastal ocean.

In January 2011, we implemented a nested and flexible sampling network to measure the physical and biological features of penguin foraging locations. We coupled 13 satellite-tagged Adélie and seven satellite-tagged Gentoo penguins with multiple deployments of a buoyancy-driven Slocum glider and a propeller-driven REMUS-100 (Figure 1A). When tags, autonomous underwater vehicles (AUVs), and global communications are combined, it is possible to sample the polar ocean as the penguins experience it. However, these robotic assets still require guidance for coordinated sampling strategies (Kahl et al., 2010). In a novel approach, we fused AUVs with satellite-tagged penguins, thus providing a means for seabird top predators to provide the ecological guidance needed to optimize sampling of robotic networks.

The core Adélie and Gentoo penguin foraging regions from Humble Island and Biscoe Point are near the submarine canyon (Figure 1a). We sampled historic penguin foraging locations according to AUV capabilities. The Slocum glider can maintain continued in-water presence for 30 days (Schofield et al., 2007). Therefore, we used the Slocum glider to map larger-scale oceanographic features over the canyon and to gather multiday time series of currents, temperature, salinity, oxygen, and optics. The REMUS-100 mimics the endurance (8–12 hrs), speed (~ 2.5 m s^{-1}), and depth range (0–75 m) of the foraging penguins, and was therefore used to sample temperature, salinity, optics, and acoustic krill densities in the shallow area of the core penguin foraging regions (Figure 1a).

The main feature of our sampling design is that it allowed us to react quickly to new penguin foraging locations. The new locations were relayed via the Argos satellite system to our team in Palmer Station. We then implemented a time-resolved utilization distribution kernel (Keating and Cherry, 2009) with bandwidths corresponding to the location errors of our Argos penguin positions to map likely foraging habitats at hourly resolution. The result was a multispecies dynamic probability map of penguin foraging locations that could be opportunistically targeted by both the Slocum glider and the REMUS-100 AUVs (Figure 1b). The dynamic foraging map enabled creation of a real-time adaptive sampling plan for the penguin foraging locations. Our team of seabird ecologists and oceanographers could change the mission of the AUVs to intersect the penguin foraging locations in order to sample them at high resolution. The fusion of seabird tracking and AUV guidance through the modeling of near-real-time distributions allows researchers to target critical sampling assets to understand the complex interactions between these species and to provide insight on how penguins access their environment in a changing climate.

These efforts were only possible with funding support provided by the NASA Biodiversity program (NNG06GH75G1/3 to M. Oliver), the NSF Office of Polar Programs (ANT-0823101 to PI Ducklow and Co-PI Schofield; ANT-1019839 to M. Moline), and the Gordon and Betty Moore Foundation. We thank the Palmer Station support staff for facilitating our data collection efforts. We also wish to thank Kaycee Coleman for AUV deployment support, Jennifer Blum, Marc Travers, and Kelsey Ducklow for penguin field support, and Dave Aragon and John Kerfoot for remote AUV control.

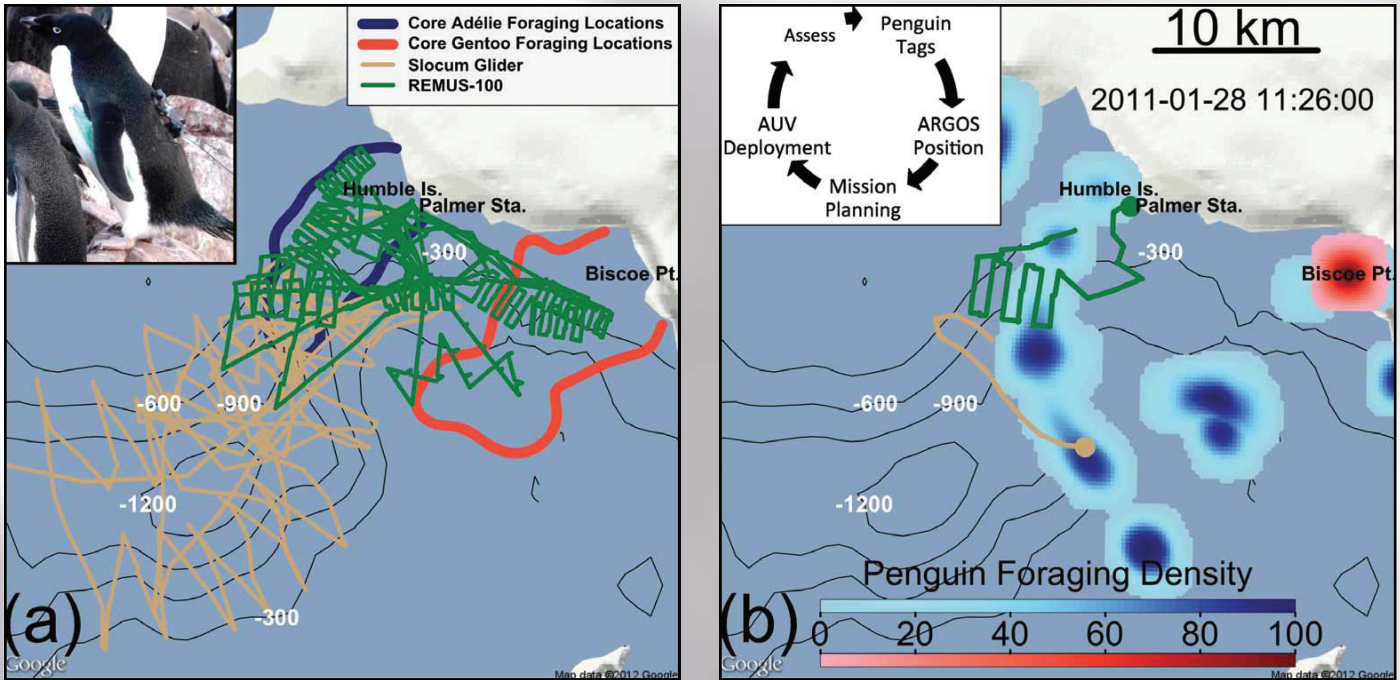

Figure 1. Adélie and Gentoo penguin colonies are located at Humble Island and Biscoe Point near Palmer Station on the south coast of Anvers Island. (a) The thick contours show the historic foraging locations of tagged Adélie (blue) and Gentoo (red) penguins. The inset is an Adélie penguin carrying a satellite tag. The regions around these contours were continually sampled by Slocum glider (tan) and REMUS-100 (green) autonomous underwater vehicles (AUVs). (b) During our experiment, real-time, species-specific foraging density maps based on penguin locations allowed us to intersect our AUVs with these foraging regions. On January 28 at 11:26:00 GMT, the Slocum glider and REMUS-100 intersected an Adélie penguin foraging location (blue). Tagged Gentoo penguins (red) are close to their colony on Biscoe Point at this time.

Impact of Ocean Observations on Hurricane Forecasts in the Mid-Atlantic

Forecasting Lessons Learned from Hurricane Irene

Abstract—**Hurricane Irene followed a track that curved northward over the Bahamas and ran directly over the U.S. east coast from Cape Hatteras to New England in August of 2011, causing severe storm surges, intense inland flooding, loss of life and over $8 billon in storm damage. While the ensemble of atmospheric forecast models accurately predicted the hurricane timing and track, the hurricane intensity was consistently over-predicted. Data from the U.S. Integrated Ocean Observing System (IOOS) were used to better understand the potential impact of the Mid-Atlantic Bight's coastal ocean on the Hurricane Irene intensity forecast.**

I. Introduction

The Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS), one of eleven Regional Associations comprising the regional component of the U.S. Integrated Ocean Observing System (IOOS), operates a Regional-Scale Coastal Ocean Observatory that includes coastal weather mesonets, satellite data ground stations, a 1000 km long High Frequency (HF) Radar network (Roarty et al., 2010), and a distributed fleet of autonomous underwater gliders (Schofield et al., 2010). The Regional-Scale Coastal Ocean Observatory was fully operating when Hurricane Irene (Fig. 1) tracked along the U.S. East Coast over Labor Day weekend in 2011 (Glenn et al, 2011). Irene was the first hurricane to threaten New York City since Gloria in 1985. Intense rain from Irene broke flooding records on 26 rivers, causing at least 56 deaths and $8 billion in property damage. Power outages along the flood path lasted from days to weeks.

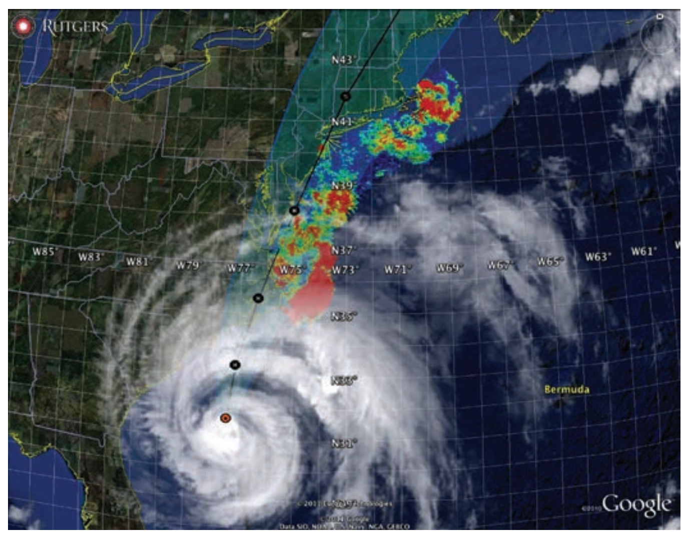

Fig. 1. Hurricane Irene in the South Atlantic Bight and forecast track as it approaches the Mid-Atlantic Regional HF Radar network.

Forecasts of Hurricane Irene's track (Fig. 1) derived by the National Hurricane Center (NHC) from the ensemble of forecast models were highly accurate. Surprisingly, much less damage than expected was caused by the hurricane winds, waves and storm surge along the beach. One reason for this was the consistent overestimate of Irene's intensity by the ensemble of atmospheric forecast models (Fig. 2). This led to numerous newspaper articles and television reports publicly reaffirming that "Intensity remains a big gap in storm science".

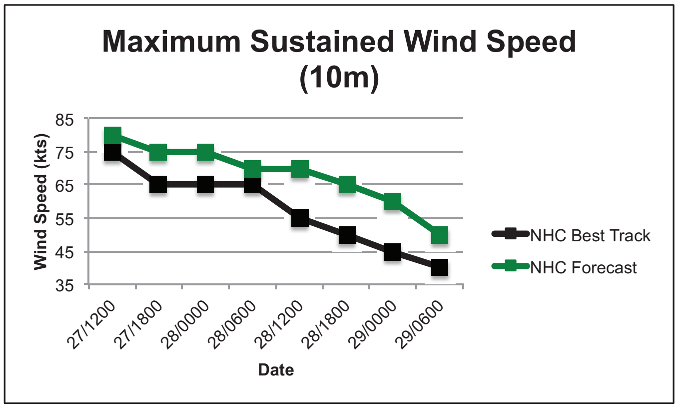

Fig. 2. Maximum sustained wind forecast (green) and best track reanalysis (black) showing the forecast overestimate of Irene's intensity.

In this paper, we discuss selected highlights of real-time ocean data acquired by the MARACOOS regional-scale network during Irene. Through a series of atmospheric model sensitivity studies, the potential impact of real-time ocean data on hurricane intensity forecasts in the Mid-Atlantic is demonstrated.

II. HF Radar Observations

The MARACOOS HF Radar network captured the shelf-wide surface current response to the intense hurricane forcing at the spatial scale of the storm. The direct wind forcing includes a rapid shift from intense onshore, to alongshore, and finally to offshore currents over the time scale of a day (Fig 3). As the eye of Hurricane Irene enters the Mid Atlantic Bight (MAB) on August 27 at 17:00 GMT, strong winds from offshore that precede the eye are forcing onshore currents and increasing the storm surge over much of the southern MAB (Fig 3a). Fifteen hours later on August 28 at 8:00 GMT, the eye of Hurricane Irene is offshore Delaware Bay, and the outer edge on the northeast side is reaching Cape Cod. Currents in the northern portion of the MAB are onshore, currents in the middle are alongshore, and currents in the southern portion have switched to offshore. By 14:00 GMT on August 28, the eye of Irene passes over New York City and the storm heads inland. Surface currents directly east of the eye are now onshore, and surface currents on the trailing side of the storm in the southern MAB are now diminishing and are beginning to turn in inertial circles.

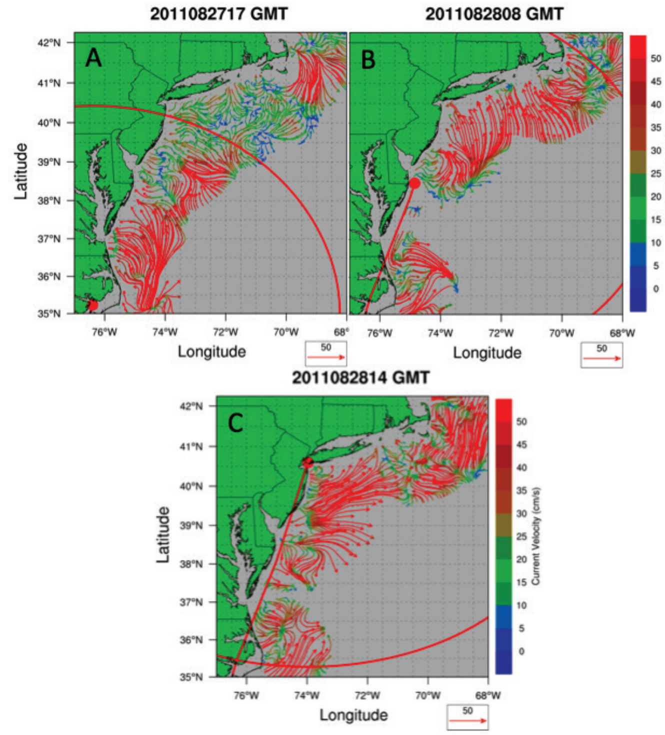

Fig. 3. Surface current response due to Hurricane Irene winds as (a) the eye enters the MAB near Cape Hatteras, (b) the eye crosses Delaware Bay, and (c) as the eye crosses over New York City and heads inland.

Observations of the lingering inertial current response to hurricanes are numerous in deepwater. Kohut et al. (200?) found the inertial response to Tropical Storm Floyd was quickly diminished in very shallow water as the stratification was eroded. The MAB HF Radar network provides the first look at the inertial tail of a hurricane over the full scale of the MAB shelf over a range of water depths and stratification. Starting with a single point at midshelf where an autonomous underwater glider was located (see Section III), a time series of the observed total currents along with the inertial component of the current derived from a least-squares fit to the current data is plotted for a 1 week period starting on August 26 before Hurricane Irene entered the MAB (Fig. 4). The peak in the direct wind forcing occurs on the scale of 1 day on August 28 (Fig. 4, top). The amplitude of the inertial component of the current (Fig. 4, bottom) increases until it peaks on August 29 as the back side of the storm crosses onto land in New England and New York. The inertial amplitude remains high for much of the day on August 29, then slowly decays at a linear rate over several days from August 29 through September 1.

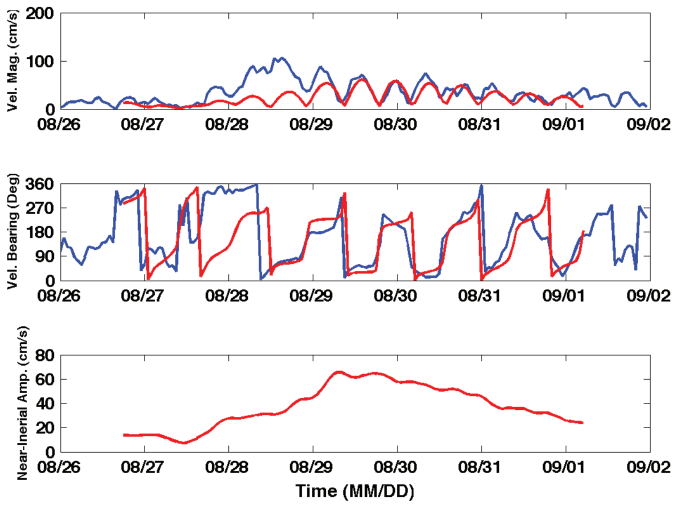

Fig. 4. Time series of total current (blue) and near-inertial current (red) calculated for a point on the outer shelf of NJ.

Spatial maps of the energy content in the diurnal and near-inertial frequency bands derived from a wavelet analysis of the surface currents are shown in Fig. 5. As the eye of Hurricane Irene moves into southern New England (Fig. 5a), the large amount of energy in both the diurnal and near-inertial frequency bands on the outer half of the shelf in the central MAB is visible. Two days later (Fig. 5b), the energy level in the diurnal band is reduced over the full MAB, while the energy in the near-inertial band persists.

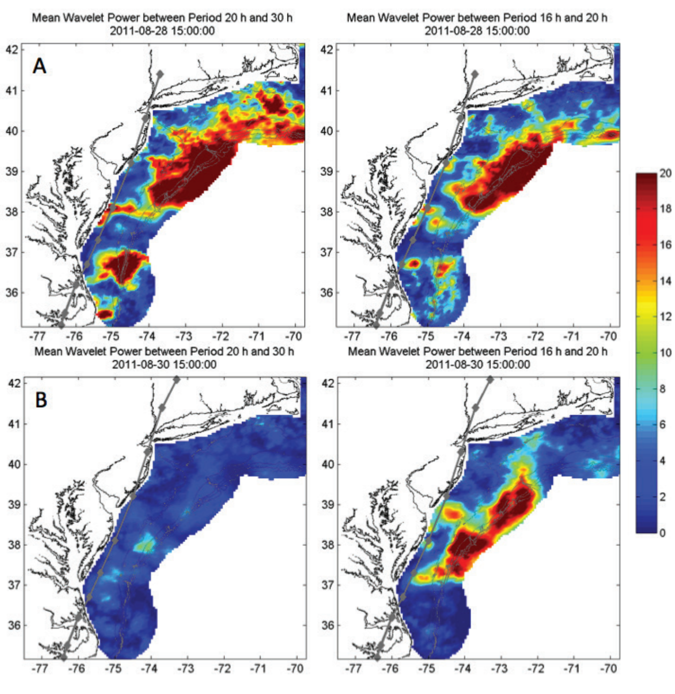

Fig. 5. Spatial maps of the diurnal (left) and near-inertial energy (right) as (a) the eye passes over NJ, and (b) 2 days later.

III. Glider Observations

Two autonomous underwater gliders were operating in the MAB when Hurricane Irene transited the region (Fig. 6). RU23 was deployed on a regional MARACOOS mission by UMass Dartmouth to map the subsurface temperature and salinity structure of the MAB during the decay phase of the Cold Pool to support ocean modeling activities for fisheries applications. RU23 was damaged early in the storm and was purposely kept at the surface through the storm to prevent its loss. Its track as a surface drifter illustrates the combination of the initial direct and persistent inertial forcing. RU23 was recovered after the storm by a sport-fishing vessel before it entered the shipping lanes as a drifter. RU16 was deployed on a New Jersey state mission to monitor dissolved oxygen concentrations for the Environmental Protection Agency. As Irene approached, RU16 was moved offshore to a mid-shelf point where it rode out the storm. This glider provides information on the magnitude and timing of the subsurface mixing that occurred during Irene.

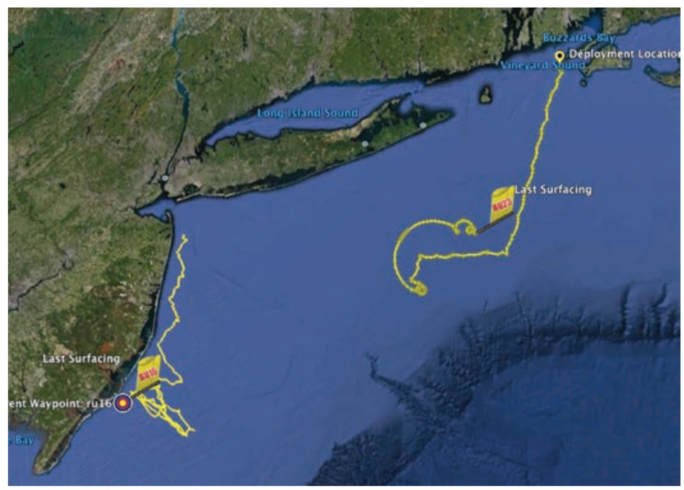

Fig. 6. Tracks for Gliders RU23 (deployed from Martha's Vineyard by UMass) and RU16 (deployed from New York Harbor by Rutgers).

The vertical sections of temperature, salinity and dissolved oxygen from the full RU16 EPA deployment are shown in Fig. 7. Initially in the deployment, as RU16 zig-zags along the New Jersey coast, the T,S and DO profiles illustrate the two distinct surface and bottom layers with the sharp interface typical of the New Jersey shelf in summertime. The surface layer is warmed by the sun, freshened by the riverine outflows from the MAB watersheds, and is oxygenated through its atmospheric interface. The bottom layer is known as the Cold Pool. It is what remains of the cold and salty winter water slowly flowing to the south along the shelf. Isolated from the surface waters by an intense pycnocline that inhibits mixing, dissolved oxygen values in the lower layer often plummet to values that can stress or even kill benthic organisms.

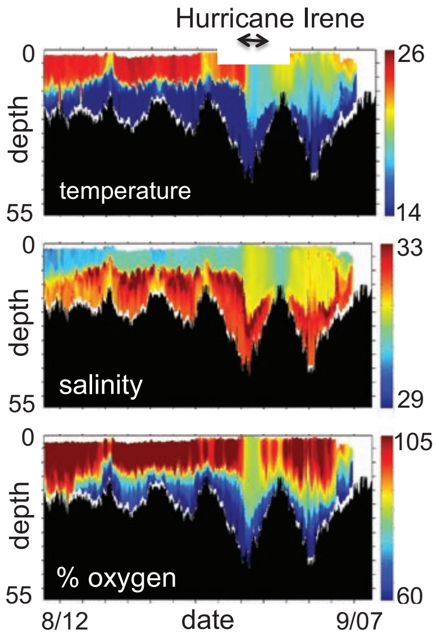

Fig. 7. Temperature, Salinity and Dissolved Oxygen sections from the full deployment of RU16.

Fig. 7 further illustrates the significant impact of Irene on the T, S and DO structure as it passes over the glider on August 28. The response is rapid. The interface between the two layers deepens and the surface layer gets cooler and saltier while the dissolved oxygen level decreases. Oxygen levels in the upper layer quickly recover after the storm, but the surface layer temperature never returns to its summertime pre-storm values. Zooming into the storm mixing period in the temperature section (Fig. 8), the transition from pre-storm to post-storm conditions occurs during the short time period between 00:00 GMT and 14:00 GMT as the eye of Irene passes the glider on August 28.

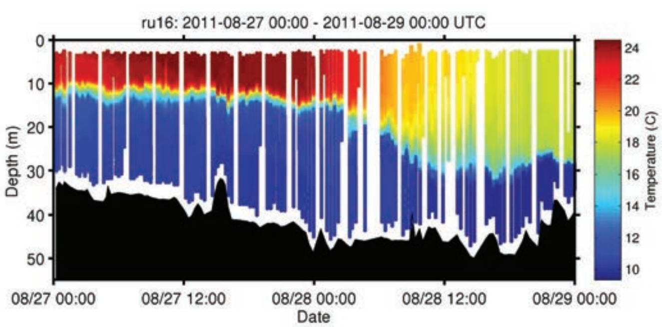

Fig. 8. Detailed plot of the temperature section showing the rapid mixing and cooling of the surface layer that occurred during Irene.

IV. Satellite Observations

V. Atmospheric forecasts over oceanic domains require a boundary condition for sea surface temperature. Numerous sea surface temperature products from a variety of sources are available for this purpose. The major difference between the products is how the cold pixels contaminated by clouds are removed and the resulting data gaps filled. Most commonly used methods include warmest pixel composites that combine multiple images in time, or by interpolating in space across pixels flagged as clouds.

VI. The existing product used to forecast Hurricane Irene's transit through the region is the Real-Time Global High Resolution Sea Surface Temperature product shown (Fig. 9a). For this product, the mixing that occurs during Hurricane Irene is not picked up by this product for several days after Irene left the region.

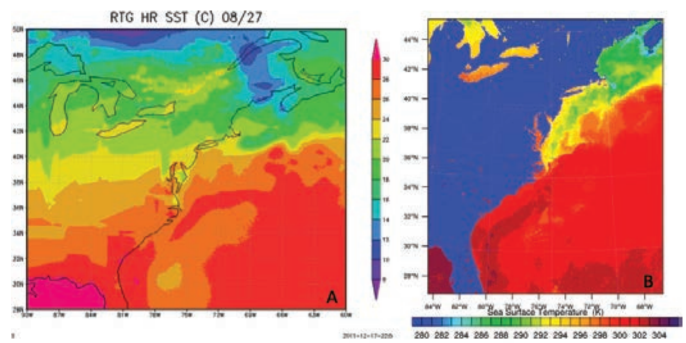

Fig. 9. Sea surface temperature maps (a) used in real time weather forecasts and (b) observed immediately after the clouds cleared from Irene.

To explore the impact of surface cooling during Irene, a new satellite SST product was produced that does not rely on warmest pixel compositing to remove clouds. Instead, daytime images of sea surface temperature where checked for their reflectivity in the visible part of the spectrum. High reflectivity pixels were flagged as clouds, and cooler pixels with low reflectivity were considered ocean pixels cooled by the storm. Retaining these cold but dark pixels observed after the storm produces the image in Fig. 9b. Significant cooling of order 5C-8C is observed on the MAB shelf, with the greatest cooling occurring in the middle of the shelf above the core of the Cold Pool.

VII. Atmospheric Forecast Sensitivities

The Rutgers University implementation of the Weather Research and Forecast (WRF) atmospheric model was used in a series of sensitivity studies to examine the impact of the cooler sea surface temperatures on the Hurricane Irene forecasts. Two endpoints of the sensitivity matrix are illustrated in Fig. 10 where the windfields are plotted at 18:00 GMT after the eye has propagated onto land. In all cases, the track of Hurricane Irene was reproduce, but the intensity of the forecast winds varied. The wind forecast on the left is the run with the standard sea surface temperature product that was available to the real-time forecast models (Fig. 9a). Maximum winds are located over the ocean and are in the 45-55 knot range. The wind forecast on the right is for the same time period but using the cooler sea surface temperature map of Fig. 9b assembled after the event. When this cooler sea surface temperature is used as a boundary condition, the forecast overwater winds are reduced to the 35-45 knot range.

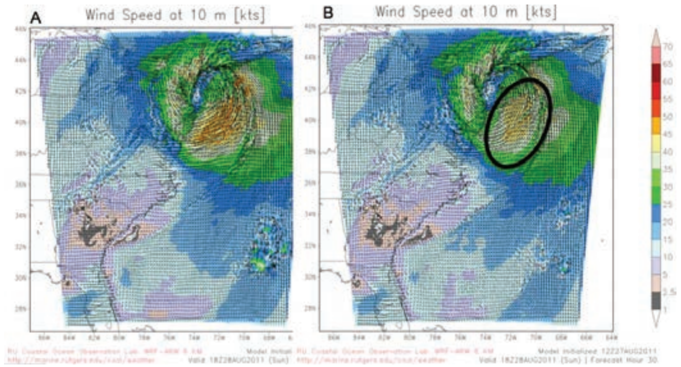

Fig. 10. Wind forecast from RU-WRF (a) using the warm sea surface temperature in figure 9a, and (b) applying the cold sea surface temperature in figure 9b at the time of the mixing observed by glider RU16.

The following table compares the Root Mean Square Error of the National Hurricane Center's best track estimates of Irene's intensity with their real time forecast, two runs of the RU-WRF model run with the warm SST from Fig. 9a, and one run of the RU-WRF model with the cold SST from Fig. 9b. The RSME of the RU-WRF model run using the warm sea surface temperature is similar to the RMSE of the real-time NHC forecast. The difference between the regular WRF model run and the "Hurricane WRF" with the attached Ocean Mixed Layer model is negligible. The WRF model run with the cold SST reduces the RMSE by a factor of 2-3.

TABLE I. MAXIMUM WIND SPEED FORECAST ERROR (KNOTS)

Date/Time (UTC)	*NHC Intensity Forecast*	*RU-WRF Warm SST (RTG) only*	*RU-WRF Warm SST (RTG) + OML Model*	*RU-WRF Cold SST (RTG+SPoRT+ AVHRR)*

RMSE	9.43	7.13	7.09	3.61

VIII. CONCLUSIONS

Sensitivity studies of Hurricane Irene were conducted using the ensemble of MARACOOS atmospheric forecast models. The impact of a variety of Sea Surface Temperature (SST) boundary conditions were studied, ranging from persistence of the warm pre-storm SST to applying the cold post-storm SST at the time mixing was observed by the autonomous underwater gliders. The resulting timing and track are consistent with the real-time forecast ensemble. The composite SST developed using the observed variation in sea surface temperature was found to reduce the intensity of the storm, in some cases by 15 knots, bringing the hindcasts in line with offshore buoy and onshore mesonet observations.

The sensitivity matrix results indicate the potential importance of a coupled atmosphere-ocean model to hurricane intensity forecasting in the Mid Atlantic Bight. The coupled model will be required to produce realistic forecasts of sea surface temperature fields during intense mixing events before the clouds clear after the storm. This will require improved understanding of subsurface mixing processes during intense coastal storms, and sufficient subsurface data from autonomous gliders for assimilation into the ocean model to provide the proper initial state.

ACKNOWLEDGMENT

Support for this research was provided by the U.S. Integrated Ocean Observing System (IOOS) through the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS). The deployment and operation of Glider RU16 was funded by the Environmental Protection Agency and the New Jersey Department of Environmental Protection.

ABSTRACT

Storm-driven sediment resuspension is an episodic process that is an important constraint on sediment transport on continental shelves; unfortunately, the spatial variability of the resuspension and transport processes are poorly quantified using traditional sampling techniques. Using two autonomous underwater gliders, long-range high frequency radar and buoy data, we quantified spatial variability of sediment resuspension and transport in a large fall storm in November of 2009. Wave, wind and current data in conjunction with glider profiles showed that waves and winds mixed the water column, waves initially mobilized the sediment and shear induced turbulence advected sediment throughout the water column. The separation of over 50 km between the two gliders (RU05 and RU21) is used to highlight the spatial variability of sediment resuspension. Both gliders were operating along the 40 m isobath with RU21 located 50 km north of RU05. Sediment resuspension on the New Jersey (NJ) shelf responded to synoptically forced turbulent motions. Currents transported this sediment toward the southwest in the along-shelf axis and onshore on the cross-shelf axis during the peak resuspension on November 13th through November 14th, with resuspension and transport on the southern NJ shelf measured by RU05 approximately twice that of RU21 on the northern MAB. Variability in resuspension profiles between the two gliders was largely a product of smaller mean grain sizes on the southern portion of the NJ shelf. These smaller grain sediment particles had a reduced fall velocity and were more easily retained throughout the water column by turbulent motions.

1. Introduction

Coastal storm-driven mixing events are episodic processes (Wiggert et al., 2000; Chang et al., 2001; Zedler et al., 2002) that are important for sediment transport. Despite numerous focused field campaigns on storm induced sediment resuspension (Traykovski et al., 1999; Styles and Glenn, 2002; Traykovski, 2007), the processes dominating the spatial variability of the storm response remains unresolved. The Mid-Atlantic Bight (MAB) is a region impacted by numerous physical forcing processes such as freshwater input from a complex network of rivers and estuaries, wave tidal and inertial fluctuations, variable topographic features such as the Hudson Shelf Valley and the ridge and swale topography (Beardsley and Boicourt, 1981; McBride and Moslow, 1991), the shelf-break jet (Chen and He, 2010) and Gulf Stream eddies near the shelf-break, seasonal wind variability (Gong et al., 2010), the summer cold pool (Lentz, 2008) and powerful winter storms (Beardsley and Boicourt, 1981).

Strong solar insolation drives the formation of the summer cold pool that results in large seasonal variations in the water column stratification between winter and summer seasons (Houghton et al., 1982; Lentz, 2003). This stratification is broken down by extra-tropical cyclones, commonly referred to as fall transition storms (Bigelow 1933, Beardsley and Boicourt, 1981). These storms result in a well-mixed water column in the winter until early spring (Lentz, 2003). The erosion of the stratification is important for the MAB ecosystem as it replenishes nutrients to the surface layer, which stimulates phytoplankton blooms (Xu et al., 2011). The winter phytoplankton bloom is the largest and most predictable biological event on the MAB (Xu et al., 2011). Resuspension of sandy sediments, which are dominant on the middle to outer-shelf of the MAB (Swift and Field, 1981; Amato, 1994; Reid et al., 2005; Goff et al., 2008), is commonly driven by fall transition storms through a combination of waves and currents (Glenn et al., 2008). For example, Styles and Glenn (2005) identified 25 sediment transport events over a 2-year period, with 63% of these events occurring in fall and winter on the MAB.

A combination of waves and currents are responsible for the resuspension and transport of sediment on the continental shelf. Though non-linear interactions between waves and currents

dominate sediment resuspension, seminal work by Grant and Madsen (1979; 1896) provides a qualitative explanation of the independent role each process plays. Wave bottom boundary shear stress can be an order of magnitude larger than current bottom boundary shear stress. From linear-wave theory wave-induced bottom orbital velocities have a similar magnitude to low-frequency currents but operate over a much smaller bottom boundary layer and thus result in an observed order of magnitude larger shear stress. Despite the high shear stress, wave velocities are orbital and therefore result in little net horizontal transport to first order. When sediment is suspended in the water column even relatively minor low-frequency currents are capable of horizontal sediment transport.

Keen and Glenn (1995) and Styles and Glenn (2005) show storm-induced sediment transport is generally aligned along-shelf toward the southwest through modeled and observed bottom currents during Nor'easter storms. Modeled cross-shelf sediment transport was offshore (Keen and Glenn, 1995); however the observed cross-shelf component of the transport was predominantly onshore in Styles and Glenn (2005). These observations are surprising as it might be expected that Nor'easters produce downwelling circulation with offshore bottom transport that is reinforced by the tides; therefore a more complex combination of processes must be important.

Several processes have been hypothesized to account for the onshore transport. Potential factors include topographic interactions that operate over the relatively small (a few kilometers) scale of the ubiquitous ridge and swale topography of the MAB inner shelf (McBride and Moslow, 1991), or over the larger (a few tens of kilometers) scale of the topographic highs associated with ancient river deltas (Glenn et al., 2004). Additionally, Gargett et al. (2004) identified full water column Langmuir cells as a significant driver of sediment resuspension events on the Mid-Atlantic Bight. Keen and Glenn (1995) also identified tides as critical to resuspension and transport modulation, as tidal currents can alternately enhance or reduce the more slowly varying storm driven currents. In their work, the tidal phase was important in determining onshore or offshore veering of the predominant along-shore bottom current. Styles and Glenn (2005) did not observe current veering with tidal phase and saw onshore transport near bottom, though their observations were limited to the 10 m water depth. Given this, the cross-shelf magnitude and direction of sediment transport are still unresolved.

Shipboard observations are likely biased to fair weather conditions as these sampling techniques are limited by the extreme conditions experienced in storms. Benthic tripods are ideally suited to resolve temporal variability effectively during extreme conditions but are expensive to deploy and are not designed to sample horizontal spatial variability. Recent work by Glenn et al. (2008) has demonstrated the potential of using autonomous Slocum gliders for sampling sediment transport events on the continental shelves. This work demonstrated that it is possible to average optical backscatter profiles of a single sensor and obtain results that are consistent with the theoretical understanding of coastal storm induced sediment resuspension. This manuscript builds on these results, using two simultaneously deployed gliders to examine the spatial and temporal variability during a fall transition storm on the MAB.

Hurricane Ida, was a low pressure system that developed into a category two hurricane over the Gulf of Mexico. Ida transitioned into an extratropical cyclone over the southeastern United States on November 10th, 2009. This system, commonly referred to as Nor'Ida, tracked northeastward along the eastern United States coast and into Canada causing extensive damage and coastal flooding. We present data from multiple gliders during Nor'Ida over large along- and cross-shelf spatial scales and incorporate shelf-wide HF radar surface currents (Roarty et al., 2010) measured with 6 km resolution for the duration of a fall transition storm. Both gliders started from the same location off Tuckerton, New Jersey (Fig. 1) and performed cross-shelf transects offshore. As in Glenn et al. (2008), deviation from flight paths and increases in glider depth-averaged currents indicate storm passage. Glider tracks and depth averaged currents for RU05 and RU21 can be seen in Figs. 2 and 3. RU05 took a brief northeastward turn followed by a long southwestward along-isobath track, which was enhanced by southwestward storm induced currents. RU21 finished its offshore cross-shelf transect and returned to complete an onshore cross-shelf transect, with deviations as a result of southwestward storm induced currents.

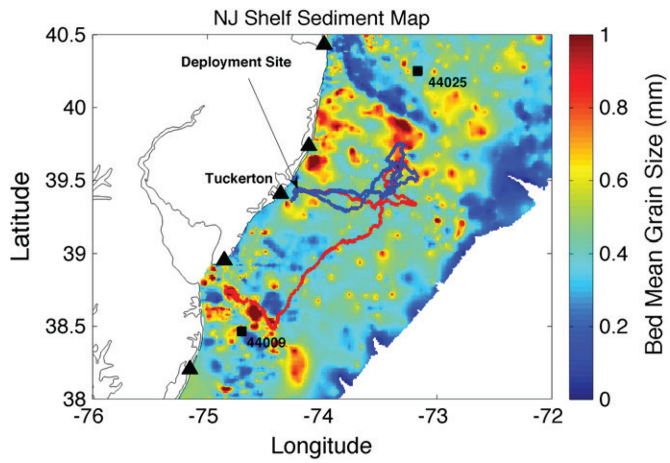

Fig. 1. The study location and 2 km resolution mean grain size map in mm with glider tracks from RU05(red), RU21 (blue), CODAR locations within the study region (black triangles) and Buoys 44009 and 44025 (black squares). Only CODAR stations in the immediate vicinity are shown, though others contributed to the data. The deployment site for both gliders is off Tuckerton, NJ. RU21 was recovered near the deployment site while RU05 was recovered in the south off of Delaware Bay, near buoy 44009. Details of sediment compilation from the usSEABED program are covered in Goff et al. (2008).

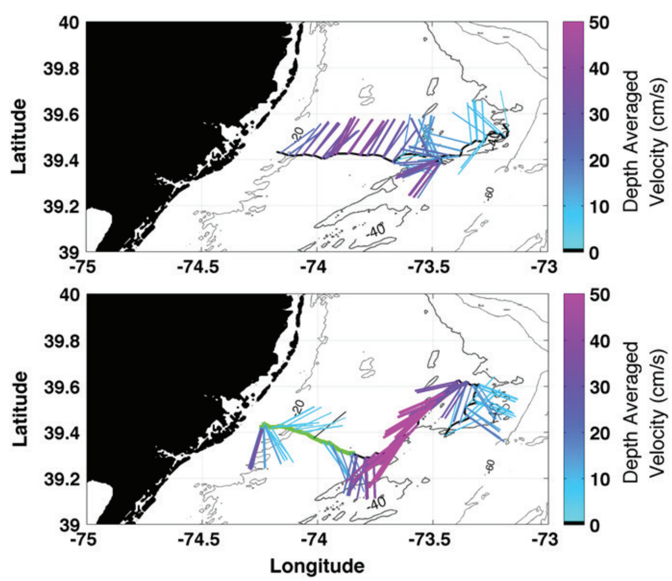

Fig. 2. RU21 depth averaged currents and offshore glider track from 10/31 to 11/05 (Top Panel) and onshore glider track from 11/10 to 11/18 (Bottom Panel). The green line indicates the portion of the transect from 11/15 to 11/18.

2. Materials and methods

This project relied on infrastructure operated by the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) that is part of the United States Integrated Ocean Observing System (U.S. IOOS) (Roarty et al., 2010; Schofield et al., 2010a). MARACOOS provides a suite of data collected by satellites, a high frequency CODAR network, and a fleet of Webb Slocum gliders (Glenn and Schofield, 2009). All of the above remote sensing techniques are coupled to a super ensemble of data assimilative numerical ocean models (see below).

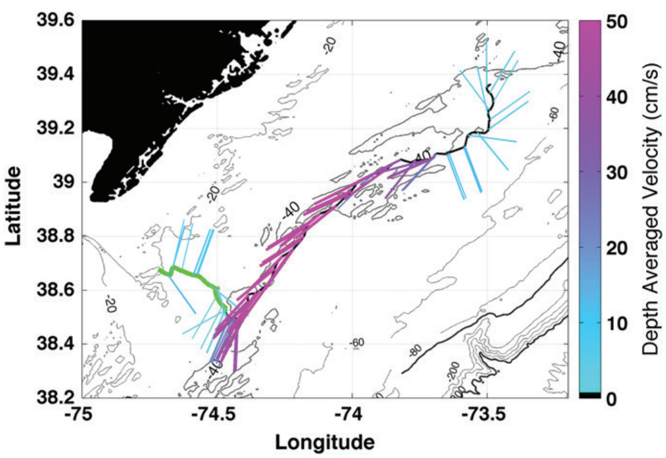

Fig. 3. RU05 glider track and depth-averaged currents between 11/10 and 11/18. The green line indicates the onshore glider track on 11/16 to 11/18.

2.1. Ocean observation dataset

A network of CODAR Ocean Sensors SeaSonde HF Radar systems measures surface currents on the MAB. The CODAR network consisted of 13 5-MHz HF Radar systems located along the northeast of the United States (Fig. 1). The HF Radar uses the Doppler Shift of a radio signal backscattered off the ocean surface to measure the component of the flow in the direction of the antenna (Barrick, 1971a, 1971b; Teague, 1971). Descriptions of the CODAR data and its shelf-wide applications are outlined in Dzwonkowski et al. (2009b) and Gong et al. (2010). The network provides surface current observations at the estimated equivalent depth of 2.4 m (Stewart and Joy, 1974). To minimize the geometric uncertainty in the radials we used the recommended threshold for the Geometric Dilution of Precision (GDOP) (Chapman and Graber, 1997) value of 1.5 or less to identify the vectors with acceptable GDOP (Dzwonkowski et al., 2009a). This value is chosen based on current comparison studies using CODAR and ship-mounted Acoustic Doppler Current Profilers (Kohut et al., 2006) and drifters (Ohlmann et al., 2007). The spatial resolution of the final total vector current maps is 6 km with a typical cross-shelf range of 150 km.

Sediment mean grain size is determined by taking a regional subsample of a 2 km resolution interpolated sediment map developed by Goff et al. (2008) from data compiled as part of the usSEABED project (http://walrus.wr.usgs.gov/usseabed/). We convert phi units into mm grain size as the sandy sediment only varies over two phi units (Fig. 1).

Oceanographic data from NOAA NDBC buoys 44009 and 44025 were used in this effort (Fig. 1). The moorings provided data on atmospheric pressure, wind speed/direction, wave-height, period and direction (Fig. 4).

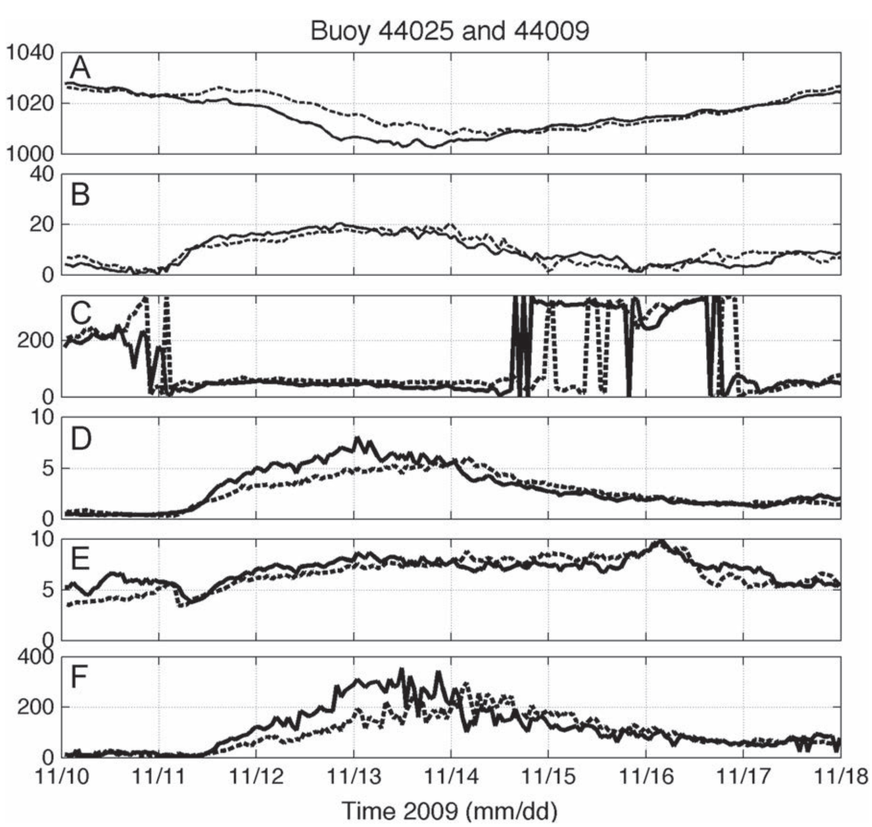

Fig. 4. Buoy 44009 (solid line) and 44025 (dashed line) (A) sea-level-pressure, (B) 5 m wind speed, (C) wind direction (D) wave height (E) wave period and (F) bottom orbital velocities for 11/10 to 11/18. Wave induced bottom orbital velocities were calculated from linear wave theory as in Glenn et al. (2008).

Please cite this article as: Miles, T., et al., Temporal and spatial variability in fall storm induced sediment resuspension on the Mid-Atlantic Bight. Continental Shelf Research (2012), http://dx.doi.org/10.1016/j.csr.2012.08.006

Slocum gliders are an autonomous underwater scientific platform (Davis et al. 2003; Schofield et al., 2007) manufactured by the Teledyne Webb Research Corporation. They are 1.8-m long, torpedo-shaped, buoyancy-driven vehicles with wings that enable them to maneuver through the ocean at a forward speed of 20–30 cm s^{-1} in a sawtooth-shaped gliding trajectory. A full description of our scientific operation of the Slocum gliders can be found in Schofield et al. (2007). Each Slocum glider has a payload bay that houses a SeaBird conductivity–temperature–depth sensor and includes space for a range of additional sensors. The glider acquires its global positioning system (GPS) location every time it surfaces, a programmable interval that was set to 3 h for the purposes of this study. By dead reckoning along a compass bearing while flying underwater, estimates of depth averaged current can be calculated based on the difference between the glider's expected surfacing location and the actual new GPS position. Depth averaged current measurements obtained in this manner have been validated against stationary Acoustic Doppler Current Profiler data (Davis et al. 2003). These physical measurements are complemented with several bio-optical sensors (Glenn and Schofield, 2009).

Two Webb Slocum gliders were deployed prior to November 1, 2009 and operated for two weeks. During that period the gliders traversed 1673 km underwater collecting 23,332 vertical profiles (Fig. 1). The gliders were outfitted with WetLabs Inc. EcoPucks, which provide measurements of optical backscatter, chlorophyll fluorescence and colored dissolved organic fluorescence. The EcoPucks measure optical backscatter at 440 (b_b470) and 660 (b_b660) nm. Optical backscatter, to first order, is used to measure the relative concentration of particulate matter (Roesler and Boss, 2008). A growing body of work indicates that optical backscatter is not only a function of particle concentration but also sediment characteristics such as refractive index, size, shape and particle composition (Twardowski et al., 2001; Boss et al., 2004). While we do not characterize sediment in great detail during the measured resuspension events, we use changes in backscatter ratios to indicate a change in character of suspended particles.

2.2. Adaptive sampling

To coordinate the numerous observed and forecast model data streams, we were able to utilize a novel cyberinfrastructure (CI) tool set being developed as part of the Ocean Observing Initiative (OOI). The software was used to coordinate sampling using multi-model forecasts to optimize glider missions (Schofield et al., 2010b). In brief, numerical model ocean forecasts allowed the simulation of future *in situ* glider trajectories. This guidance could be used by the team to optimize sampling based on the science needs. This provided scientists with a guide to determine whether desired target areas could be reached by Webb Slocum gliders in a predicted current field. Thus the CI software could deliver the community science needs back to the *in situ* observation network in a timely manner. Field operations were coordinated through a

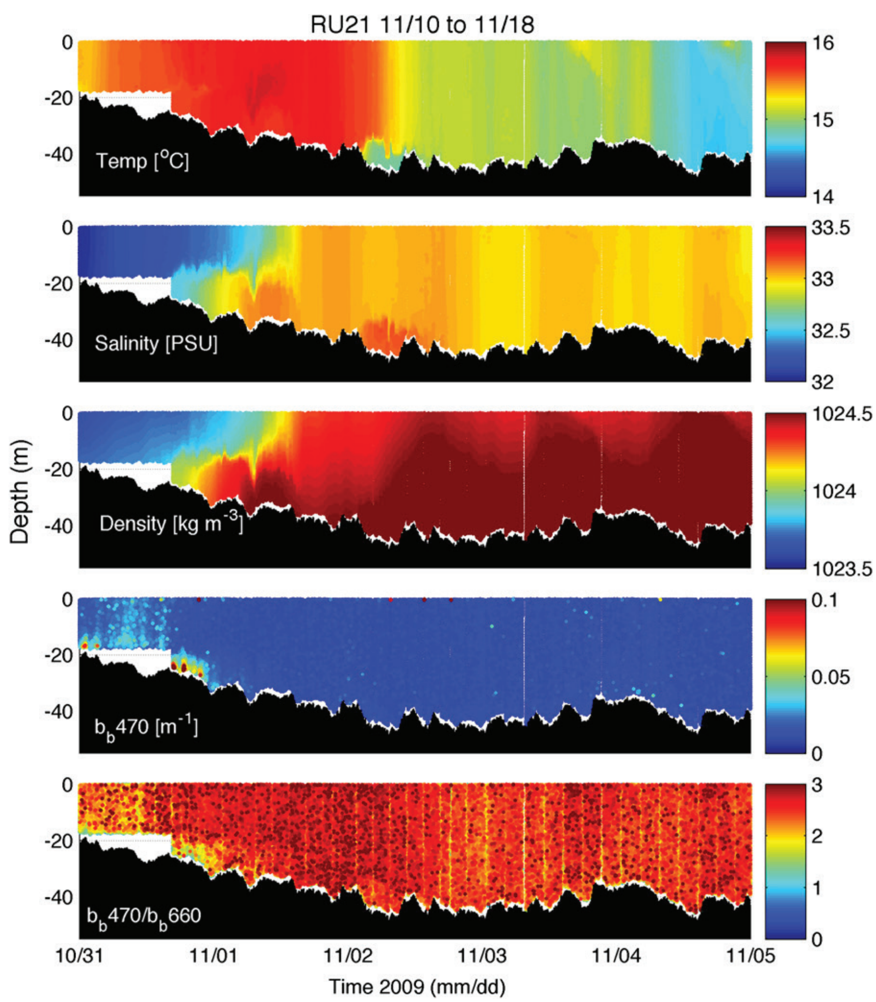

Fig. 5. RU21 Pre-storm cross sections of temperature, salinity, density, b_b470 and the ratio of b_b470/b_b660.

web portal (http://ourocean.jpl.nasa.gov/CI) that provided an access point for real-time observational data and model forecasts.

3. Results

3.1. Pre-storm hydrography

Pre-storm conditions were typical for fall on the MAB with predominantly vertical isotherms and a cross-shelf temperature gradient. RU21, on its offshore transect (Fig. 2) between October 31st and November 5th, showed a near-shore water mass that was approximately 1 kg m^{-3} lighter than offshore waters (Fig. 5). This lower density coastal water was largely due to the variability in salinity. Additionally, there was a warm core of water centered at 15 m depth, on the 35 m isobath, which contributed to the regional vertical and horizontal density gradients. This glider data shows that New Jersey shelf waters were generally colder, saltier and denser in the offshore direction. B_b470 was low (<0.005 m^{-1}) for the majority of the offshore pre-storm transect. There is a small region of elevated backscatter near-shore located below the pycnocline. RU21 was not programmed to dive below 20 m until after it reached the 25 m isobath so the optical backscatter at the bottom in the near-shore region was not completely sampled. Pre-storm water column b_b470 to b_b660 ratios were high ($\sim$3) relative to storm signatures (see below). There was a short period of elevated currents toward the north-east in the coastal region (Fig. 2). Prior to the storm both the gliders and CODAR (Figs. 2, 3, 6) showed variable currents between 5 and 40 cm s^{-1} along the coast of New Jersey, with daily averaged currents immediately prior to the storm event somewhat higher than the climatological mean of 5 cm s^{-1} (Beardsley and Boicourt, 1981).

3.2. Storm data

Buoy 44009, off of Delaware Bay, and 44025, off Long Island are separated by approximately 230 km with 44009 encountering Nor'Ida first (Fig. 4). As the storm entered the MAB region from the southwest, pressure fell from above 1020 mbar at both buoys to a minimum of 1002 mbar on November 13th at 2000 Greenwich Mean Time (GMT) at 44009 and a minimum of 1007 mbar on November 13th at 2350 GMT at 44025 (Fig. 4A). Winds at both locations began to increase at 0000 GMT on November 11th, but peak winds at 44025 lagged 44009 by 28 h with slightly lower magnitude until they reached a maximum of 20.5 ms^{-1} at 23:50 GMT on November 13th (Fig. 4B). Prior to November 11th wind direction was variable. Between November 11th and late on the 15th,wind direction at both buoys was from the northeast (Fig. 4C). Wave-heights began to build after a few hours of rising winds at both locations (Fig. 4D). Wave heights reached over 8 m at 0050 GMT on November 13th at 44009 and over 6 m at 0350 GMT on the 14th at 44025. Wave spectral periods were between 7 and 9 s for the duration of the storm at both locations and continued to increase after storm passage, eventually peaking at $\sim$10 s on the morning of November 16th (Fig. 4E). Maximum wave bottom orbital velocities were calculated from buoy data using linear wave theory as described by Glenn et al. (2008). Wave bottom orbital velocity estimates peaked at 2.4 m s^{-1} and 1.8 m s^{-1} at buoy 44009 and 44025 respectively (Fig. 4F), significantly higher than glider depth-averaged and CODAR surface currents (Figs. 2, 5, 8).

CODAR daily averaged currents (Fig. 6) were toward the south-west on November 11th and reached 30 cm s^{-1} on the central and southern MAB with values offshore nearing 50 cm s^{-1}. CODAR daily averaged surface currents peaked in excess of 50 cm s^{-1} shelf-wide on the central and southern MAB on the 13th. There was a low velocity region on the northwestern MAB near the Hudson River outflow. Over the two days following peak values, shelf-wide currents decreased back to near pre-storm values, below $\sim$15 cm s^{-1}.

3.3. RU21 northern glider storm variability

As Nor'Ida approached the New Jersey shelf, RU21 turned onshore and attempted to retrace the path of its offshore transect (Fig. 2). Initially it flew southwestward along the 40 m isobath until it turned onshore on the 15th. Cross-sections of glider measurements (Fig. 7) show that during its southwestward transect RU21 initially measured vertically uniform temperatures of 15 °C, salinity of 33 PSU, density near 1024.6 kg m^{-1}, optical backscatter at b_b470 nm was near 0 m^{-1} and the ratio of b_b470 to b_b660 was $\sim$3. Downcast vertical glider velocities were uniform at $\sim$0.3 m s^{-1}. Vertical glider velocities were calculated by the change in measured pressure over time and we used them to serve as a proxy for vertical water velocities. In uniform water masses with no external turbulent forcing and the glider on a new constant glide slope, vertical velocities should have also remained approximately constant except when the glider was inflecting near-bottom or near-surface.

As winds, waves and currents increased beginning on the 11th, there was a distinct water column response. First, glider vertical velocities began to undergo high-frequency variability of $\sim$0.1 to

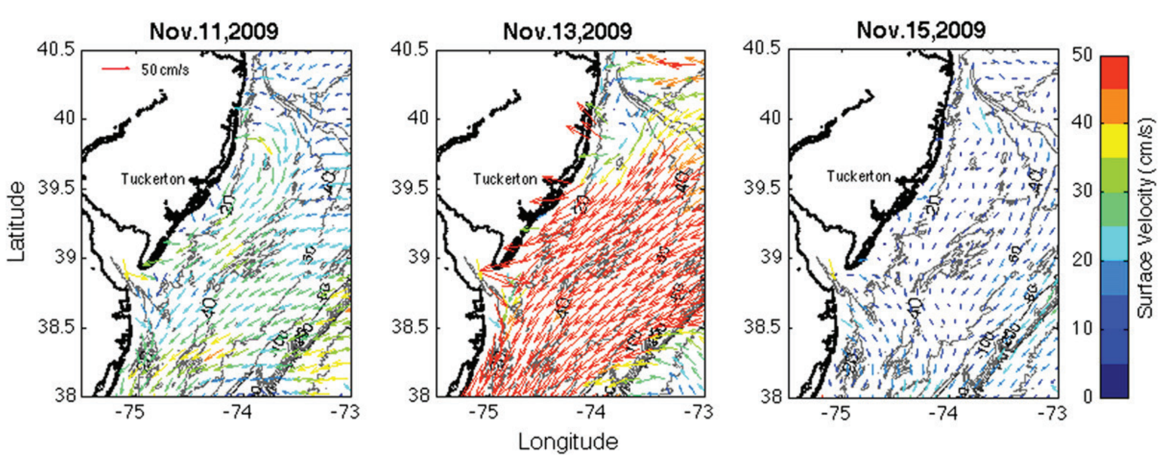

Fig. 6. Daily averaged CODAR surface currents for the New Jersey shelf for November 11th 13th and the 15th. Black contours represent bottom topography in units of meters.

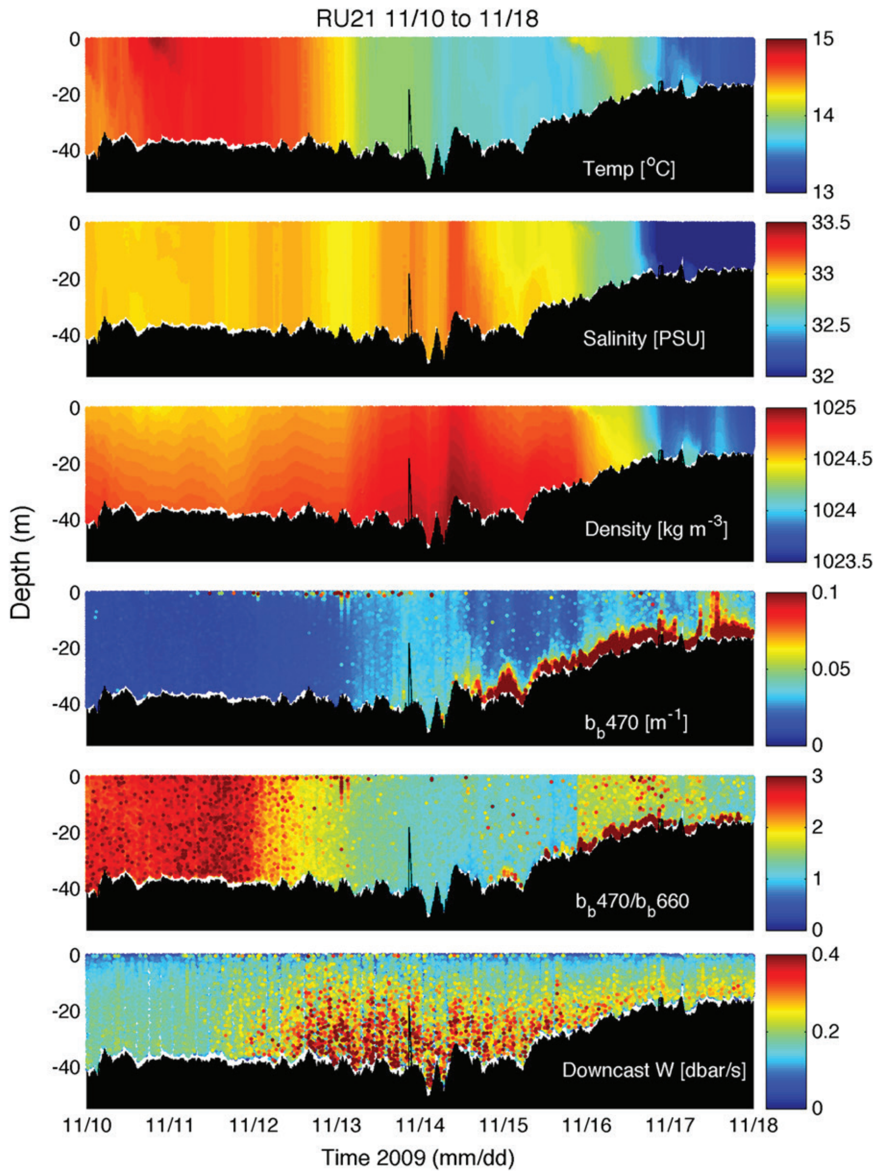

Fig. 7. RU21 during and post-storm cross-sections of temperature, salinity, density, b_b470, b_b470/b_b660 and downcast glider vertical velocities.

$0.2\ \mathrm{m\,s^{-1}}$ through the entire water column. These vertical velocity variations persisted through the 14th until they were restricted to a bottom layer and eventually relaxed after the 16th. As the magnitude of vertical velocities increased, temperatures cooled to 14 °C, salinity was elevated above 33 PSU and $1025\ \mathrm{kg\,m^{-1}}$ density water was raised to the surface. Values of b_b470 of $\sim 0.05\ \mathrm{m^{-1}}$ were evident throughout the water column on the 13th. The enhanced particle load remained suspended until the afternoon of the 14th. Optical backscatter spectral ratios changed from 3 to 1 as Nor'Ida impacted the region, reflecting a flattening of the backscatter spectra consistent with changes in either particle type and/or particle size in the water-column (Boss et al., 2004).

Previous studies have clearly defined the Rouse profile above the wave boundary layer (Glenn et al., 2008; Styles and Glenn, 2000; Glenn and Grant, 1987) as

$$C(z) = C(z_r)\left[\frac{z}{z_r}\right]^{[-\gamma w_f/\kappa u_*]} \quad (1)$$

where $C(z)$ is the concentration profile varying with depth z, $C(z_r)$ is the concentration at the reference height z_r, γ is a constant ratio of eddy diffusivities between momentum and mass, κ is von Karman's constant and u_* is friction velocity. Assuming constant γ (Glenn and Grant, 1987), the slope of $\ln(C(z)/C(z_r))$ to $\ln(z/z_r)$ is proportional to the ratio of the fall velocity, the tendency of sediment to fall out of the water column, to the friction velocity representing the turbulent shear that acts to keep sediment suspended in the water column, or w_f/u_*. In order to identify this ratio, we use optical backscatter as a proxy for sediment concentration similar to Glenn et al. (2008). Optical backscatter profiles were interpolated every 1 m in a reference frame measured from the bottom and averaged over three-hours. These three-hour profiles were then normalized using the backscatter observed at a 3.5 m reference height and plotted as the $\ln(z/z_r)$ *versus* $\ln(b_b(z)/b_b(z_r))$. The 3.5 m reference height ensures all profiles in each three-hour segment have data at this height and above. Normalized backscatter profiles from RU21 (Fig. 8) demonstrated Rouse-like character from the 14th at 04:24 GMT until the

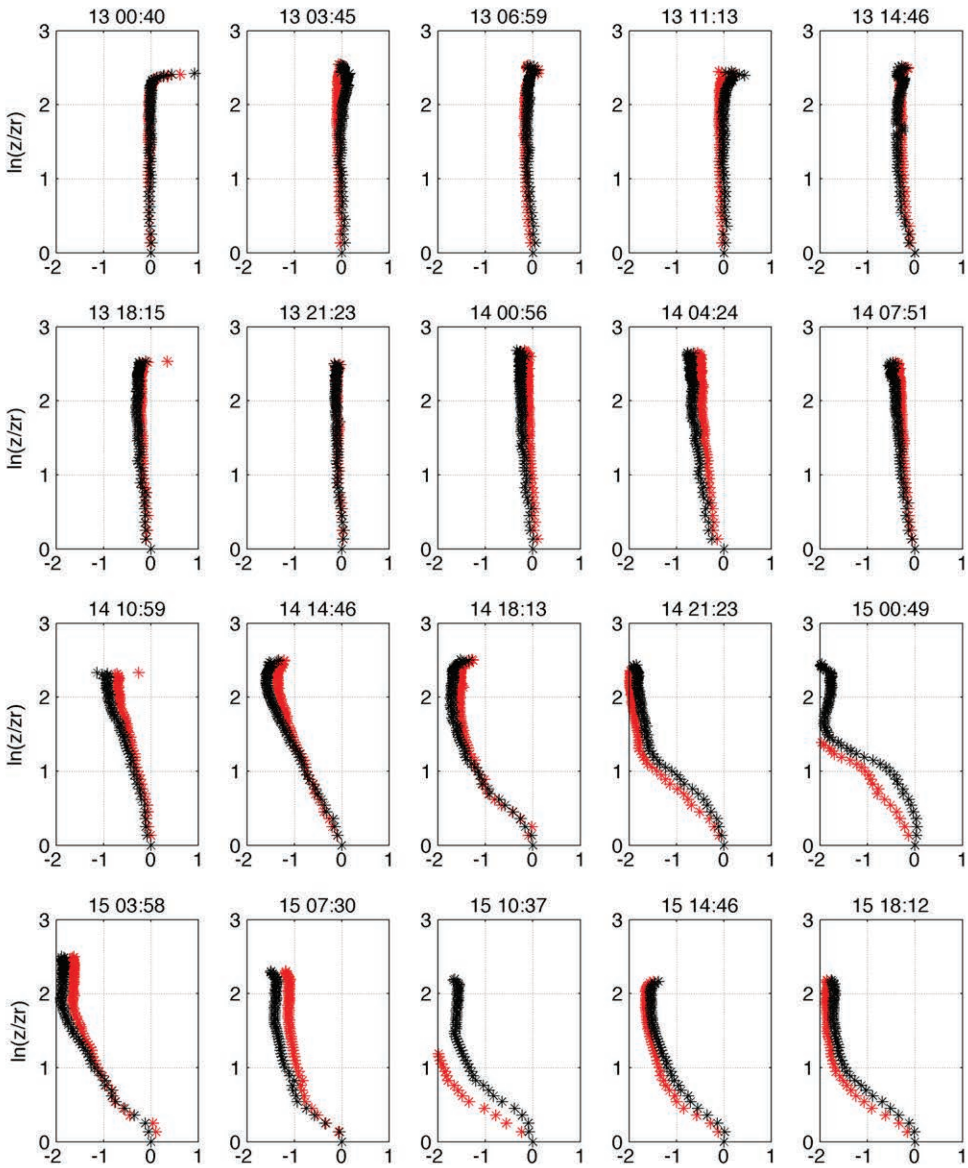

Fig. 8. RU21 log-normalized profiles of optical backscatter at b_b470 (red) and b_b660 (black). *Y*-axis is the natural logarithm of depth divided by z_r, a reference depth of 3.5 m. The *X*-axis is the natural logarithm of optical backscatter, b_b, divided by the optical backscatter at the reference depth b_r or $\ln(b/b_{zr})$. Titles are timestamps of November dd HH:MM.

14th at 21:23 GMT. High near-surface values in rough seas are likely due to bubbles being entrained by breaking waves. Terrill et al. (2001) has observed optical backscatter values of over 0.016 m^{-1} inside bubble clouds.

On November 15th, at approximately 06:00 GMT, RU21 turned onshore and left the 40 m isobath, indicated by the green section of Fig. 2b. As the glider entered the shallow coastal region, temperature, salinity and density remained well-mixed in the vertical while there were horizontal gradients of $\sim$1 °C, $\sim$1.5 PSU and $\sim$1.5 kg m^{-3} respectively (Fig. 7). On the 15th to the 18th a layer of high b_b470, over 0.1 m^{-1}, was apparent, elevated to 10–15 m off the bottom (Fig. 7). Profiles (Fig. 8) show a layer restricted below $\ln(z/z_r) = 1.5$, roughly equivalent to 15 m. The lower layer persists through the remainder of the deployment. Though winds and currents were reduced, wave-heights, wave-periods and bottom orbital velocities remained significantly elevated (Fig. 4). Glider measured vertical velocity variability remained elevated in the near-bottom layer through the 16th (Fig. 7).

3.4. RU05 southern glider storm variability

Between the 10th and 16th of November, RU05 was on a southwestward track along the 40 m isobath (Fig. 3). RU05 turned onshore toward the mouth of the Delaware River on the 16th through the 18th. RU05 cross-sections (Fig. 9) show that on November 10th the water column was initially stratified with relatively cool ($\sim$14 °C) and salty ($\sim$33.5 PSU) bottom water, likely a remnant of the summer cold pool. Cross-sections show that dense bottom water was advected through the lower half of the water column late on the 10th into the 11th. There were periodic bulges of weakly stratified water (0.6–0.2 kg m^{-3}), which grew progressively weaker until the water column was vertically well mixed on the 16th. Similar to RU21, b_b470 was low initially and spectral ratios of b_b470 to b_b660 were $\sim$3. Vertical velocities were initially constant at $\sim$0.3 m s^{-1} and variations of 0.1–0.2 m s^{-1} were apparent during elevated wind, waves and currents. A consistent background b_b470 value of 0.05 m^{-1} is apparent throughout the water column, and near-bottom values

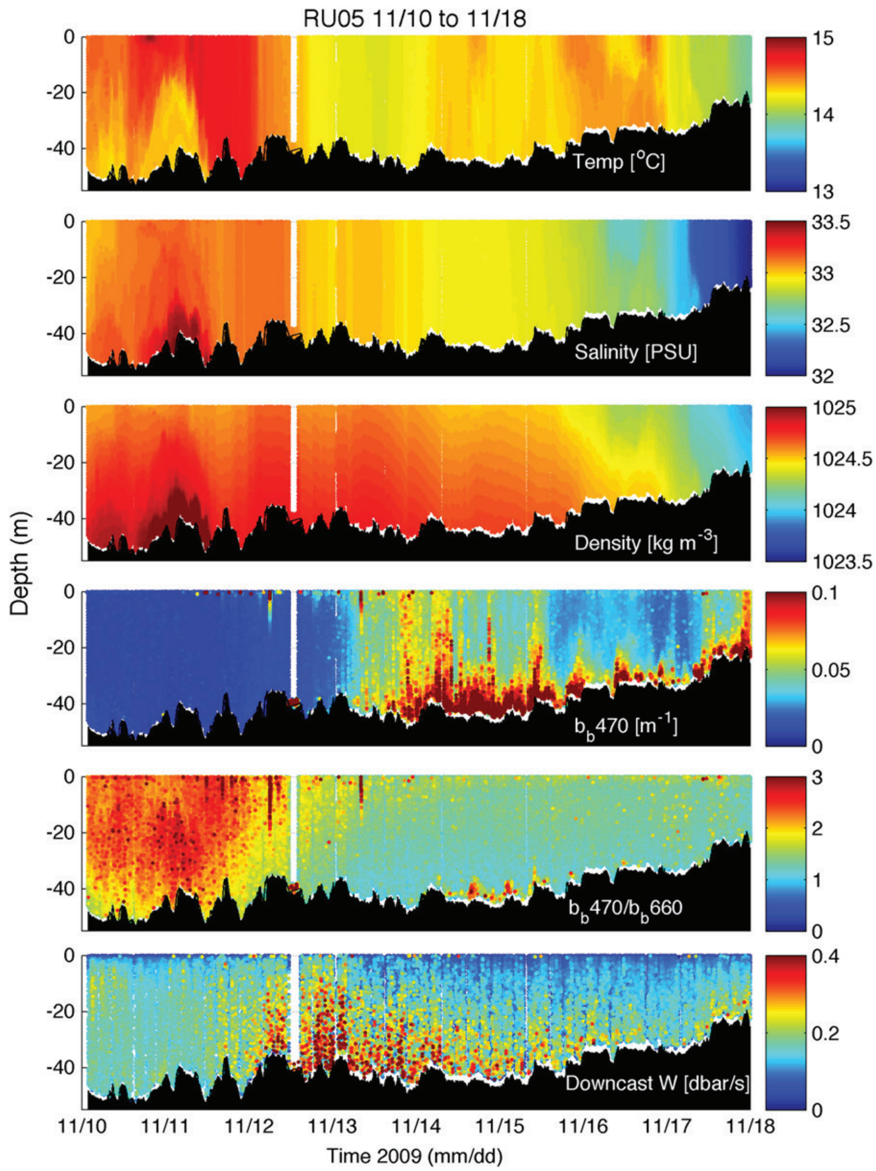

Fig. 9. RU05 cross-section of temperature, salinity, density, b_b470, b_b470/b_b660 and downcast glider vertical velocities.

are near 0.1 m^{-1} until RU05 turns onshore on the 16th. Unlike RU21, there were periodic full water column resuspension events with b_b470 of 0.1 m^{-1} that occur on time-scales less than a day. Similar to RU21, ratios of b_b470 to b_b660 dropped, which indicated changes in either particle type and/or particle size (Boss et al., 2004). Regardless of the periodicity seen in b_b470 cross-sections, the ratios are constant and $\sim$1 after the resuspension event was initiated.

RU05 profiles of optical backscatter (Fig. 10) were calculated in the same manner as for RU21 and for the same duration, from November 13th through the 15th. Reference depth normalized profiles were near 0 until 21:02 GMT on the 13th when the profiles became Rouse-like approximately eight hours earlier than the northern glider, RU21. RU05 then turned onshore toward the Delaware River mouth on the 16th to the 18th (indicated by green in Fig. 3), vertical velocities, winds and currents were reduced, while wave- height, period and orbital velocities remained elevated relative to pre-storm conditions.

3.5. Sediment transport

Three-hourly averaged CODAR surface velocities were compared with approximately three-hourly depth-averaged glider currents (Fig. 11). CODAR velocities are averaged in a 10 km radius of each glider surfacing latitude and longitude. There is a minor temporal and spatial mismatch between glider depth-averaged and CODAR currents as glider currents are averaged over a three-hour subsurface transit obtained by dead reckoning along a compass bearing and comparing the expected glider surfacing location with the actual surfacing location. Depth-averaged currents obtained in this manner have been validated against traditional current measurements from stationary ADCPs (Davis et al., 2003) While we could not obtain any subsurface current structure information directly, by comparing depth-averaged and surface currents, we can make some inferences about how subsurface currents change during the storm.

RU21 and RU05 depth-averaged along-shelf currents both showed similar results when compared with CODAR currents

Please cite this article as: Miles, T., et al., Temporal and spatial variability in fall storm induced sediment resuspension on the Mid-Atlantic Bight. Continental Shelf Research (2012), http://dx.doi.org/10.1016/j.csr.2012.08.006

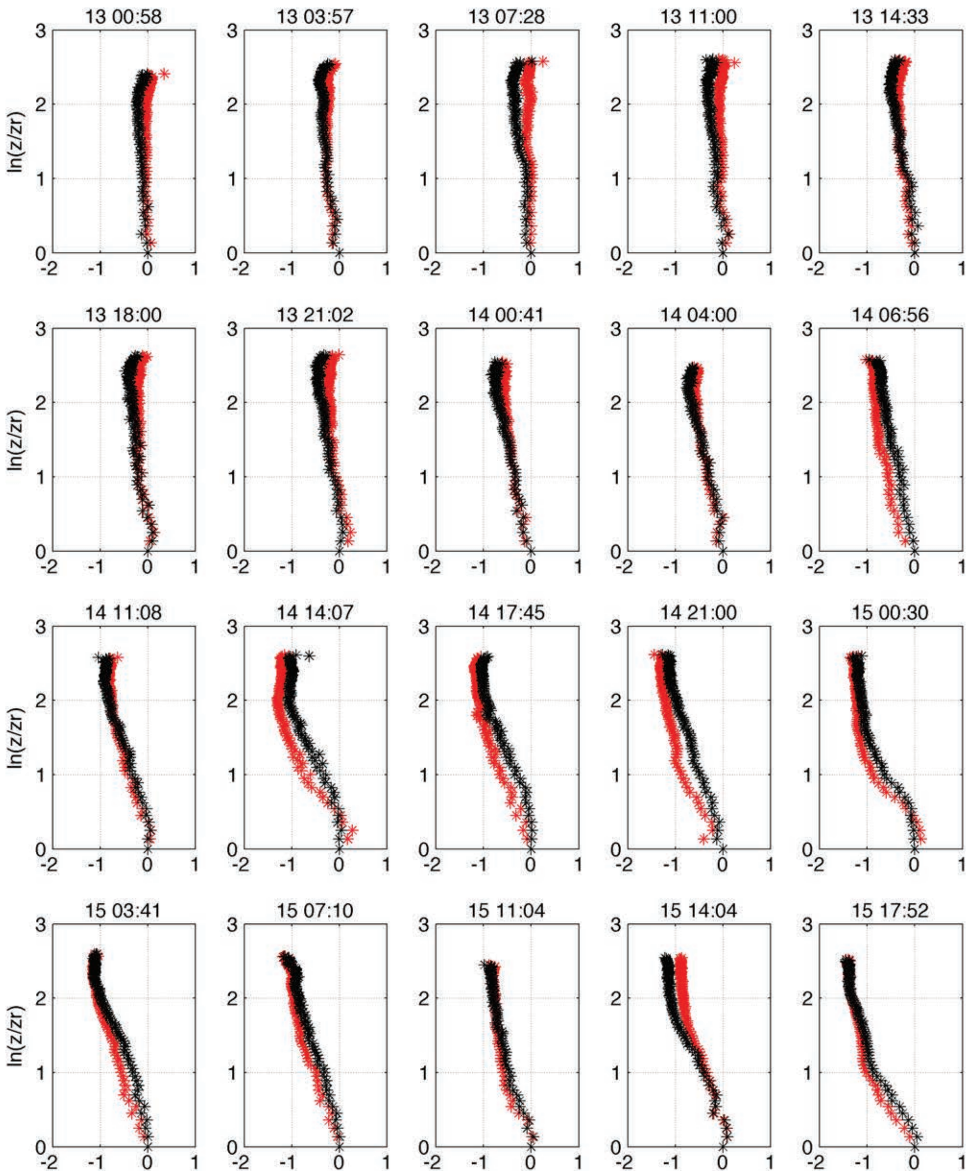

Fig. 10. RU05 log-normalized profiles of b_b470 (red) and b_b660 (black). *Y*-axis is the natural logarithm of depth divided by z_r, a reference depth of 3.5 m. The *X*-axis is the natural logarithm of optical backscatter, b_b, divided by the optical backscatter at the reference depth b_r or $\ln(b/b_{zr})$. Titles are timestamps of November dd HH:MM.

for the duration of each glider deployment. The storm event is easily identifiable in both gliders, which were approximately along the 40 m isobath, between the 10th and 15th, with onshore currents up to 40 cm s^{-1} and alongshore currents toward the southwest of up to 80 cm s^{-1}. Correlation coefficients calculated between glider and CODAR currents for the entire deployment showed a weak correlation in cross-shelf currents of 0.30 for RU05 and 0.33 for RU21. Correlation coefficients in the along-shelf direction were much greater, with values of 0.81 for RU05 and 0.77 for RU21. Correlation coefficients of CODAR and glider comparisons limited to during and after the storm, from the 10th to the 18th, showed that the cross-shelf components increased to 0.44 for RU05 and 0.5 for RU21 and the along-shelf components remained essentially the same at 0.81 for RU05 and 0.84 for RU21. The weak cross-shelf correlation coefficients suggest that deeper currents were initially weaker and not necessarily in the same direction as surface currents. Increased correlation during and after the storm suggest that subsurface currents in the cross-shelf direction either increased in magnitude or aligned more closely with surface currents.

In order to estimate sediment transport magnitude and direction, a time-series of integrated b_b470 was calculated by integrating over depth and segment b_b470 during the RU05 and RU21 deployments and then (Fig. 12). These depth and time integrated plots show elevated values of backscatter that initiated on the 13th and remained elevated through the duration of the storm until the 16th with the southern glider, RU05, showing much larger values during the storm. The northern glider, RU21, had a second peak after the storm, which was approximately double the size of the storm-induced values. Estimated transport was calculated by multiplying the integrated backscatter by the along- and cross-shelf depth-averaged currents reported by the gliders (Fig. 12). Prior to the storm, low sediment concentrations and low currents result in transport near 0 s^{-1}. During the resuspension event, sediment was transported toward the southwest in the along-shelf (Fig. 12) direction for both RU05 and RU21. RU05 showed approximately twice the along-shelf sediment transport as RU21 during the storm. RU05 and RU21 cross-shelf transport was approximately half of the along-shelf transport and in the onshore direction during the storm. Following the storm RU05

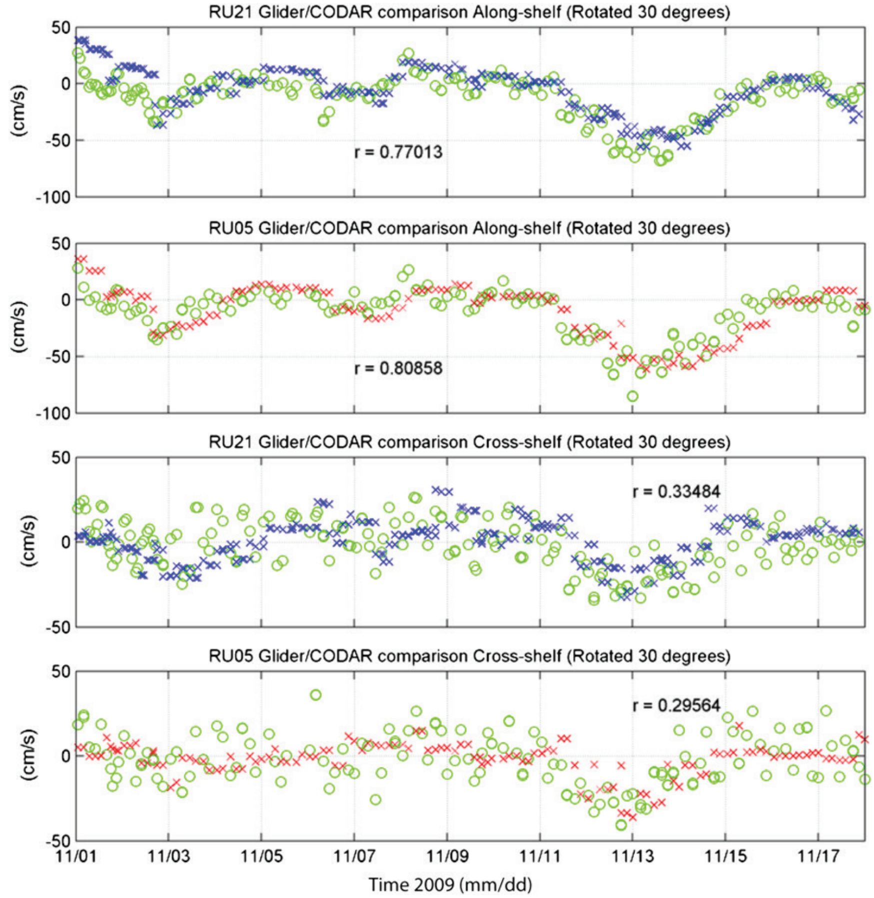

Fig. 11. Along-shelf currents for RU21 and RU05 (Top two panels) and cross-shelf currents for RU21 and RU05 (Bottom two panels) depth averaged glider currents(*x*'s) and along-track 3-hourly averaged CODAR surface currents (*o*'s) rotated clockwise 30 degrees to be in the cross- and along-shelf directions with positive along-shelf currents to the northeast and positive cross-shelf currents to the southeast. Correlation coefficients for the full time-period are displayed as *r*.

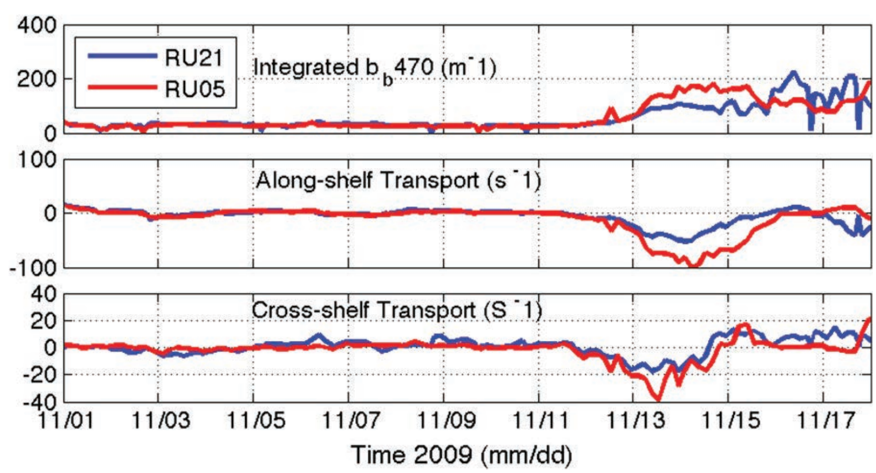

Fig. 12. Time-series of the (blue) RU21 and (red) RU05 (top) three-hour integrated b_b470 (m^{-1}) and estimated transport in the (middle) along- and (bottom) cross- shelf directions. Positive values indicate northeastward transport for along-shelf and southeastward transport for cross-shelf transport. Estimated transport is calculated by multiplying depth-averaged glider currents by integrated optical backscatter at b_b470.

transport was reduced to near $0\,s^{-1}$ when currents and integrated backscatter were both reduced (Fig. 12). RU21 transport shifted to the offshore direction as high b_b470 still remained in the water column (Fig. 12) and current velocities were reduced (Fig. 11) as it approached the coast.

4. Discussion

While many studies have focused on sediment resuspension at a single point on the MAB shelf (Traykovski et al., 1999; Agrawal and Pottsmith, 2000; Harris et al., 2003; Agrawal,

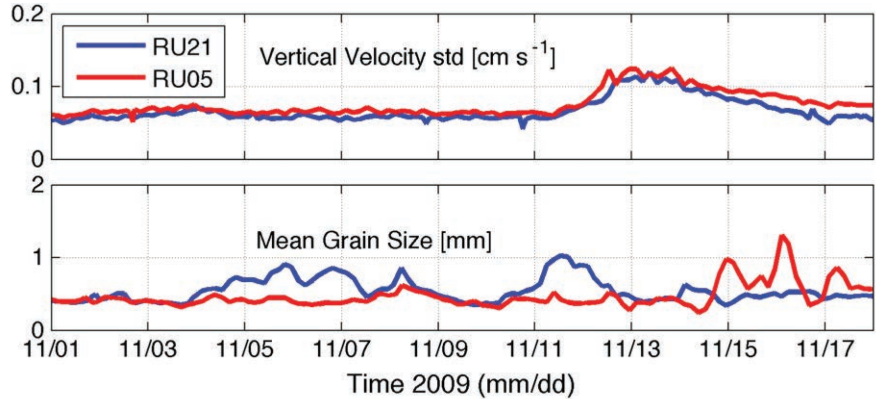

Fig. 13. Time-series of the (blue) RU21 and (red) RU05 (top) three-hour segment standard deviation of vertical velocity (cm s^{-1}) and (bottom) mean bed grain-size from Fig. 1 interpolated to the along-track glider positions.

2005; Traykovski, 2007; Cacchione et al., 2008) few observational studies have focused on the shelf-wide spatial variability of these processes. We were fortunate to have several gliders deployed to assess the spatial variability of sediment resuspension on the MAB during the Nor'Ida fall transition storm (Schofield et al., 2010b). The two gliders equipped with optical sensors, separated by ~50 km at the onset of storm conditions, documented the initiation of sediment resuspension through the increases in optical backscatter. Just like the two gliders, buoys 44009 and 44025 (separated by 230 km) showed similar characteristics, with a 1-day lag in peak values, through the initiation of elevated storm winds and waves. Despite the separation distances, along-shelf transport toward the southwest was a ubiquitous feature of both glider deployments with a lag in resuspension of approximately eight hours. With a separation distance of ~50 km this lag is on the same order as the lag seen in peak storm conditions at buoys 44025 and 44009. Peak sediment transport was associated with a combination of a maximum in suspended sediment concentration and high relative along-shelf southwestward currents. The nearly coincident maximum in sediment transport suggests that along-shelf transport is a common feature of the entire NJ shelf and MAB and is consistent with previous modeling studies (*e.g.* Keen and Glenn, 1995). The event duration is longer than the temporal lag between the southern and northern gliders so the large-scale storm effectively forces the shelf as a whole and there is little spatial variability in the timing of resuspension and transport as a result of storm passage.

While resuspension and transport occurred with an approximately eight hour lag, the strength of resuspension and transport varied by as much as a factor of two in the along-shelf direction, with higher transport associated with RU05 located on the southern NJ shelf. The major difference in sediment resuspension, and consequent transport, was related to the numerous discrete resuspension events that resulted in high sediment concentrations up into the water-column during the storm. The difference in the scale and frequency of resuspension events over spatial scales much smaller than the storm event points out the importance of local processes, which affect the magnitude of sediment resuspension and transport. Previous work by Styles and Glenn (2005); Keen and Glenn (1995); Gargett et al. (2004) have highlighted tidal forcing, topographic variations and Langmuir cells as potential processes affecting sediment resuspension and transport on time-periods shorter than a day. For both gliders, vertical velocity variability appeared random rather than spatially banded (Figs. 7 and 9), indicating that Langmuir cells were not likely the cause of the suspended sediment spatial heterogeneity. RU21 and RU05 were both flying approximately southwestward along the 40 m isobath during elevated winds, currents and waves therefore topography was essentially constant during the resuspension event (Figs. 7 and 9). RU21 did not experience fluctuations of sediment resuspension or transport on time-scales shorter than a day after the resuspension event was initiated, thus tidal forcing was not likely a dominant modulation process as in Keen and Glenn (1995). The scale of tidal forcing on the shelf is also much larger than the separation distance between the gliders; therefore variability seen in RU05 on shorter time-scales is likely not related to tidal fluctuations.

Glenn et al. (2008) suggested that in the absence of stratification, turbulence in the combined wind-driven surface layer and wave-enhanced bottom boundary layer is responsible for sediment resuspension upward through the water column, but observations were sparse. During the Nor'Ida storm there was a distinct change in vertical glider velocities, which serves as evidence of turbulence in the water column. The standard deviation of each three-hour glider segment for RU21 and RU05 vertical velocities show a distinct increase in vertical velocity variability beginning on the morning of the 12th and persisting through the 16th (Fig. 12). These fluctuations in the glider's vertical velocity serve as an estimate of the turbulent motions due to high storm-induced current-shear, similar to neutrally buoyant lagrangian floats used in Harcourt and D'Asaro (2010). Vertical velocity standard deviation values were approximately the same for RU05 and RU21. Uniform vertical velocity standard deviations suggest that the vertical component of turbulence was similar between the northern and southern portions of the NJ shelf, which is consistent with the scale of the storm and the uniform winds, waves and currents.

With little variability in turbulent vertical velocities between gliders, the differences in bed grain size likely play a major role in modulating the magnitude of resuspension by storm-induced turbulence. In order to assess the importance of local variability in grain size we interpolate mapped values (Goff et al., 2008; Reid et al., 2005) plotted in Fig. 1 to glider latitude and longitude. The resulting time-series (Fig. 13) shows mean grain size below the gliders throughout the deployment. The time-series shows mean grain sizes ranged from ~0.3 to ~1.4 mm with largest grain sizes seen by RU05 after storm passage, when it turned into the mouth of the Delaware. RU21 passed over a region of over 1 mm grain sizes between the 11th and 13th, after storm initiation but prior to peak conditions. The map in Fig. 1 shows a patch of coarse sediment along the northern portion of the NJ shelf where RU21 was flying and relatively smaller grain sizes in the along-shelf region where RU05 sampled, prior to turning in toward Delaware Bay. During the resuspension events on the 13th through the 15th, RU05 was located over a patch of sand with a mean grain size of 0.3 mm–0.4 mm (Fig. 13) before flying through a region

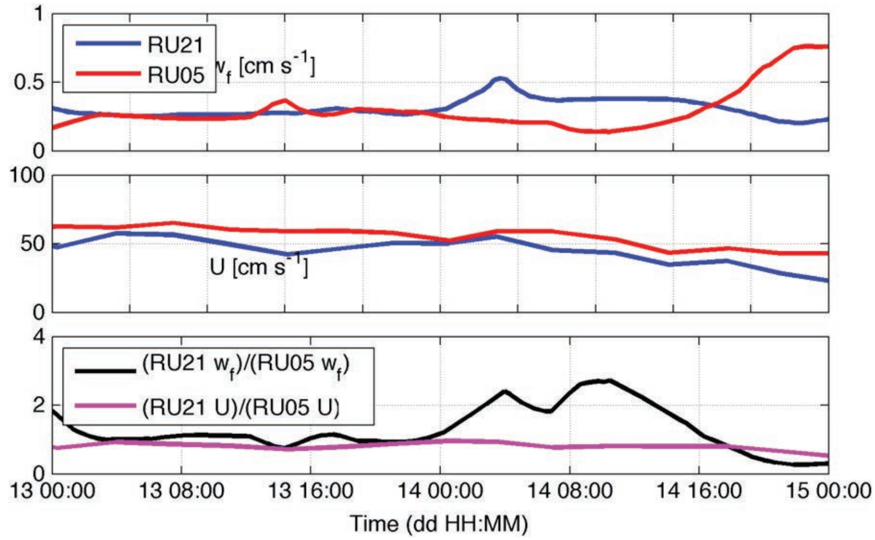

Fig. 14. Time-series of (top) estimated fall velocities for (blue) RU21 and (red) RU05, (middle) magnitude of depth-averaged currents for (blue) RU21 and (red) RU05, and (bottom) the ratio of (black) RU21 to RU05 fall velocities and (magenta) depth-averaged currents, all during the resuspension event.

with mean grain size of over 0.8 mm on the 15th. Conversely, RU21 was in a region with mean grain sizes from 0.4 mm to 0.6 mm on the 13th through 14th. On the 15th RU21 entered a region of reduced mean grain size of $\sim$0.3 m^{-1}.

A study by Agrawal and Pottsmith (2000) as part of the LEO-15 project, which took place within a few kilometers of the deployment location of RU05 and RU21, developed a local model for the fall velocity: $w_{f,n} = 0.45 \times 10^{-3} a_n^{1.2}$ where a_n is the radius in microns and w_f is the settling velocity in cm s^{-1}. As mentioned previously fall velocity is essentially the tendency of sediment to fall out of concentration and u_* is the tendency for particles to remain in suspension. Following the above equation we calculate fall velocities for the sediment grain sizes mapped below the glider during the resuspension event on the 13th through 15th (Fig. 14). Fall velocities are initially greater for RU21 at the peak of the storm, and initiation of the resuspension event at midnight on November 13th. As the gliders progress fall velocities are approximately equal for RU21 and RU05 until the 14th when RU21 fall velocities increase and RU05 fall velocities decrease. While we use the standard deviation of glider vertical velocities as a relative approximation of the timing of turbulent motions, these values are not sufficient to directly substitute for values of u_*. Lentz et al. (1999) uses depth-averaged velocities to estimate bottom stress τ_b. If we follow this model and subsequently calculate a depth-averaged representative friction velocity then we would see u_* values proportional to glider velocities. A time-series of depth-averaged velocities during the storm event are shown in Fig. 14. RU05 depth-averaged velocities are $\sim$5–10 cm/s greater than RU21 through the 13th and are approximately equal on the 14th. As our depth-averaged velocities are only proportional to friction velocity we cannot calculate a direct ratio of w_f/u_*.

For comparison, we calculated the ratio of RU21 to RU05 estimated fall velocities between the two gliders as well as the ratio of RU21 to RU05 depth-averaged glider velocities, which should be approximately equal to the ratio of friction velocities (Fig. 14). Fall velocity ratios were initially high, similar to RU21 fall velocities and grain-size. From 4:00 to 22:00 GMT on the 13th fall velocity ratios are near one. On the 14th the RU21 to RU05 fall velocity ratio increased by over a factor of two, until they drop again late on the 14th as the gliders began to turn onshore. The ratio of RU21 to RU05 depth-averaged glider velocities was just below one for the duration of the resuspension event on November 13th through the 14th. Calculated standard deviations of RU21 to RU05 fall velocities and depth-averaged glider velocities are 0.62 and 0.08 respectively. The much larger standard deviation in the estimated fall velocity ratio shows that differences in grain size and subsequently fall velocity plays a larger role than current variability in the resuspension and transport dynamics during this storm event. Comparison of our fall velocity ratio to slopes of optical backscatter profiles in Figs. 8 and 9 for RU21 and RU05 respectively, show that profiles were Rouse-like throughout the water column for the 13th and 14th for RU05. These profiles are indicative of full water column resuspension of relatively smaller particles, which remained in suspension for the duration of the event. Optical backscatter profiles from RU21 were much more vertical than RU05 until mid-day on the 14th when resuspension peaked throughout the water column. Later on the 14th and into the 15th profiles of RU21 optical backscatter demonstrated a near bottom layer, which along with fall velocities indicates that larger particles were falling out of suspension or unable to make it into the upper portion of the water column. The differences in grain size and resuspension characteristics from the northern glider, RU21 and southern glider RU05 show that even during the largest storms local variability in bed characteristics can play a major role in modulating sediment resuspension and subsequently transport on the continental shelf. Our study demonstrates that during storms on the continental shelf, variability in bottom character also drives local variability in the magnitude and direction of sediment transport. Through glider spatial surveys of sediment transport and resuspension, we have shown that detailed spatial surveys and continually updated spatial maps similar to those produced by Goff et al. (2008) may be necessary to fully understand water-column sediment transport. These spatial surveys will not only support further understanding of observational data over shelf-wide spatial scales, but can also be used to quantitatively enhance realistic regional sediment resuspension and transport models.

5. Conclusion

Here we have demonstrated the importance of utilizing novel ocean observation technology, such as gliders and CODAR to resolve shelf-scale resuspension and transport during storms. A fleet of autonomous gliders not only provided information on sediment transport and resuspension over large spatial areas, but

Please cite this article as: Miles, T., et al., Temporal and spatial variability in fall storm induced sediment resuspension on the Mid-Atlantic Bight. Continental Shelf Research (2012), http://dx.doi.org/10.1016/j.csr.2012.08.006

also emphasized the importance of local variability in grain-size on estimates of shelf-wide sediment resuspension and transport, even in the largest storms. With little observed influence from tides, Langmuir cells or topography, the simple balance between turbulent shear stress and fall velocity, which varies with grain-size, played a major role in observed differences in sediment resuspension and transport along the mid-shelf. Future inclusion of glider fleets and CODAR networks along with traditional tripod and buoy instrumentation will allow for a more holistic view of sediment transport and resuspension along continental shelves, during storm events in particular, when shipboard measurements are not possible. These data will also aid in developing more robust regional models by feeding real data into predictive models as storms occur. In order to further understand the dynamics of sediment resuspension and transport on shelf-wide scales, the inclusion of acoustic and holographic sensors in addition to optical sensors on glider platforms will be necessary. This will help to accurately identify the nature of suspended particles when sediment bed information is lacking and will also provide more *in situ* information regarding the magnitude and direction of current profiles and transport during storm events.

Acknowledgments

Data used in this study was acquired by the Rutgers University Coastal Ocean Observation Lab (R.U.COOL) and NOAA. R.U.COOL is supported by ONR, NOAA, IOOS, NSF, DHS, DoD, NASA, NOPP and the State of New Jersey. Glider data for this study came from a deployment for the NSF Ocean Observing Initiative as part of a Cyber Infrastructure Implementing Organization testbedding activity. We would also like to thank Teledyne-Webb Research for graduate student support and continued technical support. The Mid-Atlantic Bight High Frequency Radar network is funded by IOOS. ***Abstract*— During the summer of 2011 a large phytoplankton bloom occurred off the New Jersey coast, which was monitored using an existing ocean observatory. There was public concern about the root causes of the phytoplankton bloom and whether it reflected anthropogenic loading of nutrients from the Hudson River or whether it reflected coastal upwelling. We used the MARACOOS network to determine what were the likely drivers of the phytoplankton bloom. The bloom was studied using satellites, HF radar, a Hydroid REMUS and Webb Slocum gliders. Chlorophyll concentrations were over an order of magnitude larger than the decadal mean of ocean color data and the bloom was initiated by upwelling winds throughout the month of July that continued to dominate the wind patterns until the passage of Hurricane Irene. The high concentrations of phytoplankton resulted in the supersaturated oxygen values in the surface waters; however the flux of organic matter resulted in oxygen saturation values of <60% in the coastal bottom waters, which is sufficient to stress benthic communities in the MAB. Discrete samples identified the bloom was dominated by mixed assemblages of motile dinoflagellates. The passage of Hurricane Irene increased the oxygen saturation at depth by close to 20%, but was not sufficient to terminate the bloom. A re-analysis of the CODAR clearly indicated that the shelf wide bloom most likely originated from nearshore the New Jersey coast. Upwelling provided the source water that fueled the bloom. Alternating winds transported the bloom offshore and across the Mid-Atlantic Bight. This is consistent with past studies that observed regions of recurrent hypoxia on the New Jersey inner shelf are more related to coastal upwelling than riverine inputs.**

***Index Terms*—ocean observatories, hypoxia/anoxia, phytoplankton blooms**

I. Introduction

A widespread decline in bottom dissolved oxygen (DO) levels to hypoxic/anoxic conditions impacted nearly the entire New Jersey continental shelf in 1976, resulted in significant economic losses in shell-fishing and related industries [1, 2]. It was driven by a causal series of events that included large runoff during a warm winter resulting in early stratification of the shelf, followed by the development of a strong deep summer thermocline during an unusually hot summer, persistent southerly winds with fewer than usual storms, a large phytoplankton bloom with low grazing by zooplankton, and respiration and decomposition of the bloom below the seasonal thermocline. The source of the nutrients fueling the bloom was the major question. The initiation of coastal monitoring conducted in response to the 1976 event focused on the working hypothesis that the major source of nutrients was due to anthropogenic loading from urbanized riverine inputs [3]. An alternative hypothesis was posited by Glenn et al. [4], that regions of recurrent hypoxia on the New Jersey inner shelf were more related to coastal upwelling than riverine inputs of nutrients. The largest variations in ocean temperatures along the New Jersey coast, other than seasonal, are due to episodic summertime upwelling events driven by topographic variations associated with ancient river deltas that cause upwelled water to evolve into an alongshore line of recurrent upwelling centers [5]. These centers are co-located with historical regions of low dissolved oxygen [4].

In summer 2011, a series of visible images [Figure 1], indicated the presence of a large phytoplankton bloom off the coast of New Jersey. The dramatic imagery captured the

Massive algae bloom off New Jersey coast not expected to move in near future

Figure 2. Headlines in response the release of the satellite imagery of the phytoplankton off the New Jersey coast.

resulting discourse resulted in a series of debates of the cause ranging from the bloom being fueled from anthropogenic loading of nutrients from the Hudson River estuary or that it reflected the upwelling processes. Having access to an existing ocean observatory [6], we conducted an analysis of the factors to assess the likely causes of the algal bloom, its potential impact on the coastal water quality and the response to Hurricane Irene. The multiple assets present in the waters reflected a range of projects funded by a range of sponsors that included National Oceanic and Atmospheric Administration, Environmental Protection Agency, Office of Naval Research, and Department of Homeland Security.

Analysis of the Bloom. For this analysis we will focus on the mid-July through Hurricane Irene in late August. Throughout early July wind were largely from the Southwest, which is upwelling favorable followed by a week with generally weak downwelling winds [Figure 3]. An analysis of the satellite imagery shows the bloom in late July or early August. Prevailing cloud cover unfortunately resulted in relatively poor coverage during this time. The sea surface temperatures prior to the passage of Hurricane Irene show the Mid-Atlantic Bight (MAB) bounded by the Gulf Stream offshore and cooler waters to the north [Figure 4]. In mid-July along the coast of New Jersey and Delaware, there were small zones of cooler water, which is indicative of coastal upwelling. The amount and spatial extent of the cooler water was variable and reflected the variability in the winds; however overall the amount of upwelling appeared to decline into the month of August prior to the arrival of Hurricane Irene. The ocean imagery showed low phytoplankton in the middle of July however little of the coastlines were visible given the prevailing cloud cover [Figure 5]. There was a significant increases in biomass by the second week of August. By Mid-August chlorophyll concentrations were well above 10 mg m^{-3}, which is significantly greater than climatological summer mean of chlorophyll which is ~0.5 mg m^{-3} for the MAB shelf [7]. The high concentrations of chlorophyll was confirmed with *in situ* fluorometery measurements made with a Hydroid REMUS system that surveyed the inner half of the bloom offshore Tuckerton New Jersey. Discrete surface samples were collected and were analyzed on a microscope and the dominant alga present within the bloom appeared to be *Gymnodinium*

species. This is a motile dinoflagellate species, potentially allowing it access nutrients below the strong pyconcline and maintain themselves in the well lit euphotic zone.

The high concentration of phytoplankton had significant impacts on the biogeochemistry of the MAB which was documented by autonomous underwater vehicles. A Teledyne

Webb glider had been deployed on the shelf and was outfitted with an Anderra Optode to provide measurements of oxygen concentrations for the New Jersey Department of Environmental Protection and the Environmental Protection Agency. The goal was to assess conduct a nearshore survey mapping if there were regions of low dissolved oxygen in bottom water offshore New Jersey. The glider conducted a southerly alongshore transect. The glider encountered super saturated oxygen concentrations in the upper mixed layer [Figure 6]. In contrast the bottom water show low dissolved oxygen concentrations with pre-Irene bottom water values heavily weighted to values lower then 5 mg L^{-1} [Figure 7]. These values were approaching values associated with potential animal mortality at 2.2 mg L^{-1} (indicated by the red arrow). The low values observed by the gliders prompted a series of adaptive surveys conducted by NOAA to confirm the presence of low bottom water oxygen levels. As part of those surveys, a Hydroid REMUS was utilized, outfitted with an Anderra Optode, and was deployed in low bottom water regions identified by the glider. The REMUS confirmed the low DO values during its high-resolution survey (inset in upper panel of Figure 7). The higher resolution surveys identified regions with low DO values close to the animal mortality concentrations. The passage of Hurricane and the associated mixing [Figure 6] significantly increased the oxygen concentration in the bottom water [Figure 7].

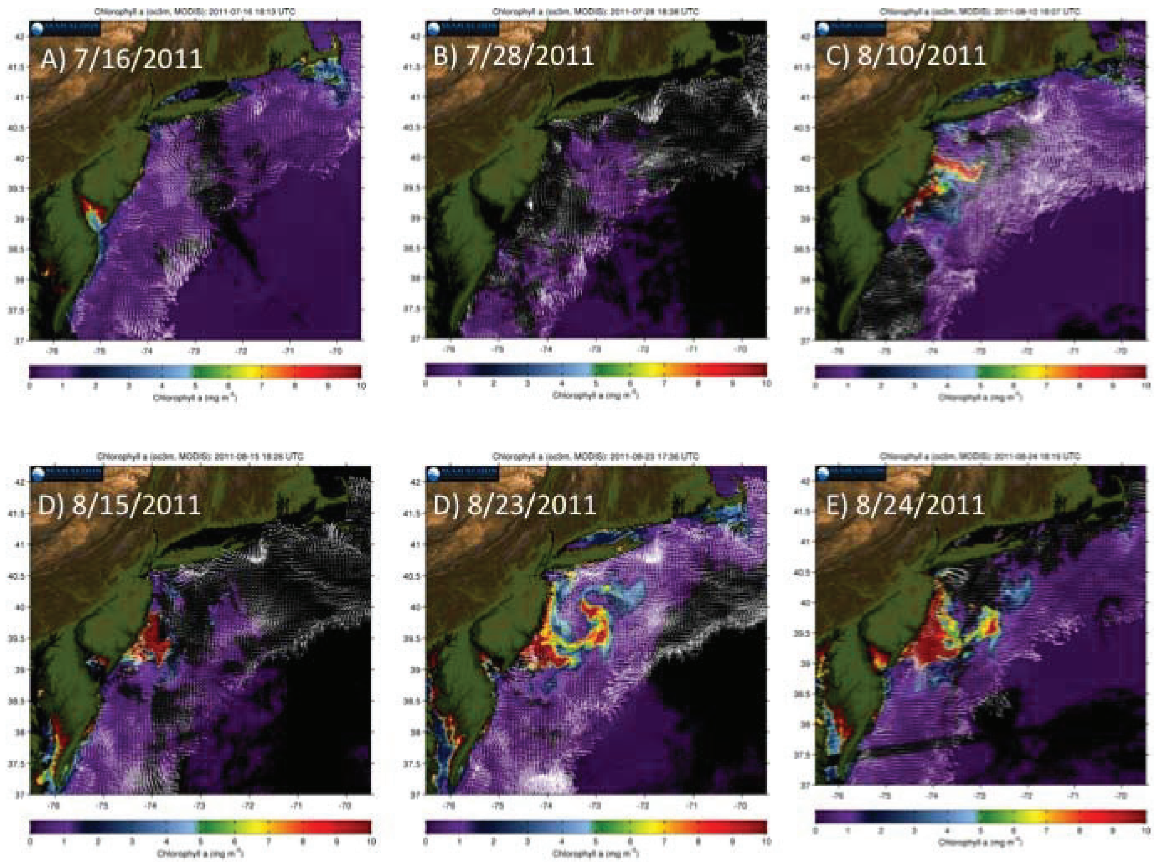

Figure 5. Ocean color estimates of chlorophyll a with the overlaid daily averaged surface currents measured by HF Radar.

The bloom was the result of nutrients provided by either riverine inputs, dominated by outflow from the Hudson river, and/or upwelling. So ultimately tracing the bloom back to its source waters is critical to understanding which processes fueled the bloom. At the start of the bloom and during the bloom, river outflow from the Hudson was low [Figure 8]. The impact of Irene is clearly visible, seen as a double peak in the river outflow [Figure 8], the first associated with the storm and the second to due the enhanced run-off associated with drainage of the water shed which received the majority of the rainfall associated with the storm. Therefore given the low river outflow, it is unlikely the bloom was caused by the Hudson river. This was in contrast to much of general media suggesting pollution run-off from the Hudson River estuary was to blame. To further assess the probable transport of the river and/or upwelled water we utilized the continuous record of data collected by the MARACOOS HF Radar array.

The HF radar surface currents maps were seeded with hypothetical passive particles, which were advected forward in time based on the measured currents. The trajectory of particles were tracked. Each day new particles were added, at three source locations [Figure 9]. The experiment was conducted for the month of July and up to the arrival of Hurricane Irene at the end of August. The final locations for all the drifters is shown in bottom panels in Figure 9. The left-handed panel is the trajectory of the particles released at the mouth of the Hudson river estuary. The majority of the particles are trapped at the mouth of the estuary, which reflects the bottom topographic

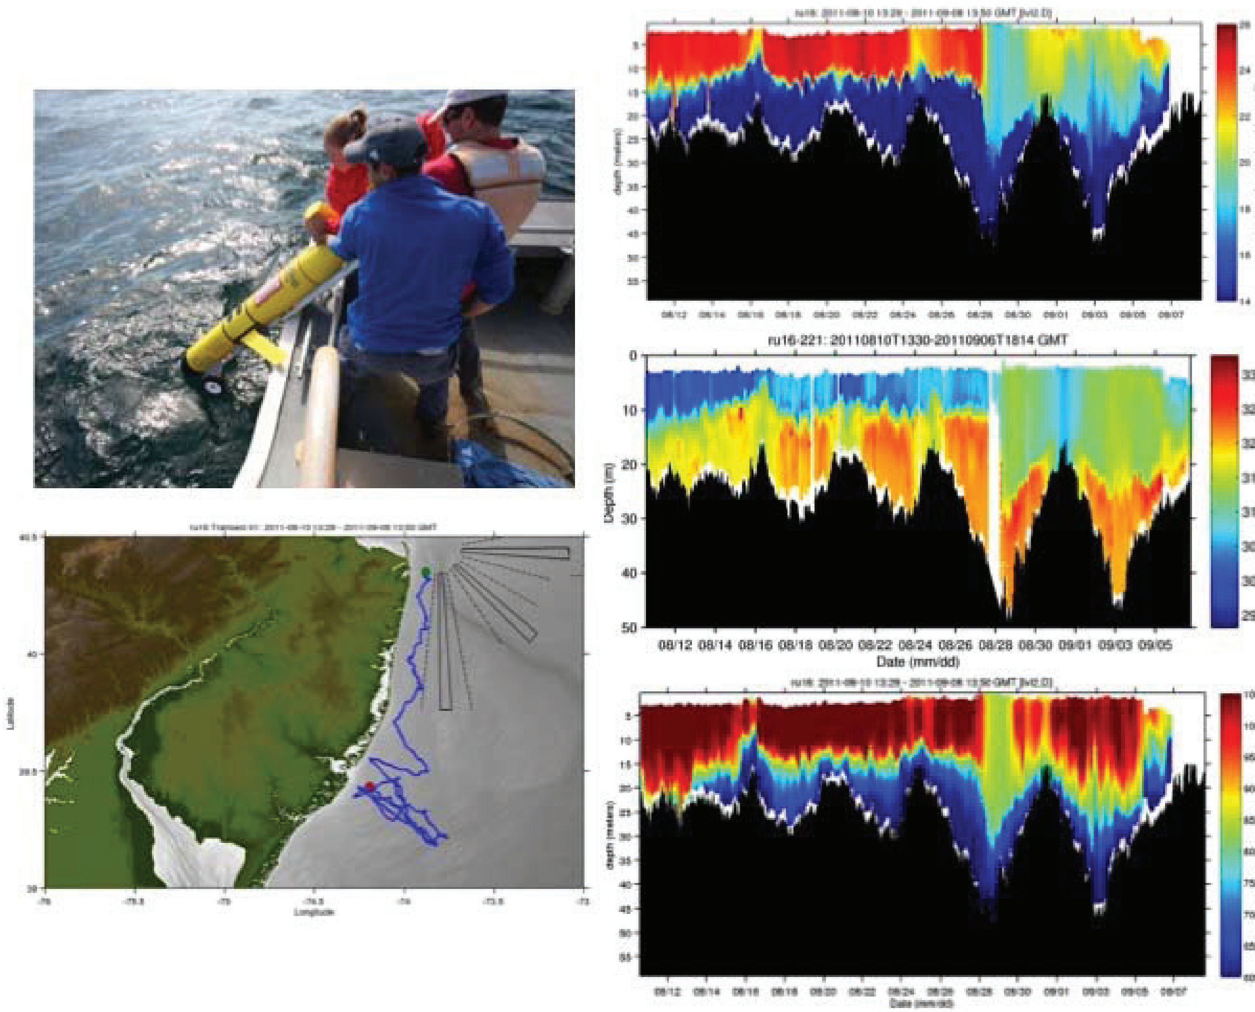

Figure 6. A Webb glider collected data offshore New Jersey in the summer of 2012. The glider, deployed by Rutgers collaborating with the New Jersey State of Environmental Protection (NJ DEP) and the EPA, was focused on measuring the water quality status in the New Jersey coastal waters. The mission consisted of a southerly transect "zig-zaging" inshore and offshore. Upon the approach of Hurricane Irene the glider was directed offshore and then was recovered after the conditions permitted boat operations. The right hand panels show glider data from the deployment. From top to bottom, the data is for temperature, salinity and the percent saturation of oxygen respectively. The passage of Hurricane Irene is clearly visible on August 28-29 as an immediate decline in surface water temperature. The mixing increased the salinity in the surface waters and increased the percent oxygen concentrations in the bottom water (see Figure 7).

affects on the river outflow circulation [8, 9]. The offshore boundary of the particles is associated with the edge of the Hudson Canyon. The majority of chlorophyll observed in the ocean color imagery is associated with the waters offshore and south of the river advection footprint. This combined with the overall low river outflow does not support hypothesis that the Hudson river is the source of chlorophyll (and/or nutrients promoting high growth) during the summer bloom in 2012. The right hand panel shows the advection footprint for the central New Jersey coast. The particles fan out over the broader shelf and high concentrations of advected particles are associated with the waters phytoplankton bloom. This is consistent with the hypothesis that the bloom is driven by upwelled water driven by the persistent Southwest winds found during the bloom. These maps represent a relatively

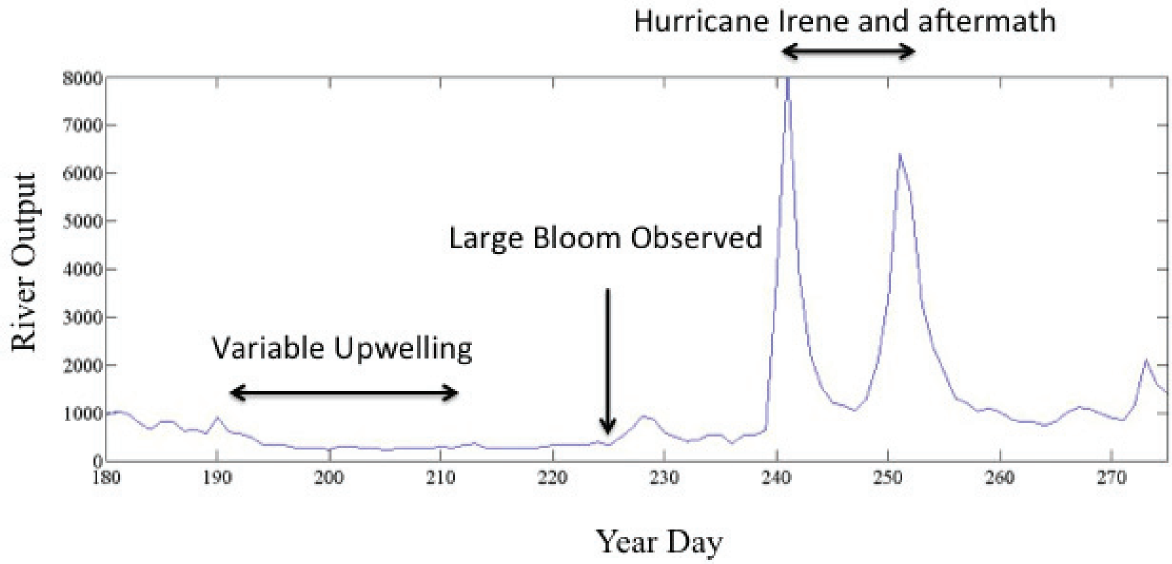

Figure 8. The outflow of the Hudson River during the summer bloom of 2012.

conservative estimate, as the phytoplankton biomass will be more dynamic given the variability in growth rates as well as the associated export to the sea floor.

CONCLUSIONS:

1) The phytoplankton bloom was most likely driven by upwelling, which induced the dinoflagellate bloom. The bloom was able to thrive given the ability of the cells to access nutrients in the subsurface waters.

2) The export of organic carbon associated with the bloom was likely the main culprit in driving the declines in the bottom water oxygen.

3) The availability of a existing ocean observatory allowed the bloom dynamics to be adaptively sampled in near real-time. This illustrates a unique tool for managing water quality of coastal waters.

ACKNOWLEDGMENT

This work represents the effort of the entire team of the Rutgers University Coastal Ocean Observation Lab (RU COOL). The work was supported by the IOOS MARACOOS program (NA11NOS0120038) and the ONR MURI program (N000140610739). Finally the support of Rutgers School of Environmental and Biological Sciences and the great state of New Jersey is acknowledged.

Accomplishments and future perspective of coastal ocean observing systems

Coastal oceans are the most densely urbanized regions on the planet with populations growing at rapid rate. In the near future close to 40% of the human population of Earth will live within 100 km of the shore. Many of the largest environmental changes are also found in coastal zones. The associated pressures will only increase as communities increasingly rely on the coastal ocean to provide additional sources of energy (wind, waves, oil and gas), demand that coastal fisheries remain a vital food source, and support enhanced maritime commerce and recreation. As coastal populations disproportionately drive national economies, the changes in coastal systems resulting from continued growth and resource use have the potential to influence national and international social and economic systems. Therefore management and policy need to be informed by science that can provide a quantitative understanding of coastal ecosystems.

Despite these pressing needs, our ability to map and forecast the coastal ocean remains low. While certain areas are difficult to sample, the turbulent nature of the coastal ocean makes it difficult to model. This has lead to repeated calls to develop and deploy coastal ocean observing systems throughout the world. Many of proposed networks will consist of distributed ocean observing/model networks that could provide a seamless 4D (3D in space plus time) view of the ocean with information being delivered to users through wireless networks allowing for two-way control of the network on demand. Ideally these networks map the future trajectory of the world's oceans allowing management/mitigation strategies to be explored based on quantitative understanding.

Advances in technology make these visions a reality in the near future. This special issue of Continental Shelf Research is focused on the coastal ocean observatories and highlights technical advancements that will form the foundation for distributed marine networks. This special issue draws on the results collected from the Alaska Ocean Observing System (AOOS) and the Mid-Atlantic Regional Coastal Ocean Observing System (MARCOOS). These two regional systems are part of the evolving Integrated Ocean Observing System (IOOS) in the United States [see Marine Technologies Society Journal volumes 44(No.6) and 45(No. 1)]. In this special issue we highlight key technologies that are central to coastal observatories spanning from satellites, data assimilative and forecast models, autonomous underwater vehicles (AUVs), and high frequency (HF) radars. As the AOOS and MARCOOS systems are rapidly maturing, they have collected valuable data. We therefore highlight how the observatory data is improving our understanding of coastal ecosystems. Examples provided in this special issue show how the observatories are improving our understanding of sediment resuspension and transport during storms, circulation in enclosed seas, atmosphere ocean coupling, role of mixing in structuring marine food webs, the dynamics and consequences of buoyant plumes into coastal waters, and atmosphere/ocean interactions.

This special issue will hopefully contribute to demonstrating how the expanding network observatories will improve our understanding of coastal ecosystems. This will in turn increase the number of tools available to us to better utilize, manage and sustain our coastal waters. This comes at a critical time, given the increasing human pressures being placed on our coastal waters.

Small-scale variability of the cross-shelf flow over the outer shelf of the Ross Sea

Josh Kohut,[1] Elias Hunter,[1] and Bruce Huber[2]

Received 31 May 2012; revised 11 December 2012; accepted 17 January 2013; published 10 April 2013.

[1] The importance of cross-shelf transport across the Ross Sea on local and remote processes has been well documented. In the Ross Sea, mid-water intrusions of Circumpolar Deep Water (CDW) are modified by shelf water near the shelf break to form Modified Circumpolar Deep Water (MCDW). In 2010–2011, we deployed multi-platform technologies focused on this MCDW intrusion in the vicinity of Mawson and Pennell Banks to better understand its role in ecosystem processes across the shelf. The high-resolution time and space sampling provided by an underwater glider, a short-term mooring, and a ship-based survey highlight the scales over which these critical cross-shelf transport processes occur. MCDW cores were observed as small-scale well-defined features over the western slopes of Pennell and Mawson Banks. The mean transport along Pennell Bank was estimated to be about 0.24 *Sv* but was highly variable in time (hours to days). The observations suggest that the core of MCDW is transported by a predominately barotropic flow that follows topography around the banks toward the south until the slope of the bank flattens and the warmer water moves up and over the bank. This pathway is shown to link the source MCDW with an area of high productivity over the shallows of Pennell Bank.

1. Introduction

[2] The shelves of Antarctica's continental seas are critical centers for water mass transformation. The water masses that undergo these transformations have origins in the deep ocean and on the shelf itself [*Foster and Carmack*, 1976; *Killworth*, 1977; *Baines and Condie*, 1998]. The seasonal cycle of the high latitudes plays an important role in their formation, transformation, and exchange between the shallow shelves and the deep waters of the Southern Ocean [*Assmann et al*., 2003; *Assmann and Timmermann*, 2005]. In the winter, strong katabatic winds streaming off the Antarctic continent maintain open water polynas with nearly continuous ice formation [*Budillon and Spezie*, 2000; *Fusco et al*., 2009]. The newly formed dense water mixes completely to the bottom and eventually becomes Antarctic Bottom Water (AABW) [*Orsi et al*., 1999; *Gordon et al*., 2009b]. AABW is a key component of the global climate system, bringing cold, recently ventilated water to lower latitudes [*Orsi*, *et al*., 2002; *Jacobs*, 2004]. The austral summer brings warmer temperatures, weaker winds, and nearly continuous solar radiation. This leads to a more stratified water column with a cold fresher layer over the dense bottom water formed the winter seasons before. In the Ross Sea, relatively warm Circumpolar Deep Water (CDW) originating off the shelf preferentially intrudes onto the shelf at sites where the bottom topography changes direction relative to the coastal flow [*Klinck and Dinniman*, 2010]. The CDW then mixes with these shelf water masses at the shelf break to form Modified Circumpolar Deep Water (MCDW) [*Whitworth et al*., 1998]. With neutral densities between 28 and 28.27 [*Orsi and Wiederwohl*, 2009], these intrusions move onto the shelf as mid-water features sandwiched between the dense bottom and lighter surface water masses. This large mass of water injects onto the shelf as mid-water features at specific locations, bringing with it nutrients and heat [*Dinniman et al*., 2003; *Hiscock*, 2004; *Smith et al*., 2006]. The interaction, mixing, and exchange of these water masses helps to maintain deep ocean heat exchange, ventilation, and important ecosystems processes like seasonal blooms [*Arrigo et al*., 2008; *Budillon et al*., 2011; *Fragoso and Smith*, 2012]. While these coastal seas are typically small in area, the role that they play in the exchange of water masses between the shelf and open ocean has important implications to both the global circulation and the critical ecosystem it supports.

[3] Compared to other coastal seas surrounding Antarctica, the Ross Sea in the Pacific sector of the Southern Ocean is relatively well sampled (Figure 1). Following *Orsi and Wiederwohl* [2009], we characterize the water masses of the Ross Sea based on their neutral densities as follows: (1) dense bottom water (neutral densities greater than 28.27), (2) MCDW/CDW (neutral densities between 28.0 and 28.27),

The black triangle indicates the glider's location at the start of the ship survey.

and (3) surface water with neutral densities less than 28.0 (Figure 2). The distribution of these water masses has been described in the context of available data primarily from ship surveys and moorings. In the western Ross Sea, dense High Salinity Shelf Water (HSSW) sinks to the seafloor and splits with a southward branch going under the Ross Ice Shelf and a northward branch heading toward the shelf break. The asymmetry of the deep water formation centers across the entire sea sets up an east/west density gradient with denser water under the formation centers to the west [*Jacobs and Giulivi*, 1998; *Rickard et al*., 2010]. The weaker winds and warmer temperatures of the Austral summer stratify the western Ross Sea with a layer of fresher water capping the HSSW formed the seasons before. As the small winter polyna grows to open the entire Ross Sea, blooms of phytoplankton form the base of the food web. It has been suggested that these blooms are maintained in part by the delivery of macro- and micro-nutrients from the deep water off the shelf [*Hiscock*, 2004; *Fragoso and Smith*, 2012]. In

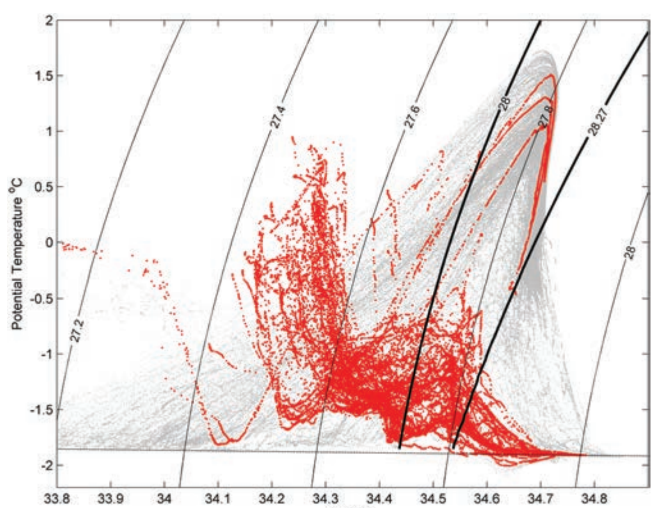

Figure 2. Potential temperature and salinity data for stations sampled by the *RVIB Nathaniel B. Palmer* from 2000 to 2005 (gray) and the SEAFAReRS cruise in 2011 (red). addition to the nutrient supply, this warmer deep water is a source of heat that impacts the rate of sea ice formation and melt through the seasons and could impact the rate of basal melt below the ice shelf if it reaches far enough south.

[4] The Ross Sea shelf break is a critical region for both the exchange of bottom water that moves down the slope and eventually forms dense AABW [*Gordon et al*., 2009a] and the injection of warm CDW that comes from the mid-depths of the Southern Ocean. Both the deep water formed on the shelf and the mid-water of the deep ocean are modified as they move across the shelf break by local mixing processes [*Whitworth et al*., 1998; *Robertson et al*., 2003]. The most energetic process that likely contributes to this mixing is the tides. The tides of the Ross Sea are predominately diurnal with higher amplitudes over the shallow banks and along the shelf break [*Robertson*, 2005; *Whithworth and Orsi*, 2006; *Padman et al*., 2009]. The tides interact with the varying topography and the background flow along the shelf break toward the west to mix and modify the water masses before they move away from the shelf break [*Dinniman et al*., 2003; *Gordon et al*., 2009a]. The dominant advective feature along the shelf break is the mostly westward jet maintained by the density gradient across the shelf break. Instabilities and interactions of this jet with the underlying topography lead to preferential centers of CDW intrusions onto the shelf [*Klinck and Dinniman*, 2010].

[5] While this shelf break region is undersampled, both observations and numerical studies have identified its importance to the north/south exchange of water masses. These studies are based on observations collected during intensive surveys and mooring deployments [e.g., *Gordon et al*., 2009a] and numerical models verified by either the direct observations [e.g., *Dinniman et al*., 2003] or climatologies determined from the observations [e.g., *Klinck and Dinniman*, 2010]. In the early 2000s, a field program was conducted as part of the AnSlope project [*Gordon et al*., 2009a] with ship surveys and mooring deployments focused on the shelf break near Drygalski Trough in the northwest Ross Sea. These critical observations have shown the importance of the shelf break as the basis for the formation of the dense water that sink and form AABW [*Muench et al*., 2009; *Gordon et al*., 2009b]. These papers cite the importance of the tides in not only mixing the parent water masses of the Ross Sea but also modulating the position of the shelf break jet. The north south movement of this jet by the tides may facilitate the exchange of dense water off the shelf and into the deep sea along the seafloor. Similarly, the variability of this jet and its interaction with the underlying topography likely control the variability observed in the movement of CDW onto the shelf [*Dinniman et al*., 2003]. At specific locations along the shelf break, sharp changes in the orientation of the isobaths along the general path of the shelf break jet lead to preferential locations for intrusions of the jet onto the shelf. The models show that these regions of consistent upwelling of CDW coincide with sharp turns toward the north in front of the flow. One region of preferential upwelling is offshore of Joides Trough between Mawson and Pennell Banks (Figure 1). Virtual dye experiments within the modeled current fields identify Joides and Drygalski Troughs as regions of consistent MCDW intrusions. *Dinniman et al*. [2003] suggest that once this CDW is up on the shelf, it mixes with the surrounding shelf water and moves south along the eastern side of Joides trough toward the interior of the shelf.

[6] In this study, we use an extensive multi-platform observation array to characterize the southward flow of MCDW from the shelf break to the interior of the Ross Sea Shelf as part of the Slocum Enhanced Adaptive Fe Algal Research in the Ross Sea (SEAFAReRS) project. The sampling is focused on the western slope of Pennell Bank along the eastern edge of Joides Trough shoreward of the shelf break and the CDW mixing sites associated with the shelf break jet. Particular emphasis on the small time and space scales of the MCDW intrusion drove the sampling design. A ship survey, glider Autonomous Underwater Vehicle (AUV) mission, and a mooring deployed at a depth of 400 m are used to characterize the spatial and temporal variability of the southward flow of MCDW. Section 2 describes the platforms and available data, and section 3 presents the results. Implications and concluding remarks are discussed in sections 4 and 5, respectively.

2. Data

2.1. Glider AUV

[7] A deep Slocum electric glider manufactured by Teledyne Webb Research was deployed. The buoyancy-driven propulsion of the glider AUV affords high-efficiency and deployment endurance [*Schofield et al*., 2007]. Throughout the mission, the glider moved in a sawtooth pattern between 10 m below the surface and 10 m above the bottom determined from onboard pressure and altimeter data. This glider was equipped with a sensor suite that characterized the ecosystem's physical structure (conductivity, temperature, depth, and dissolved O_2), in situ phytoplankton fluorescence and optical backscatter. On 10 December 2010, the deep glider was deployed from the sea ice edge near Ross Island. The 52 day mission took the glider east along 76.5°S before turning toward the northwest over Ross Bank (Figure 1). The glider then completed a cross section of Pennell Bank, Joides Trough, and up the eastern slope of Mawson Bank before heading back east toward Pennell Bank. The glider began this section near Ross Bank on 28 December 2011 and completed the section 13 days later near Mawson Bank on 10 January 2011. Nine days before the ship left the dock, these data helped guide the initial ship sampling plan with a high-resolution section of temperature, salinity, density, and dissolved oxygen (Figure 3). Once the ship started its survey on 10 January 2011, the complimentary glider sampling provided high vertical and horizontal resolutions of the physical characteristics in the vicinity of the flow along western Pennell Bank and into Joides Trough. The glider was recovered on 4 February toward the end of the ship survey. The CTD resolution was 0.25 m in the vertical and approximately 2.2 times the water depth in the horizontal. The CTD data were verified against the ship's data during two calibration casts with the glider secured to the ship's rosette.

2.2. Ship Surveys

[8] A ship survey was completed aboard the *RVIB Nathaniel B. Palmer* (NBP). The ship left McMurdo Station on 20 January 2011 on a 26 day cruise across the Ross Sea.

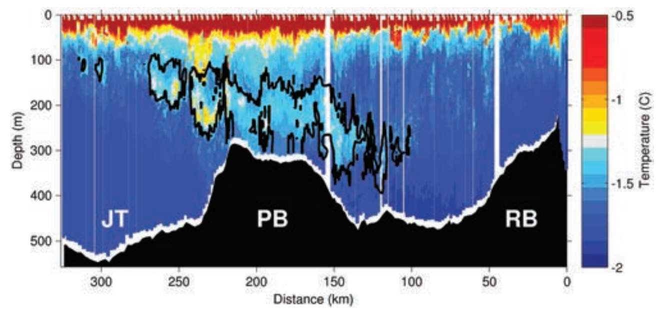

Figure 3. Glider cross section of potential temperature sampled between Ross Bank and Joides Trough. The black contour is the 5.1 ml/L dissolved oxygen isopleth showing the oxygen minimum coincident with the sub-surface temperature maximum associated with MCDW. The topographic features are labeled as in Figure 1.

The sampling focused on the banks and troughs of the outer shelf in the western Ross Sea (Figure 1). Throughout the cruise, underway measurements of temperature and salinity were taken every second with the NBP thermosalinograph at an intake depth of 6.7 m below the surface. These data were sub-sampled every 10 s along the ship's track. Vertical profiles of velocity were sampled by a ship mounted downward looking 150 KHz Acoustic Doppler Current Profiler (ADCP). These shipboard data were processed with the University of Hawaii Data Acquisition System (UHDAS) software. Five minute ensembles were collected with a vertical bin resolution of 8 m. Raw depth-averaged and depth-dependent data were de-tided using the predicted barotropic tide derived from Ross Sea sub-region of the Oregon Tidal Prediction System (Figure 4) [*Erofeeva et al*., 2005].

[9] In addition to the underway data, the ship survey completed 79 stations (Figure 1). At each station, at least one full water column profile of the ship's CTD rosette was completed. All stations were sampled at least once with more frequent repeat stations along the southern line crossing both Pennell and Mawson Banks. The Sea-Bird CTD mounted on the rosette was calibrated before and after the cruise. Our analysis will focus in on a single along-bank section from off the shelf to the southern end of Pennell Bank and eight repeat cross sections across Pennell Bank, Joides Trough, and Mawson Bank (Figure 1). The distribution of the potential temperature and salinity sampled over these stations is shown in Figure 2.

2.3. Mooring Deployment

[10] A surface-buoyed mooring was deployed on 27 January 2011 for 13 days on the western side of Pennell Bank (Figure 1). It was anchored to the bottom on 600 m of mooring wire in water 400 m deep. After recovery from a 3 year deployment as part of the Cape Adare Long-term Moorings (CALM) project earlier in the cruise, the sensors were quickly repurposed for this short redeployment focused on the MCDW intrusion. The

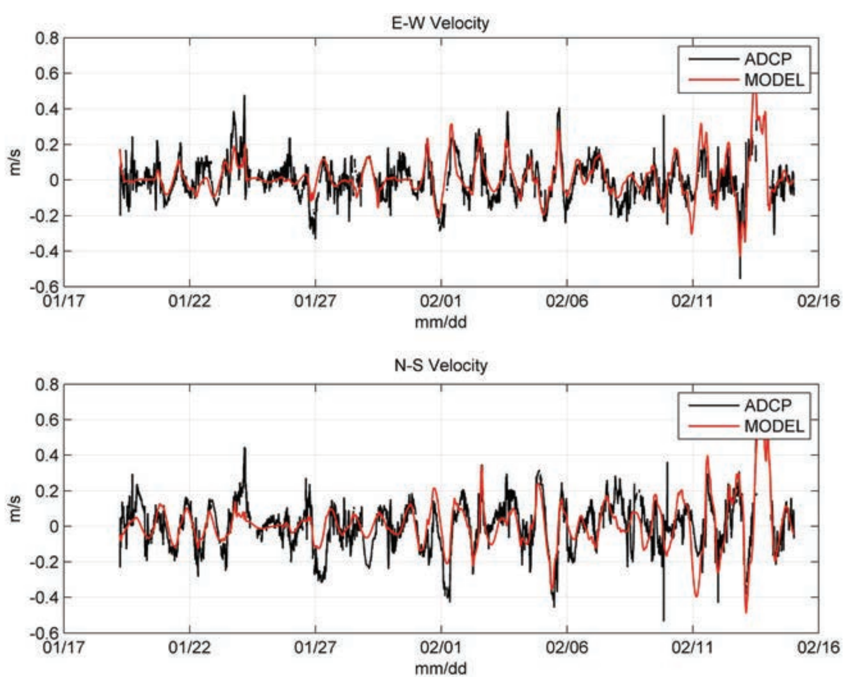

Figure 4. Time series of depth-averaged velocity in the east (top) and north (bottom) components from the NBP hull mounted ADCP (black) and matched tidal velocity estimated from the barotropic tide model Ross_TIM [*Erofeeva et al*., 2005] (red).

sensor distribution and mooring location were determined from by available ship and glider data to target the MCDW core flowing south along the western slope of Pennell Bank. Four depths were instrumented: 50 m (current meter with temperature and pressure), 225 m (current meter with temperature and pressure), 230 m (salinity, temperature and pressure), and 300 m (temperature and pressure). The two mid-water depths (225 m and 230 m) specifically targeted the MCDW water observed by the glider and ship survey. All instruments sampled every 5 min. Current meter magnetic compasses were corrected for the local magnetic declination of 112°.

3. Results

[11] A single glider section across the bank and trough topography of the Ross Sea shows the scale and possible dynamics driving the distribution of MCDW (Figure 3). The glider began the section on 28 December 2010 over Ross Bank and reached Joides Trough on 10 January 2011. The glider section identifies the relatively warmer potential temperature (greater than approximately -1.3°C) and minima in dissolved oxygen indicative of MCDW over the western slope of Pennell Bank and suggests that the core of MCDW mixes up and over the shallows of the bank (Figure 3). The location of the warmer water feature identified through the real-time data feeds from the glider guided the sampling strategy initiated on 19 January 2011 when the NBP left the pier at McMurdo Station. Unlike previous surveys conducted in the Ross Sea, the sampling design centered on this small feature seen on the glider section with repeat ship sections across the bank and subsequent mooring deployment in the core to resolve the relevant time and space scales.

[12] For this study, the observations are organized into along- and cross-bank sections. The along-bank direction was determined to be 20° clockwise from true north based on the largest bathymetric gradient over a scale of 0.5° in latitude (5.5 km) and longitude (1.7 km). In all of the figures, positive indicates flow toward the northeast (20°) and southeast (110°) for the along- and across-bank components, respectively.

3.1. Along-Bank Structure of the MCDW Intrusion

[13] The hydrographic data along the bank was taken over a series of five stations (Figure 5). The southernmost station (#2) was sampled early in the cruise based on initial guidance from the glider locating a core of MCDW along the western slope of Pennell Bank. Six days later, the along-bank section continued with a series of stations beginning off the shelf and moving south along Pennell Bank (stations 14–17, all sampled within 1.5 days of each other). For each station, we show the average profile of the upper 400 m (Figure 6). The gray-shaded region is the portion of the water column in which the neutral density fall within the range set for MCDW as defined in *Orsi and Wiederwohl* [2009]. The potential temperature-salinity plots below each profile are the data for that particular station in red plotted against all the data collected on the cruise in gray. At all the stations, there is a well-defined surface layer of warmer fresher water primarily associated with the melting of the seasonal sea ice and subsequent solar heating (Figure 6). Distinction between the stations is seen in the depth and strength of the thermal gradient between the surface layer and the cooler layer just below. Off the shelf break at the deep water station (14), the warmer CDW is seen at depths deeper than 300 m. Based on the Θ-S characteristics, this station has two clear water masses, a warmer fresh layer within the upper 70 m and the warmer saltier CDW layer below. On the inshore side of the shelf break at station 15, the deep water peak in potential temperature seen in station 14 cools and freshens as it mixes with shelf water, forming MCDW. Continuing south along the bank, the subsequent stations show that dilution of the pure CDW signal seen offshore (station 14) and a general increase in the potential temperature of the surface layer, likely driven by the earlier melt of the seasonal sea ice leading to longer exposure to solar heating. While the depth and vertical extent of the MCDW varies from station to station, this water lay within a broad range of depths between 200 m to 350 m deep.

[14] The velocity data identify how these water masses move across the shelf. Both the depth-averaged and depth-dependent velocity data show a significant rotation in the currents as the ship moved from the deep water off the shelf break southwest along the western slope of Pennell Bank (Figure 7). To the north, the depth-averaged flow of the shelf break jet peaks over the steep slope of the shelf break with a broad shoulder extending south over the shelf. Further to the south, the currents rotate counterclockwise to an approximate along-bank direction in the vicinity of the 400 m isobath west of Pennell Bank. The shelf break jet has a sub-surface velocity peak of about -0.3 m/s 100 m deep at about 73.25°S (Figure 7,

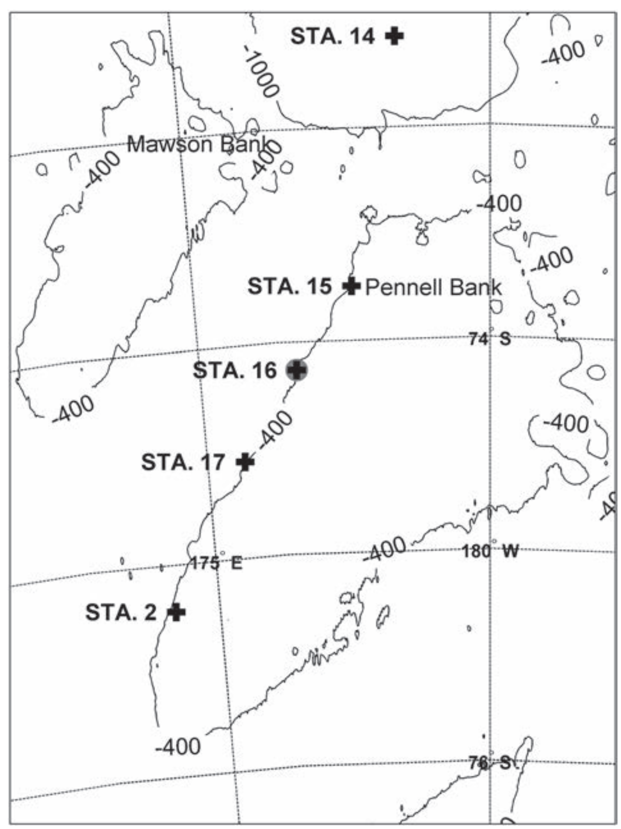

Figure 5. Map showing the ship stations (black cross) included in the along-bank section. The mooring location is shown as a small gray circle.

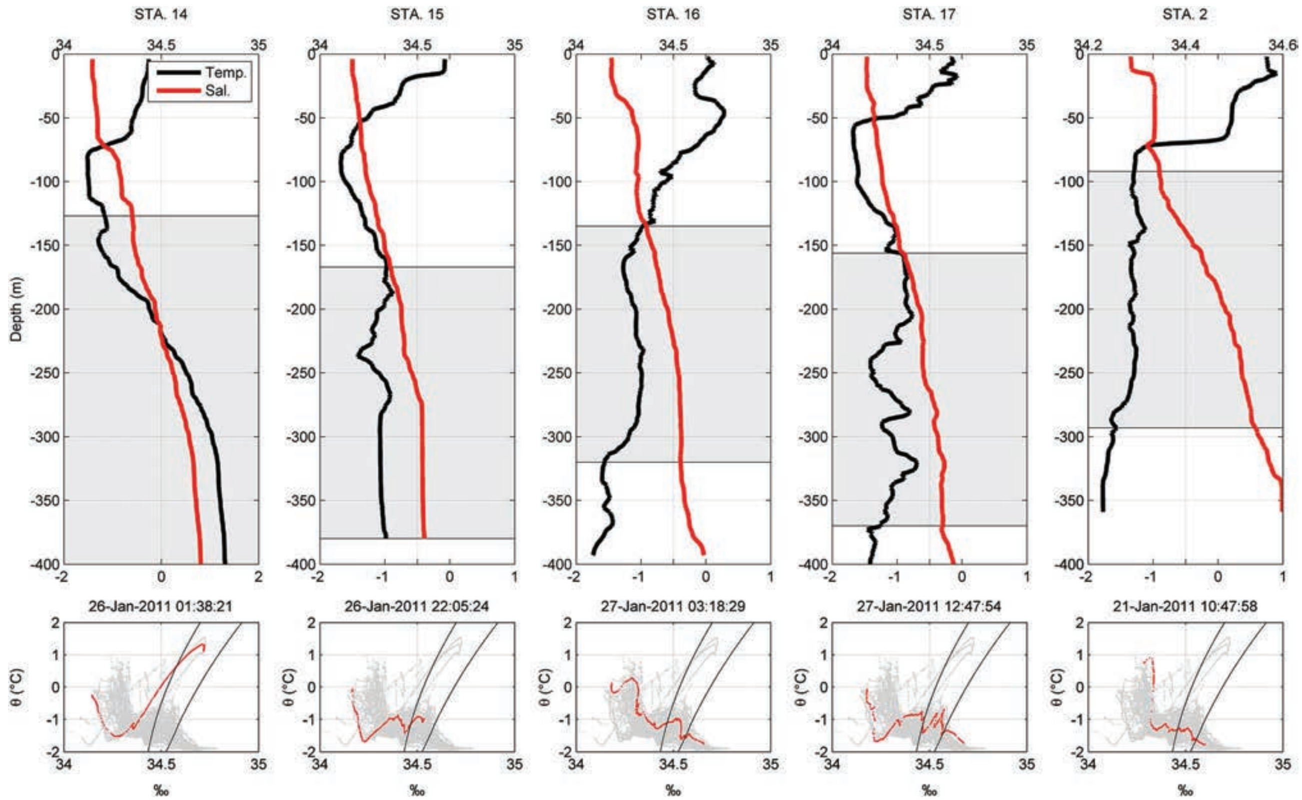

Figure 6. The average potential temperature (black) and salinity (red) for each station in the along-bank line. Vertical distributions of the neutral densities that define MCDW are shaded gray for each station. Below each section, the potential temperature-salinity plot is shown for all stations (gray) and that particular station (red). The neutral density bounds for MCDW are shown as thick black lines.

upper right). The along-bank flow further south is stronger with the strongest velocities exceeding 0.3 m/s in the upper 200 m of the water column.

3.2. Across-Bank Structure of the MCDW Intrusion

[15] Over the course of the cruise, the ship made eight repeat transects across Pennell Bank and Joides Trough (Figure 1). Along this cross section of the banks, we sampled nine stations, five over Pennell Bank, three over Mawson Bank, and one over Joides Trough (Figure 8). At each station, there were at least three CTD casts with a maximum of eight casts sampled at our mooring station over the 400 m isobath along the western slope of Pennell Bank. For each of these stations, we show the Θ-S diagrams for the casts taken at that station (red) relative to all stations sampled throughout the cruise (gray). The warmer fresher surface layer resulting from the sea ice melt earlier in the season and subsequent solar heating is seen across all stations with the warmest surface water over the shallows of the banks. The strongest MCDW signal is seen near Joides Trough and the western slope of Pennell and Mawson Banks, coincident with our mooring site over the 400 m isobath. The deep HSSW is only seen in stations at least 400 m deep.

[16] The mean cross section based on all the casts taken at each station shows the significant variation in water column properties across the complicated topography. There is a clear surface layer of warmer fresher water across the entire section with slightly fresher water over the western slopes of the banks (Figure 9). Below this roughly 80 m deep surface layer, there is significant variability in the distribution of the deeper water masses. At depth in Joides trough, there is a thick layer of dense shelf water reaching up from the bottom to a depth of about 250 m. At mid-depth, the most striking feature is the slug of warmer MCDW centered over the 400 m isobath above the western slope of Pennell Bank. The small region of MCDW is confined to a depth between 180 m and 250 m and is not seen in the neighboring stations. While there is evidence of a similar slug of MCDW over the western slope of Mawson Bank, its potential temperature and oxygen signal are more dilute and spread over a wider range of depths. The contrasting MCDW characteristics between the two banks are likely due to the more energetic tides over the narrower Mawson Bank. This section is consistent with the structure of the MCDW seen by the glider several weeks before with a core of MCDW over the 400 m isobath except that in this section, this warmer water does not extend east over the shallows of the bank (Figures 3 and 9). Unlike the glider section further south, this section completed closer to the shelf break clearly shows the presence of warmer deep water over the slope isolated from the shallows of the bank.

[17] The repeat sections of underway ADCP data describe the movement of these water masses across the shelf. The depth-averaged flow averaged over all eight cross sections shows a clear link to topography with the southward flow over the western slopes of Mawson and Penell Banks and the northward flow along the eastern slope of Mawson Bank (Figure 10, left). For both banks, the flow is about -0.3 m/s and centered just inside the

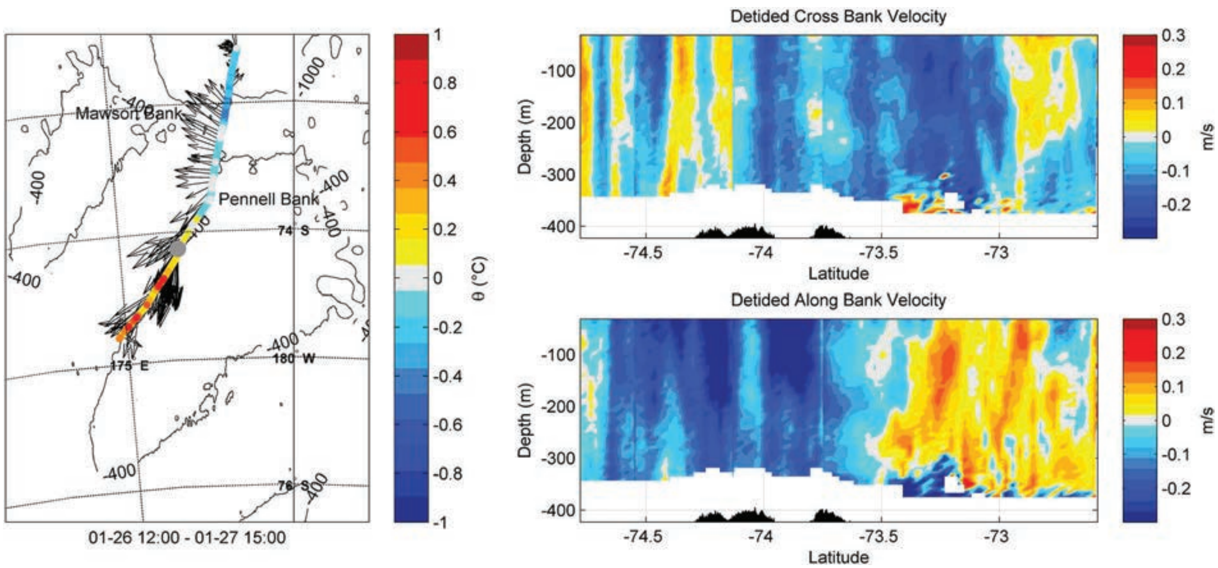

Figure 7. De-tided depth-averaged currents (m/s, black vectors) and surface temperature (colored track) over the along-bank section (left). The depth-dependent velocity sections for the cross-bank (above right) and along-bank (below right) velocity components. The mooring location is shown as a gray circle (left).

400 m isobaths. There is also a second region of southward flow centered over Joides Trough.

[18] The depth-dependent velocity data averaged across all eight cross sections of the banks show the largest vertical shear in the along-bank flows to the north and south over the eastern and western slopes of the banks, respectively. The southward flow along the banks is seen to vary with depth. This mean surface intensified flow of 0.3 m/s decays to about 0.1 m/s at 300 m but never reverses (Figure 10, right). Similarly along the western bank of Mawson, the stronger along-bank velocities are shallower and not as strong as those seen along Pennell. For both banks, this southward flow has a weak upslope component (<0.05 m/s). The upslope velocity is relatively uniform with depth except over Mawson Bank where there is a slight intensification at depth around 225 m deep.

[19] The depth-averaged flow of each individual pass across the banks shows regions of relatively constant and variable flow in time. For all eight sections, the flow over the shallows of the banks shows the most variation (Figure 11). This is particularly evident in the upper four sections sampled almost continuously between 8 February and 12 February. Over Pennell Bank, it transitions from relatively strong northward to periods of weak flow to the south. The most consistent feature across all the individual sections is the southward flow along the western slope of the banks. The depth-averaged flow over both slopes is consistently to the south. From section to section, the character of the flow changes from a relatively narrow jet to a broad feature spreading up toward the shallower depths of the banks.

3.3. Volume Transport Onto the Shelf

[20] Models and sparse observations have identified the importance of topography in steering the transport of MCDW south into the interior of the shelf [*Dinniman et al.*, 2003; *Klinck and Dinniman*, 2010]. Given the location, size, and velocity associated with the MCDW core identified over the western slope of Pennell Bank above, we characterize its transport and variability. Both the glider and ship CTD data identify a small core of MCDW centered over the 400 m isobath characterized by a sub-surface potential temperature maximum, dissolved oxygen minimum, and consistent with the neutral density definitions of *Orsi and Wiederwohl* [2009] (Figures 3 and 9). The depth of the sub-surface peak is about 250 m below the surface but is seen as shallow as 180 m and as deep as 280 m. The MCDW is characteristically warmer than the surrounding shelf water, with lower dissolved oxygen concentrations. These two traits are used in addition to the neutral density bounds defined by *Orsi and Weiderwhol* [2009] to tag water as MCDW.

[21] Using the ADCP and station data from the survey, we estimate a mean volume transport of the layer bounding MCDW (defined by neutral density surfaces as above) along the western slope of Pennell Bank. The height of the layer is estimated from the mean CTD profile taken at the 400 m isobath station. Based on this average profile, the MCDW is seen over 100 m of the water column between 180 m and 280 m deep (Figure 9). The width of the MCDW core was estimated from the ADCP sections. The mean velocity transect averaged across all eight cross sections of the bank shows a clearly defined flow moving south along the western slope of the bank. The width of this jet is approximately 20 km. Therefore, the approximate area of the MCDW layer along the western slope of Pennell bank is approximated as 20 km wide by 100 m high. Using the same ADCP data, we calculate the mean velocity in this sub-section of the average transect to be -0.12 m/s. Based on these data, the estimated transport of MCDW south along Pennell Bank is estimated at 2.4×10^6 m^3/s, or 0.24 *Sv*. Since the concentration of MCDW is not precisely known within the volume used in this estimate, this serves as an upper bound for MCDW transport onto the shelf given our available data.

3.4. Temporal and Spatial Variability of the MCDW Intrusion

[22] This estimate provides a scale for the input of MCDW onto the shelf along Pennell Bank. It does not however

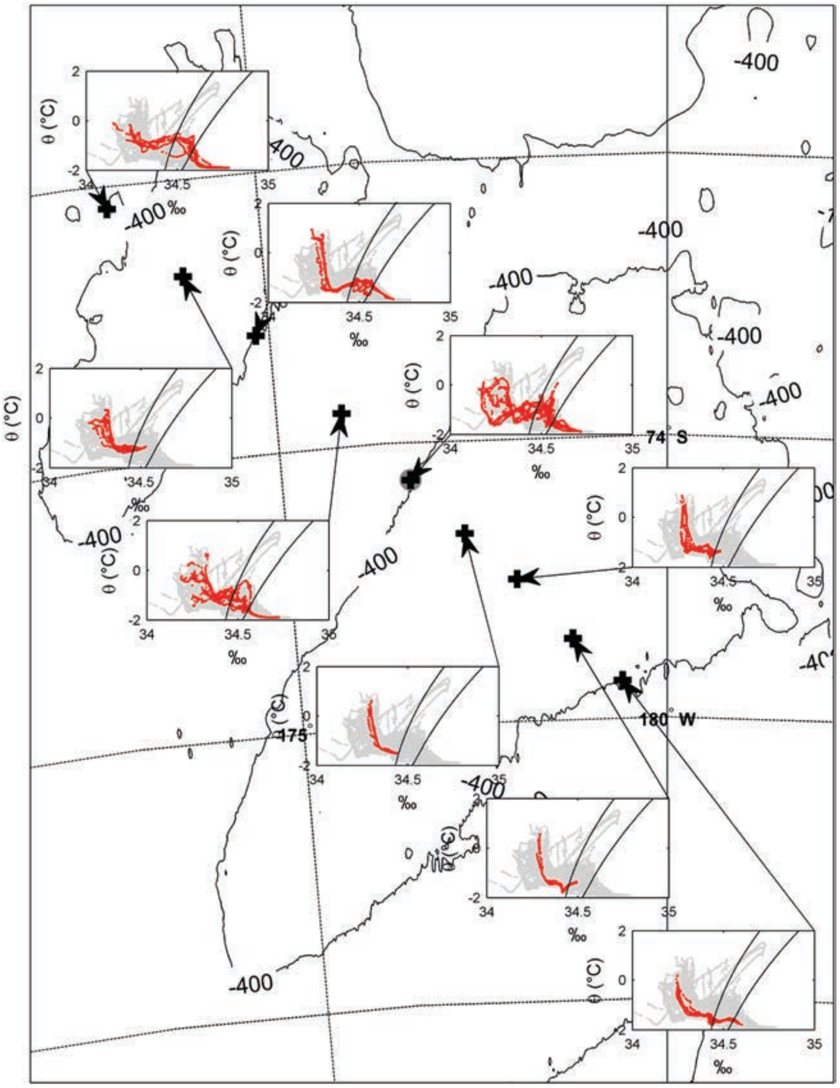

Figure 8. Potential temperature-salinity plots for the cross-bank stations for all stations (gray) and that particular station (red). The neutral density bounds for MCDW are shown as thick black lines. The mooring location (gray circle) is also shown.

adequately represent the significant time and space variability seen in the MCDW core along the banks. The velocity data used to estimate the transport was averaged over eight cross sections of the banks and eight CTD profiles over the 400 m isobath. Both the mooring and glider highlight the variability not captured in this mean estimate of transport. The mooring deployed directly over the 400 m isobath was instrumented at several depths including 225 m and 230 m within the approximate core of MCDW. The 13 day time series shows significant variation in velocity, potential temperature, and salinity. At least 85% of the variability in each velocity component is explained by the strong diurnal tide modulating the along-bank jet in both the along- and across-bank directions. The high-frequency velocity data at 225 m is dominated by the diurnal tide that transitioned from spring to neap over the duration of the deployment. Along-bank flow was consistently toward the southwest at 0.14 m/s, modulated by the tides. The cross-bank flow was upslope at 0.01 m/s, again modulated by the tides. Based on a 25 h running mean, the sub-tidal flow at 225 m depth is relatively steady along isobath throughout the deployment, slightly weakening toward the end of the deployment (Figure 12). The record mean of -0.14 m/s along isobath with a weak upslope component of 0.01 m/s is consistent with the MCDW area mean ADCP value of -0.12 m/s used in the transport calculations in section 3.3.

[23] In addition to the velocity, the potential temperature and salinity sampled at the 230 m depth within the MCDW core had significant variability (Figure 12). Like the velocity, the salinity had a large diurnal signal that ranged from 34.42 to 34.57 through the entire time series. The saltiest water is associated with a weak cross-shore velocity and strong southwestward along-bank velocity. The potential temperature data show a much different response with most of the variation occurring on scales of hours, much shorter than the diurnal signal seen in the velocity and salinity. This is strongest toward the end of 31 January when the potential temperature drops from $-0.4°$ to $-1.5°$ in a few hours. While the potential temperature data were much more variable over a large range of time scales, a diurnal signal was

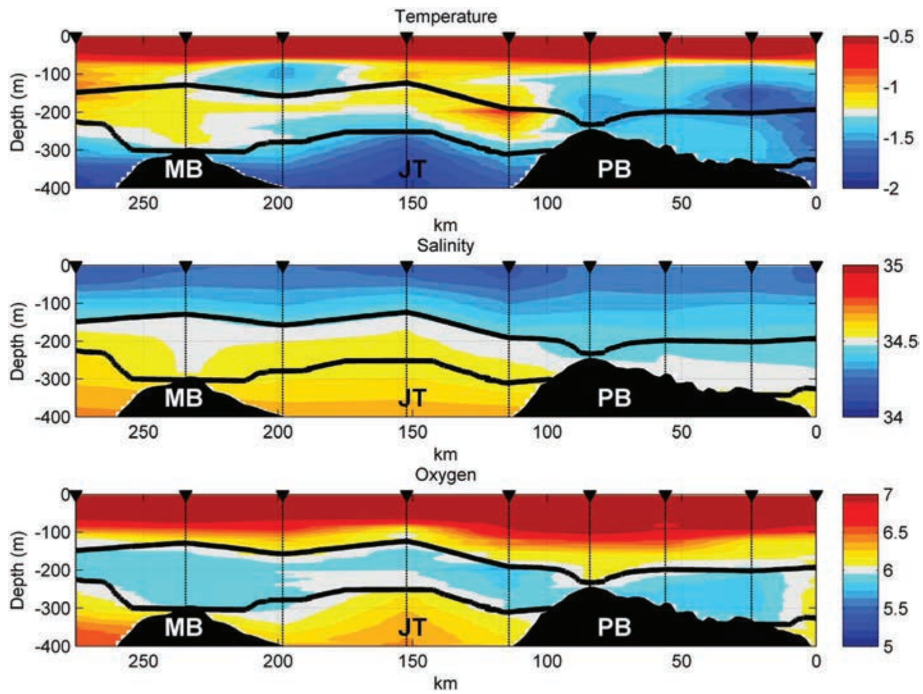

Figure 9. Average cross section of potential temperature (°C, top), salinity (psu, middle), and dissolved oxygen (ml/L, bottom). The stations sampled over the across-bank section are shown as vertical dashed lines. The neutral density bounds defining MCDW are shown in black, and the topographic features are labeled as in Figure 1.

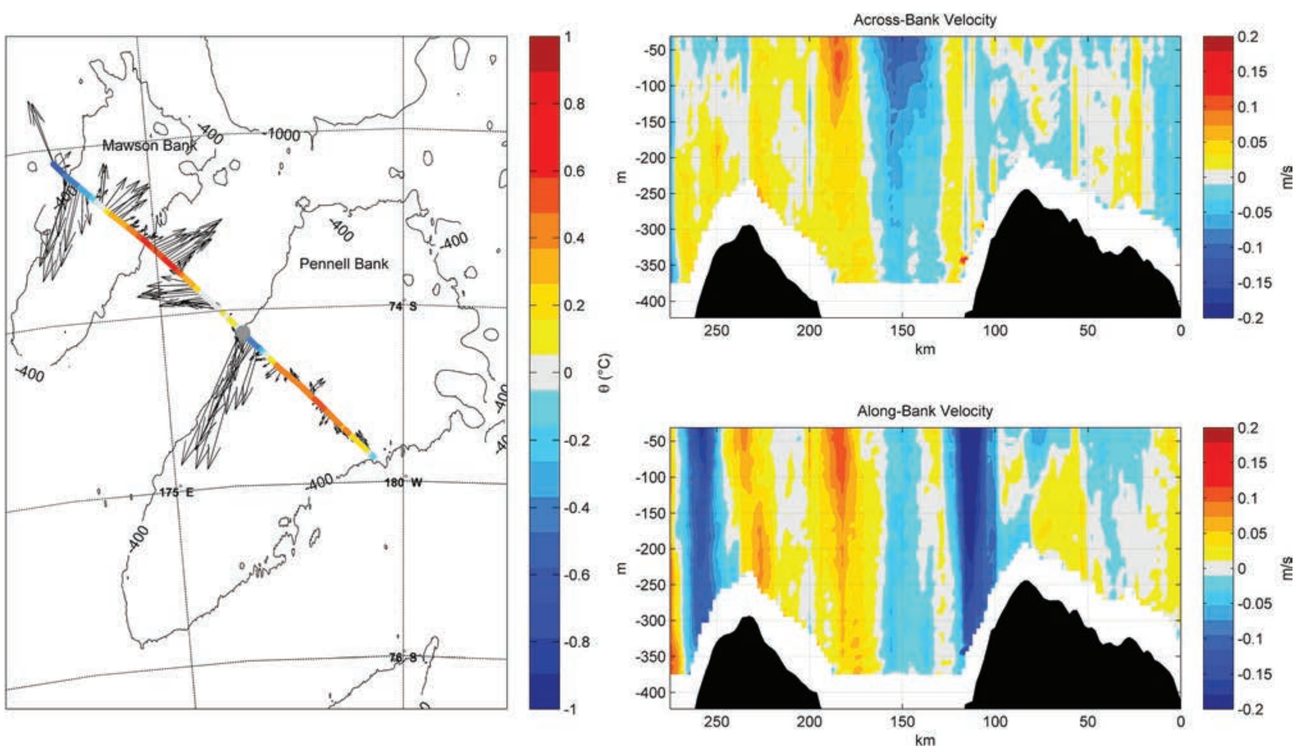

Figure 10. De-tided depth-averaged currents (black vectors) and surface temperature (colored track) over the across-bank section (left). The depth-dependent velocity sections (m/s) for the cross-bank (above right) and along-bank (below right) velocity components. These are the average of cross sections sampled between 22 January and 12 February 2011. The mooring location is shown as a gray circle (left).

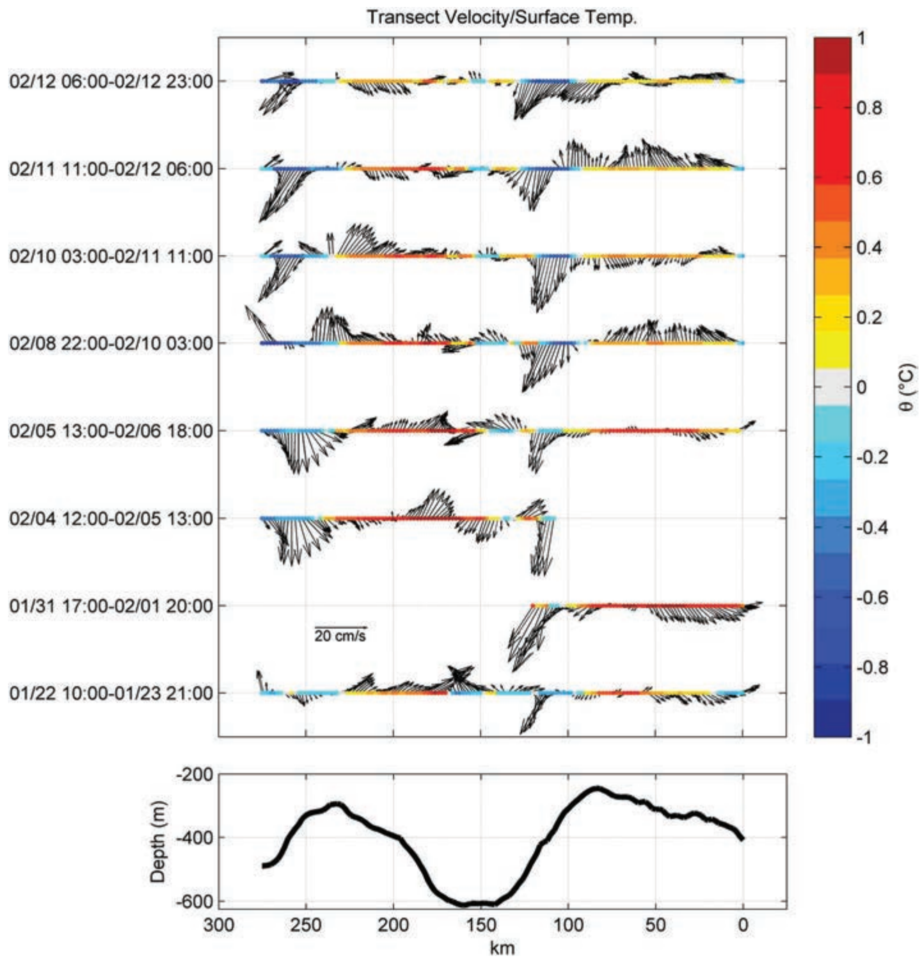

Figure 11. De-tided depth-averaged currents (black vectors) and surface temperature (colored track) for each of the across-bank sections. The topography identifying Pennell Bank (right) and Mawson Bank (left) is also shown (bottom).

present during the stronger spring tide. Throughout the record, there are also significant potential temperature shifts between -0.3°C and -1.6°C over periods much less than a day. The different response between the potential temperature and salinity time series at this depth is likely due to the difference in their vertical gradients and the relative influence each has on the density. At these salinity and temperature ranges, the ratio of beta to alpha is about 18 (beta ~ $d\rho/dS$, alpha ~ $d\rho/d\Theta$, where ρ is density, S is salinity, and Θ is potential temperature). Thus, fairly large excursions in potential temperature relative to salinity are to be expected. This is most evident at depth where there are large thermal gradients associated with MCDW. Here small vertical excursions lead to larger changes in potential temperature than salinity. The more gradual salinity changes with depth are seen only during the largest vertical excursions associated with the tides. The pressure data (not shown) indicate a fluctuation in the 225 m sensor depth of 10–30 m correlated with the tide. While significant, this sensor motion does not appear to account for all the variability in the diurnal band.

[24] The glider data collected in the vicinity of the mooring provides a spatial context for this temporal variability. A glider subsection of the transect that begins in the deeper water of Joides Trough moves up the slope of Pennell Bank toward the 280 m isobath (Figure 13). In the deeper water of the trough, the water column is seen to be relatively consistent with a layer of MCDW approximately 200 m deep. As the glider approaches the shallower water of the bank, this layer of MCDW deflects significantly in the vertical between 200 m and 350 m. The time scale of the depth variation of MCDW is consistent with the dominant diurnal tide that peaks over the shallows of the banks near the shelf break. The dashed black line approximates the location of the mooring. The apparent movement of the MCDW layer through the water column explains in part the variation in the potential temperature time series at 230 m from the mooring. This MCDW feature along the bank is highly variable over time scales of hours. This variation sampled by the glider is likely the result of tidal forcing on a spatially varying potential temperature field observed in the ship data.

4. Discussion

[25] Modified deep water intruding onto the shelf is a potential source of heat and micro-nutrients to the Ross Sea. Therefore, the magnitude and direction of MCDW transport are needed to quantify its impact on the heat and micronutrient budgets that influence Ross Sea processes. Throughout

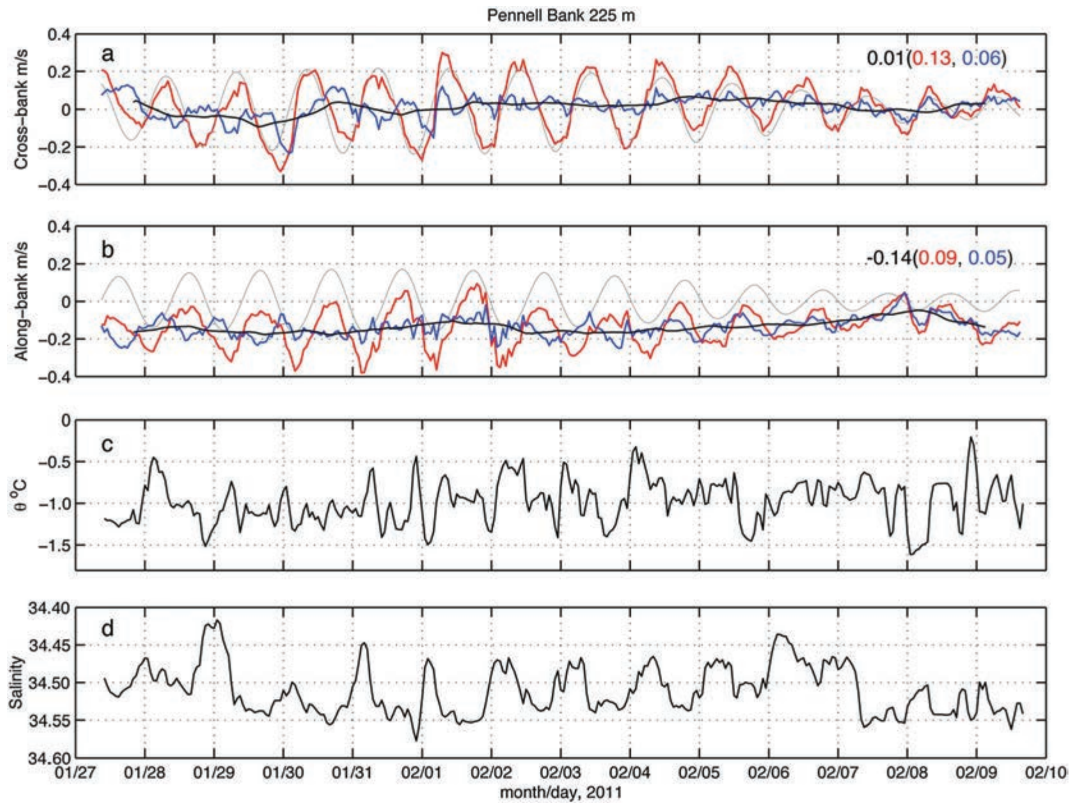

Figure 12. Moored hourly data including (a) cross-bank velocity (225 m), (b) along-bank velocity (225 m), (c) potential temperature (230 m), and (d) salinity (230 m). For Figures 12a and 12b, the red line is the hourly data, gray is velocity predicted by the barotropic tide model Ross_TIM [*Erofeeva, et al*., 2005], blue is de-tided data, and black is the 25 h running mean of the hourly data. Record-length mean of the hourly velocities is given in the upper-right corner, with the standard deviation of the hourly (red) and de-tided (blue) velocities in parentheses.

our survey, a large phytoplankton bloom was sustained over Pennell Bank (Figure 14). Both satellite remote sensing and ship board sampling identified this surface feature centered over the north east corner of Pennell Bank. Given the observed variation in MCDW transport and the apparent separation between it and the bloom, we can use our targeted dataset to identify two possible pathways that link the MCDW source waters to the bloom. The first is a direct transport eastward near the shelf break between the MCDW core observed at the mooring and the adjacent bloom over Pennell Bank. The large vertical excursion of the MCDW seen in the glider section could elevate that source above the minimum depth of the bank enabling cross-isobath transport onto the bank. During the cruise, we sampled stations between the troughs and the shallows of the bank along a line that bisected the mooring location. Along this line, there is no evidence of MCDW moving up slope over shallower water. A station 30 km east of the MCDW core in 280 m of water (80 km on the *x* axis of Figure 9) shows a water column predominately composed of a warm surface layer over a cooler, saltier bottom layer (Figure 9). The peak temperature and oxygen minimum characteristic of MCDW is not seen in any of the profiles sampled at this station. Based on these station data and the weak vertical shear in the ADCP velocities along this line, it is unlikely that the MCDW intrusion seen over the 400 m isobath is directly mixing up to the shallows of the adjacent bank, even with the significant vertical excursions of up to 100 m related to the dominant diurnal tide.

[26] An alternative pathway for the MCDW is to continue south along the bank, moving gradually upslope along the way. Once near the southern edge of the bank, the MCDW could turn north, continuing to follow the 400 m isobath back toward the shelf break. There is evidence of this isobath following flow pattern in model simulations [*Dinniman et al*., 2003]. This pathway is driven primarily by bathymetry given the mostly barotropic flow seen over the 400 m isobath. These model simulations are consistent with the mooring and ship-based ADCP data with a strong along isobath flow moving south over the 400 m isobath west of Pennell and Mawson Banks and a return flow back toward the shelf break on the eastern side of Mawson Bank. If we assume a barotropic flow following topography, we would expect the intrusion of MCDW over the 400 m isobath to be constrained by *f*/H, where *f* is the local Coriolis parameter and H is the water depth [*Marshall*, 1995]. Using the mooring site as an initial condition for the MCDW intrusion, we calculate the regions of the Ross Shelf that have consistent *f*/H values (Figure 15). If the MCDW is carried by a barotropic current south onto the shelf, then this flow would be limited to those areas shaded in tan. For Pennell Bank, we see the pathway continuing south and moving up onto the bank around the 74.5°S parallel where the steep slope of Pennell flattens. The shallower slope relaxes the dynamic constraint, allowing the MCDW to move up onto the bank. Once

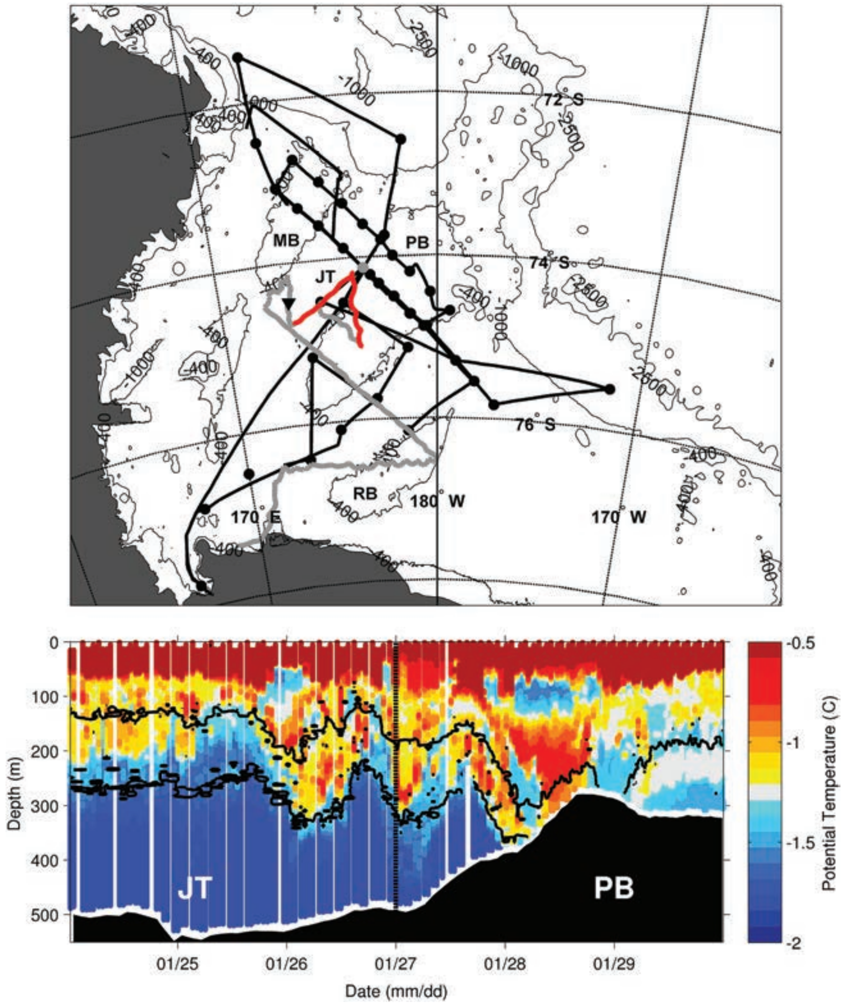

Figure 13. Subsection of the glider path that begins in Joides Trough and moves up the slope of Pennell Bank (red, above). Potential temperature along this section (below). The neutral density bounds defining MCDW are shown in black, and the topographic features are labeled as in Figure 1. The vertical dashed line (below) coincides with the sharp turn in the red transect (above).

over the bank, the MCDW is subject to the stronger diurnal tides and could be vertically mixed to the euphotic zone.

[27] The ADCP data identified a strong southward flow along the western edge of Pennell Bank coincident with the MCDW core. The depth-dependent data show that this flow is not truly barotropic. Given the observed shear, the *f*/H constraint may not apply to the MCDW intrusion along the bank. Recognizing that flow fields in the ocean are rarely fully barotropic, there is a modified denominator that considers the depth scale of the observed shear, f/F_o [*Krupitsky et al.*, 1996; *Gille*, 2003; *Gille et al.*, 2004], where

$$F_o = H_o(1 - \exp(-H/H_o)) \tag{1}$$

[28] H_o is the e-folding scale of the observed velocity shear:

$$v(z) = v(0)\ \exp(-z/H_o) \tag{2}$$

where $v(z)$ is the depth-dependent velocity, z is the depth of the measurement, and $v(0)$ is the magnitude of the surface velocity. Here we calculated H_o based on the average of the three velocity profiles within the MCDW core over the 400 m isobath (Figure 10). The exponential fit to this observed shear gives an e-folding depth scale of 380 m, approximately the depth of the water column. Since the shear is small, the modified constraint is not significantly different than the *f*/H constraint that assumes zero shear (not shown). With either definition, the flow transporting this MCDW from the shelf break onto the shelf likely follows the topography of both Pennell Bank and Mawson Bank toward the south. Unlike Pennell Bank, the water following Mawson is much less constrained to the slope and could quickly move over the shallows of the bank (Figure 15).

[29] Over Pennell Bank, there is a distinct separation between the MCDW core observed over the mooring site and the elevated chlorophyll concentrations over the shallower waters of the bank. The dynamic constraints shown in Figure 15 illustrate the isolation directly between them along ship sections sampled near the shelf break. Further south, however, the dynamic constraint relaxes and the glider section shows MCDW sliding up and over

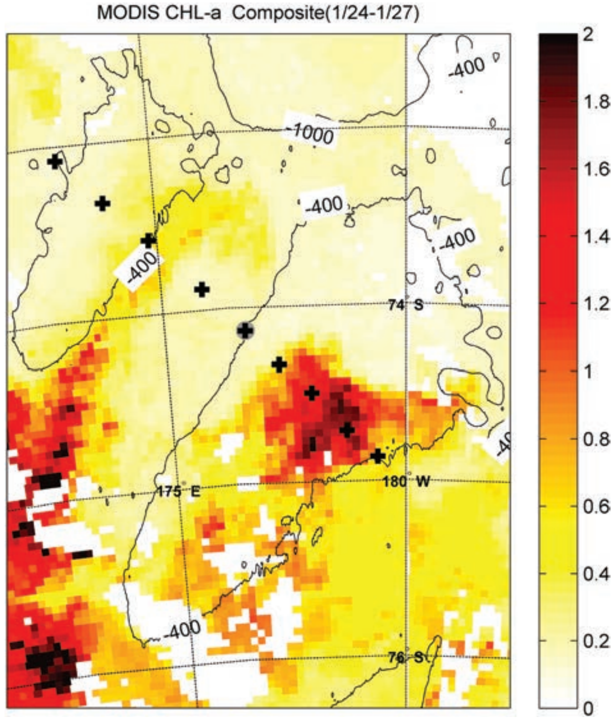

Figure 14. Surface map composite of satellite derived Chl-a concentration (mg/m^3). The cross-bank stations are shown as black crosses. The mooring location is also shown as a gray circle.

the bank (Figure 3). Once the MCDW reaches the shallows of the bank, it is subject to increased tides and could mix vertically toward the euphotic zone and the observed bloom. Through this pathway, the micronutrient supply of MCDW can reach the bloom and, if high enough concentration, help sustain its productivity.

5. Conclusion

[30] A multi-platform sampling strategy focused on the bank/trough topography near the outer shelf of the Ross Sea characterized the small scales that determine the transport of MCDW from preferred CDW intrusion sites at the shelf break south along the western slopes of both Pennell and Mawson Bank. For both banks, the MCDW signal is seen approximately over the 400 m isobath west of the banks. Using eight transects of ADCP sections across the bank/trough topography, we see a flow approximately barotropic moving southward along the bank. This flow is bringing with it cool fresher water on the surface and the warmer low oxygen water characteristic of MCDW at depth. The velocity and CTD sections averaged over eight cross sections were used to estimate a mean transport of MCDW over our survey of approximately 0.24 *Sv*. Both the glider and mooring data show that this mean transport is highly variable over scales of hours to days. The main variance, driven by the tides, appears to move this core of MCDW approximately 100 m in the water column every 12 h. At this point, we do not have the data coverage to determine the mechanism for this rapid movement of MCDW. However, we do conclude that this energetic tide is unlikely to drive the MCDW up and onto the Pennell Bank. Instead, given the small vertical shear in the flow, this intrusion of MCDW likely continues south along the bank until the slope flattens allowing the warmer mid-water to move over the bank. At that point, it is subject to the stronger tides of the bank and could be mixed up to the euphotic zone. The glider section across the southern edge of Pennell bank identifies the higher

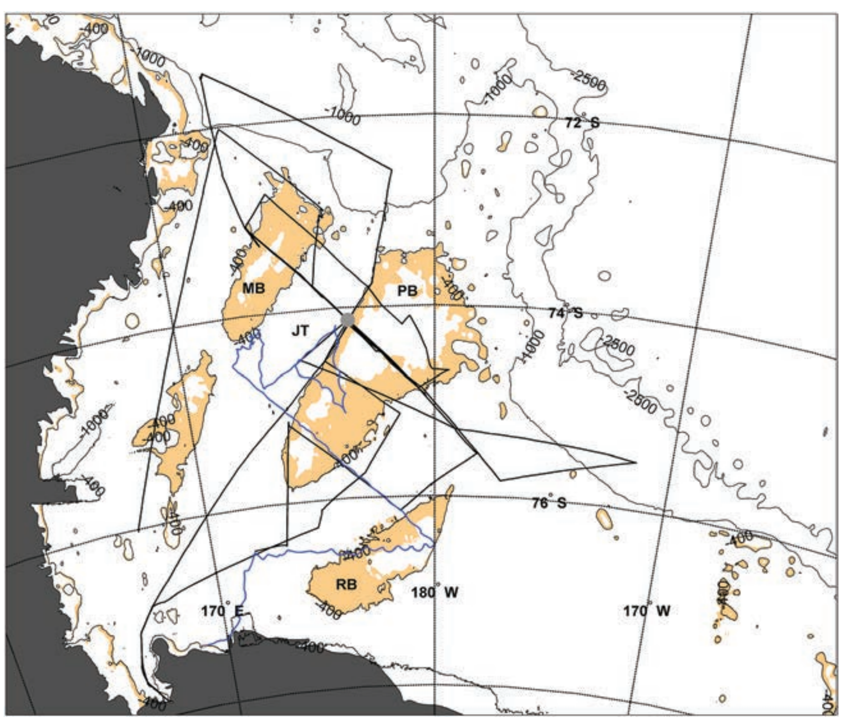

Figure 15. The regions of *f*/H (tan) consistent with the MCDW core identified in the vicinity of the mooring. The glider (blue) and ship track (black) are shown for reference. The mooring location is shown as a gray circle.

temperatures of the MCDW intrusion going up and over the bank. The scale of variability in time and space observed during this field study indicates a need for future study that incorporates longer time series, more detailed surveys, and eddy resolving models to fully describe the processes that govern the southward movement of MCDW into the Ross Sea.

[31] **Acknowledgments.** The NSF Office of Polar Programs (ANT-0839039) supported the Slocum Enhanced Adaptive Fe Algal Research in the Ross Sea (SEAFAReRS) project. The mooring was supported by the Cape Adare Long-term Moorings (CALM) project (ANT-0538148 and ANT-1141890). We want to specifically thank the project PIs for redeploying the mooring within days after recovery off Cape Adare. The successful deployment of the glider from the ice edge would not have been possible without the great effort of Chip Haldeman (Rutgers), Clayton Jones (Teledyne Webb Research), and Raytheon Polar Services. We would also like to thank the entire crew of the *RVIB Nathaniel B. Palmer* for their support throughout the cruise and John Kerfoot (Rutgers) for the glider processing before and after the deployment. This is Lamont-Doherty Earth Observatory contribution number 7662.

The Robot Ocean Network

Automated underwater vehicles go where people cannot, filling in crucial details about weather, ecosystems, and Earth's changing climate.

Oscar Schofield, Scott Glenn, and Mark Moline

In the frigid waters off Antarctica, a team of our colleagues deploy a waterborne robot and conduct final wireless checks on the system's internal engines and onboard sensors, before sending the device on its way to explore the ocean conditions in an undersea canyon over a month-long expedition. The autonomous robot's mission will be monitored and adjusted on the fly by scientists and their students remotely located in the United States; the data it returns will become part of our overall picture of conditions in the Southern Ocean.

Ocean robots—more formally known as *autonomous underwater vehicles*, or *AUVs*—are improving our understanding of how the world's ocean works and expanding our ability to conduct science at sea even under the most hostile conditions. Such research is essential, now more than ever. The ocean drives the planet's climate and chemistry, supports ecosystems of unprecedented diversity, and harbors abundant natural resources. This richness has lead to centuries of exploration, yet despite a glorious history of discovery and adventure, the ocean remains relatively unknown. Many basic and fundamental questions remain: How biologically productive are the oceans? What processes dominate mixing between water layers? What is its total biodiversity? How does it influence the Earth's atmosphere? How is it changing and what are the consequences for human society?

The last question is particularly pressing, as many observations suggest that significant change is occurring right now. These shifts reflect both natural cycles and, increasingly, human activity, on a local and global scale. Local effects include alterations in circulation, increased introduction of nutrients and pollutants to the sea, the global transport of invasive species, and altered food web dynamics due to the overexploitation of commercially valuable fish species. Regional- and global-scale changes include altered physical (temperature, salinity, sea-level height), chemical (oxygen, pH, nutrients), and biological properties (fishing out of top predators).

Addressing the many unknowns about the ocean requires knowledge of its physics, geology, chemistry, and biology. On the most basic level, one has to be able to track the movement of water and its constituents over time to understand physical transport processes. But this fundamental first step remains a difficult problem given the three-dimensional structure of the ocean and the limited sampling capabilities of traditional oceanographic tools. About 71 percent of the world is covered by the ocean, with a volume of about 1.3 billion cubic kilometers. Only about 5 percent of that expanse has been explored. A further complication is the broad scale of ocean mixing—spatially, from centimeters to thousands of kilometers, and temporally, from minutes to decades. These processes are all modified by the interactions of currents with coastal boundaries and the seafloor.

If the problem of monitoring mixing can be solved, then focus can shift to the biological and chemical transformations that occur within the water. Factors that remain unknown include the amount of inorganic carbon being incorporated into organic carbon, and how quickly that organic matter is being transformed back into inorganic compounds—processes that are driven by marine food webs. Many of these transformation processes reflect the "history" of the water mass: where it has been and when it was last mixed away from the ocean surface. Because of the vast domain of the ocean, our ability to sample the relevant spatial and temporal scales has been limited.

Oceanographers usually collect data from ships during cruises that last days to a few months at most. The modern era of ship-based expeditionary research, launched just over a century ago, has resulted in major advances in our knowledge of the global ocean. But most ships do not travel much faster than a bicycle and they face harsh, often dangerous conditions. The high price of ships also limits how many are available for research. A moderately large modern research vessel may run about $50,000 a day even before the costs of the science. Ocean exploration requires transit to remote locations, a significant time investment. Once on site, wind and waves will influence when work can be safely conducted.

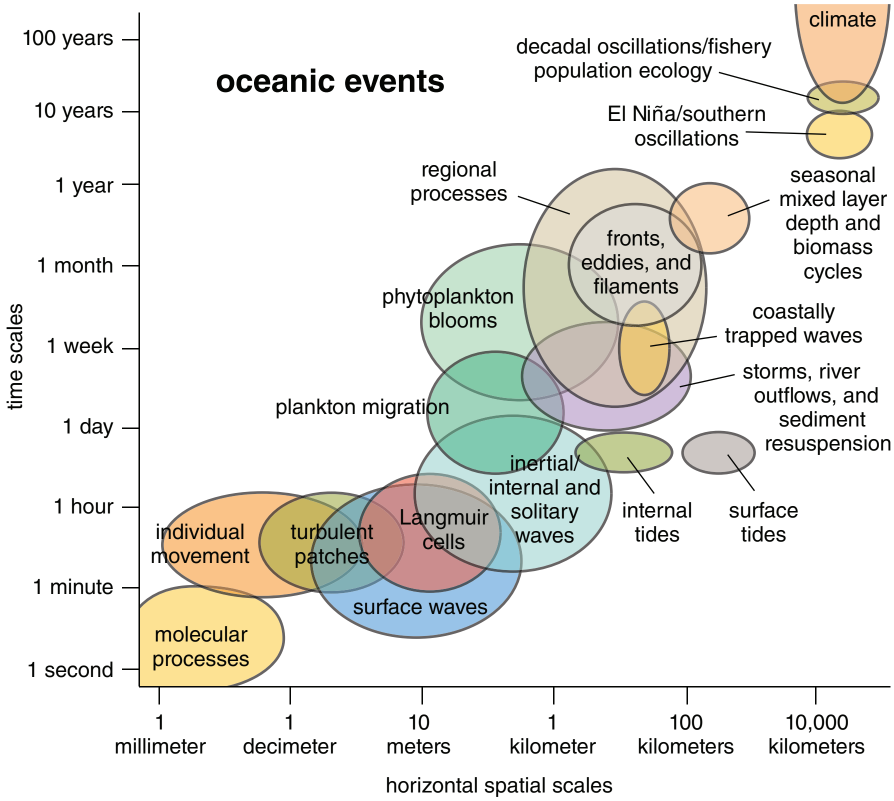
For example, one of us (Schofield) routinely works along the western Antarctic Peninsula. The travel time from New Jersey to the beginning of experimental work can take upward of a week: two days of air and land travel, one to two days of port operations, and four days of ship travel. During the writing of this article, Schofield was at sea offshore of Antarctica,

Oscar Schofield is a professor of oceanography and chair of the Department of Marine and Coastal Sciences at Rutgers University. Scott Glenn is a distinguished professor of oceanography at Rutgers. Their work has focused on developing ocean-observing networks. Mark Moline is the director of the School of Marine Science and Policy at the University of Delaware. His research centers on the diversity, interactions, and ecology of plankton. Email: oscar@marine.rutgers.edu.

In the icy waters off the Antarctic coast, researchers must be mindful of their physical safety. The aquatic robot they are deploying has no such needs and can operate in the forbidding conditions for weeks or months at a time. Legions of such autonomous underwater vehicles (AUVs) are now gathering data about the physical state of the world's ocean, collecting information that is inaccessible to ships or satellites. (Photograph courtesy of Jason Orfanon.)

where ship operations were halted for several days due to heavy winds, waves, and icy decks. All three of us have on multiple occasions experienced the "robust" work atmosphere—such as broken bones and lacerations—associated with working aboard ships. Despite these difficulties, ships are the central tool for oceanography, providing the best platform to put humans in the field to explore. But researchers realized decades ago that they needed to expand the ways they could collect data at sea.

Satellites provide a useful sampling tool to complement ships and can provide global estimates of surface temperature, salinity, sea surface height, and plant biomass. Their spatial resolution, however, is relatively low (kilometers to hundreds of kilometers), and they often cannot collect data in cloudy weather. Additionally, they are incapable of probing the ocean interior. Ocean moorings (a vertical array of instruments anchored to the seafloor) can provide a time series of measurements at single points, but their high cost (ranging from $200,000 to millions each) limits their numbers.



Processes in the ocean happen on a number of varying temporal and spatial scales, and these events often affect one other. But gathering data on these numerous scales has proven difficult using traditional research methods. AUVs may be able to bridge some of the gaps, given their long mission times and maneuverability in the ocean. (Adapted from an illustration by Tommy Dickey.)

Twenty-three years ago, those challenges inspired oceanographer Henry "Hank" Stommel to propose a globally distributed network of mobile sensors capable of giving a clearer look, on multiple time and space scales, at the processes going on in the world's ocean. His futuristic vision is finally becoming a reality. Thousands of robots are today moving through the world's ocean and communicating data back to shore. They provide crucial information on everything from basic processes—such as the ocean's temperature and salinity—to specific processes like storm dynamics and climate change.

Ocean Workhorses

The most vital component of the rapidly growing ocean sensor network is the AUV. These devices come in various types, carry a wide variety of sensors, and can operate for months at a time with little human guidance, even under harsh conditions.

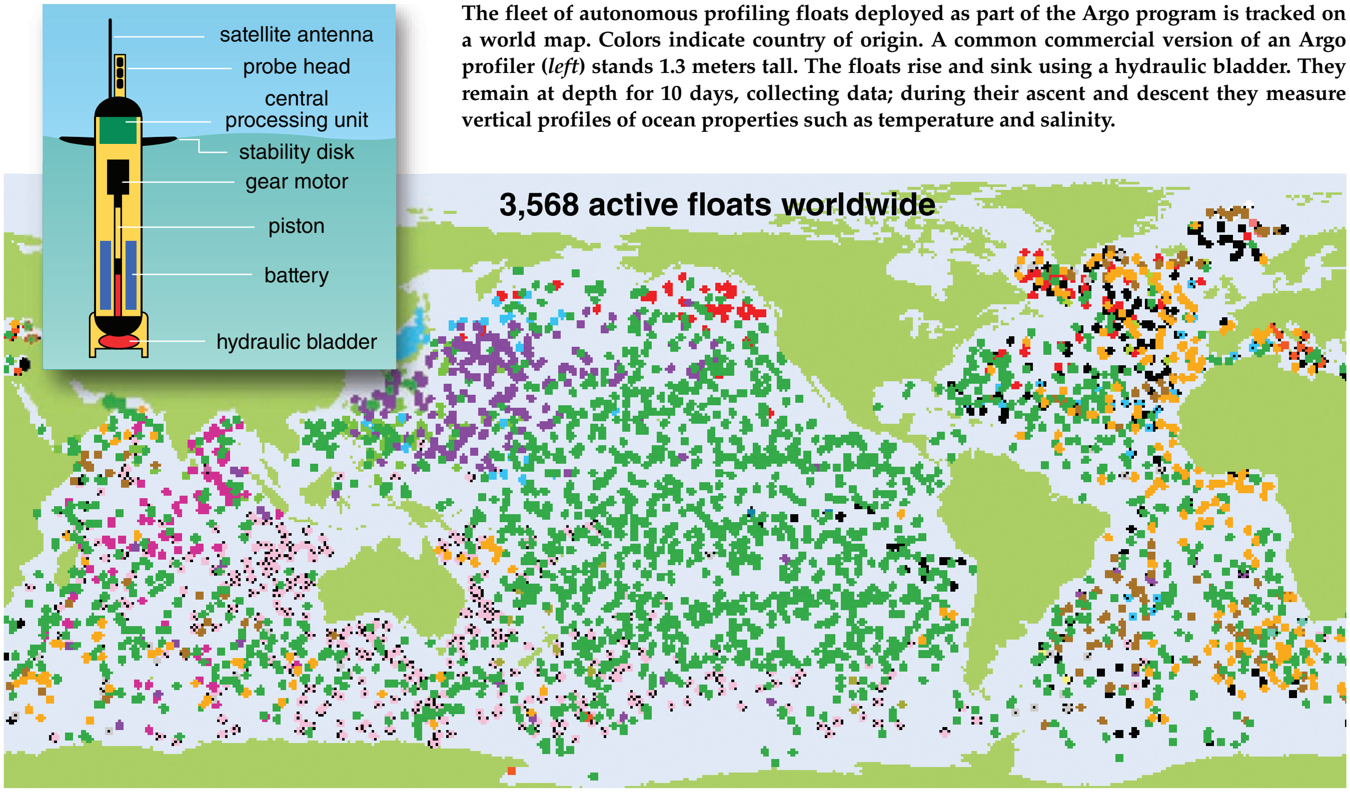
Underwater robotics has made major advances over the past decade. Key technological gains include an affordable global telecommunication network that provides sufficient bandwidth to download data and remotely control AUVs from anywhere on the planet, the miniaturization of electronics and development of compact sensors, improved batteries, and the maturation of platforms capable of conducting a wide range of missions.

The AUVs being used in the ocean today generally come in three flavors: profiling floats, buoyancy-driven gliders, and propeller vehicles. In the first category, the international Argo program has deployed more than 3,500 relatively inexpensive profiling floats (costing about $15,000 each) throughout the ocean, creating the world's most extensive autonomous ocean network. These 1.3-meter-long platforms decrease their buoyancy by pumping in water, sinking themselves to a specified depth (often more than 1,000 meters), where they remain for about 10 days, drifting with the currents. The floats then increase their buoyancy by pumping out water, and rise to the surface. During the descent and ascent, onboard sensors collect vertical profiles of ocean properties (such as temperature, salinity, and a handful of ocean color and fluorescence measurements). New chemical sensors to measure pH and nutrients are also available. Data are transferred back to shore via a global satellite phone call. After transferring the data, the floats repeat the cycle.

Profiling floats are incapable of independent horizontal travel, leaving their movements at the mercy of the currents, but they are extremely efficient. A single battery pack can keep a float operating for four to six years. The combined data from large numbers of floats provides great scientific value, offering a comprehensive picture of conditions in the upper 1,000 meters of the ocean around the globe. When these data are combined with global satellite measurements of sea-surface height and temperature, they allow scientists to observe for the first time climate-related ocean variability in temperature, salinity, and circulation over global scales.

Cousin to the profiling floats are the buoyancy-driven gliders, which were highlighted in Stommel's original vision of a networked ocean. Several different types exist, but generally they are 1 to 2 meters long and maneuver up and down through the water column at a forward speed of 20 to 30 centimeters per second in a sawtooth-shaped gliding trajectory. They operate by means of a buoyancy change similar to that for floats, but wings redirect the vertical sinking motion due to gravity into forward movement. A tailfin rudder provides steering as the glider descends and ascends its way through the ocean, which makes these devices more controllable than the floats. They are more expensive, however, costing around $125,000. Therefore, they are often deployed for specific scientific missions.

A glider's navigation system includes an onboard GPS receiver coupled with an attitude sensor, a depth sensor, and an altimeter. The vehicle uses this equipment to perform dead reckoning navigation, where current position is calculated using a previously determined position, and that position is then updated based on known or estimated speeds over elapsed time and course. Scientists can also use a buoyancy-driven glider's altimeter and depth sensor to program the location of sampling in the water column. At predetermined intervals, the vehicle sits on the surface and raises



The fleet of autonomous profiling floats deployed as part of the Argo program is tracked on a world map. Colors indicate country of origin. A common commercial version of an Argo profiler (*left*) stands 1.3 meters tall. The floats rise and sink using a hydraulic bladder. They remain at depth for 10 days, collecting data; during their ascent and descent they measure vertical profiles of ocean properties such as temperature and salinity.

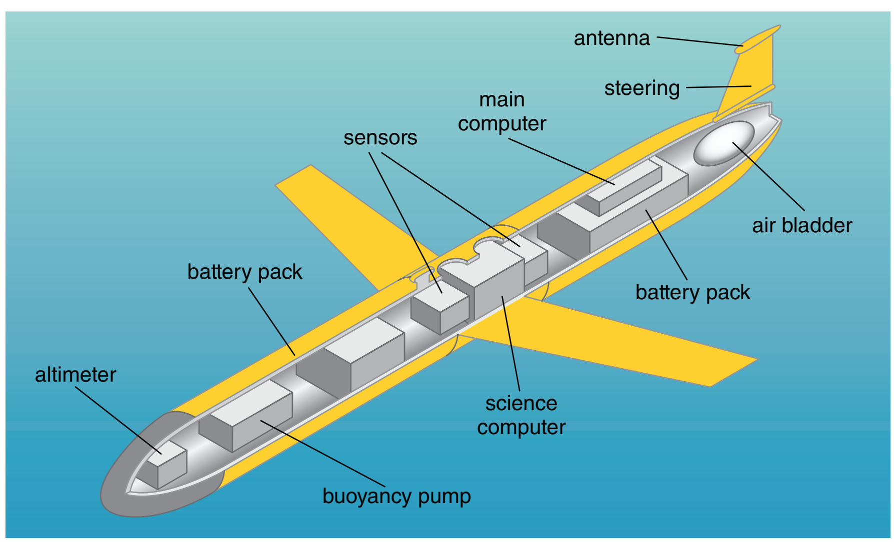
an antenna out of the water to retrieve its position via GPS, transmit data to shore, and check for any changes to the mission.

Because their motion is driven by buoyancy, the gliders' power consumption is low. They can coast for up to year on battery power. These robots are also modular: Researchers can attach sensors customized to one particular science mission, and then remotely reprogram what the sensors are searching for in near real time, based on collected data.

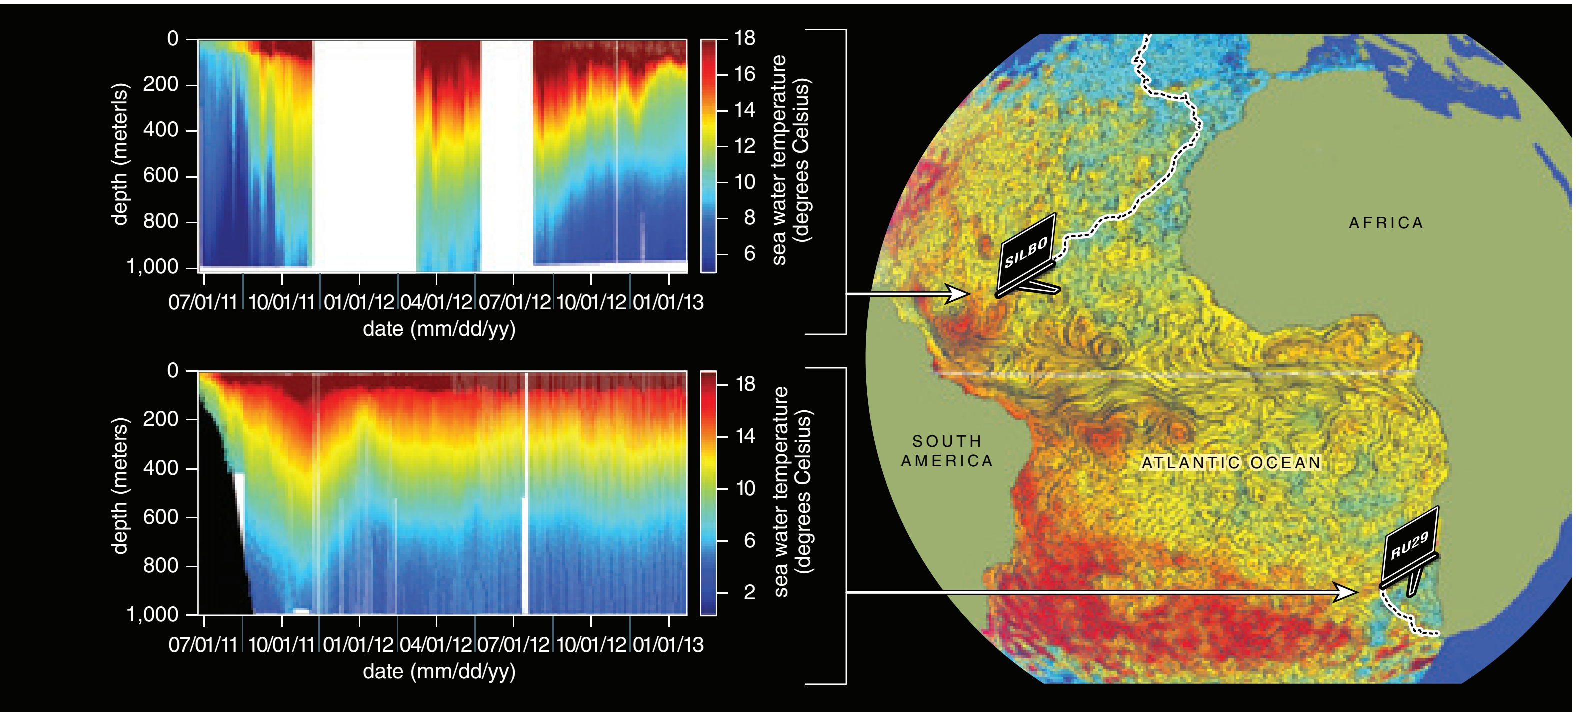
The most advanced, but also the most expensive, underwater robots are the propeller-driven AUVs. Costs can range from $50,000 to $5 million, depending on the size and depth rating of the AUV. They are powered by batteries or fuel cells, and can operate in water as deep as 6,000 meters. Like gliders on the surface, propeller AUVs receive a GPS fix and relay data and mission information to shore via satellite. While they are underwater, propeller AUVs navigate by various means. They can operate inside a network of acoustic beacons, by their position relative to a surface reference ship, or by an inertial navigation system, which measures the vehicle's acceleration with an accelerometer and orientation with a gyroscope. Travel speed is determined using Doppler velocity technology, which measures an acoustic shift in the sound waves that the vehicle bounces off the seafloor or other fixed objects. A pressure sensor measures vertical position.

Propeller-driven AUVs, unlike gliders, can move against most currents at 5 to 10 kilometers per hour, so they can systematically measure a particular line, area, or volume. This ability is particularly important for surveys of the ocean bottom and for operations near the coastline in areas with heavy traffic of ships and small crafts.

Most AUVs in use today are powered by rechargeable batteries (such as lithium ion ones similar to those in laptop computers). Their endurance depends on the size of the vehicle as well as its power consumption, but typically ranges from 6 to 75 hours of operation under a single charge, with



Anatomy of a typical buoyancy-driven AUV: A torpedo-shaped body minimizes drag. An altimeter is used to locate the seafloor. A buoyancy pump and air bladder regulate depth, and fins aid steering. Battery packs keep the robot powered for months. A main computer controls the AUV's actions; a science computer stores the data from the sensors. An antenna transmits the findings to shore.



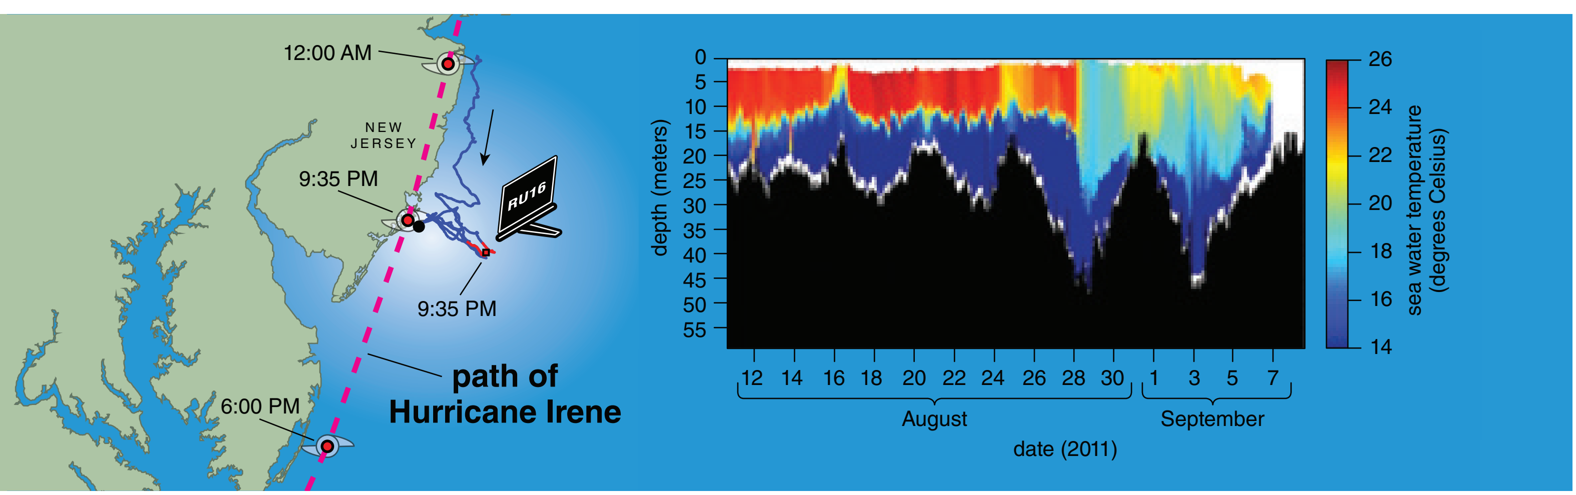
Global ocean circulation numerical models (*right*) were used by operators to guide two underwater gliders remotely. Currents are denoted by wavy lines; color indicates sea surface height. The positions of the gliders are denoted by their tailfins, with one heading toward Brazil and the other leaving the coast of South Africa. Temperature-profile data collected by the gliders are shown at left. (Unless otherwise indicated, images are courtesy of the authors.)

travel distances of 70 to 400 kilometers over that period. The sensor cargo they carry also depends on the size of the vehicle and its battery capacity.

Because of the additional power of propeller AUVs compared to gliders, they can run numerous sensor suites, and they remain the primary autonomous platform for sensor development. Hundreds of different propeller AUVs have been designed over the past 20 or so years, ranging in size from 0.5 to 7 meters in length and 0.15 to 1 meter in diameter. Most of these vehicles have been developed for military applications, with a few operated within the academic community. By the end of this decade, it is likely that propeller AUVs will be a standard tool used by most oceanographic laboratories and government agencies responsible for mapping and monitoring marine systems.

Riding a Hurricane

Together, the three types of ocean robots deployed throughout the world's ocean are bringing into scientific reach processes that are not accessible using ships or satellites. For example, these robots can study the ocean's response to, and feedback from, large storms such as hurricanes and typhoons. All three of us live in the mid-Atlantic region of the United States and have experienced Hurricanes Irene and Sandy,



When Hurricane Irene grazed New Jersey (*left*) on August 28, 2011, a glider named RU16 was traveling nearby (*blue lines*). RU16 was originally deployed to map water quality for the state's Department of Environmental Protection; by luck it was in a perfect location (*red line*) to collect critical data on the storm. Readings from the glider (*right*) showed that the passage of the storm rapidly cooled the water column. Such data could lead to improved hurricane forecasts in the future.

so we are all too familiar with storm aftermath in our local communities.

Hurricane Irene, a category-1 storm offshore, moved rapidly northward along the U.S. East Coast in August 2011, resulting in torrential rains and significant flooding on inland waterways. Hurricane Sandy, a much larger category-2 storm offshore, made an uncharacteristic left turn and approached perpendicular to the coast in October 2012, causing significant damage to coastal communities. The U.S. National Hurricane Center ranks Sandy as the second-costliest hurricane ever in this country, producing over $60 billion of damage; Irene comes in eighth place, with at least $15 billion in damages.

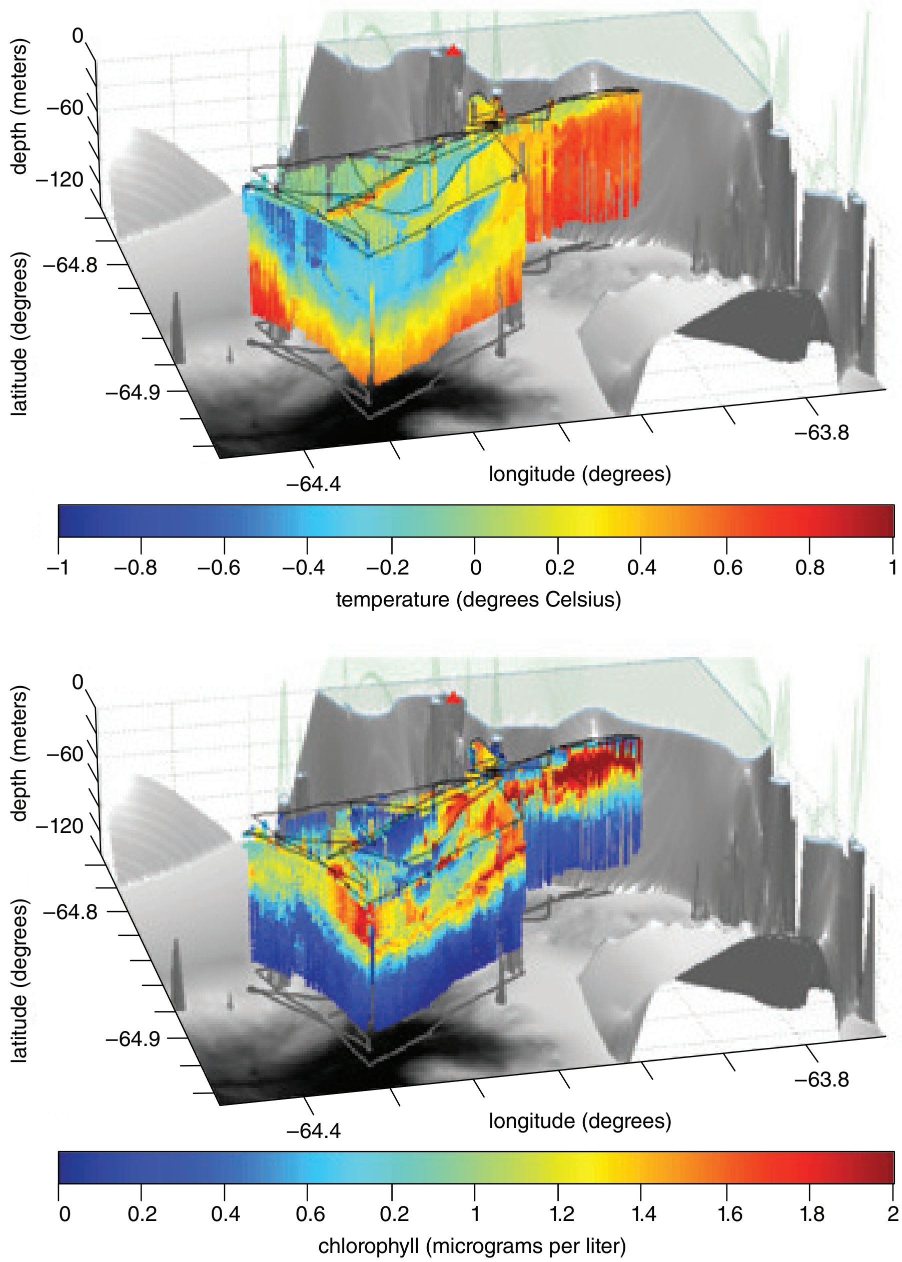
Path forecasts by the U.S. National Hurricane Center for Irene and Sandy were extremely accurate even several days in advance, enabling evacuations that saved many lives. Hurricane intensity forecasts were less precise. The force of Irene was significantly overpredicted, and the rapid acceleration and strengthening of Sandy just before landfall was underpredicted. A more accurate forecast for Sandy would have triggered more effective preparations, which might have reduced the amount of damage.

The cause of the discrepancy between track forecasts and intensity forecasts remains an open research question. Global atmospheric model development over the past 20 years has successfully reduced forecast hurricane track errors by factors of two to three. The predictive skill of hurricane intensity forecasts has remained flat, however.

One possible reason is that more information is required about the interactions between the ocean and the atmosphere during storms, because the heat content of the upper ocean provides fuel for hurricanes. The expanding array of robotic ocean-observing technologies is providing a means for us to study storm interactions in the coastal ocean just before landfall, accessing information in ways not possible using traditional oceanographic sampling.

During the summer, the surface waters of the mid-Atlantic are divided into a thin, warm upper layer (10 to 20 meters deep and 24 to 26 degrees Celsius) overlying much colder bottom water (8 to 10 degrees). Gliders were navigating the ocean waters beneath both Hurricanes Irene and Sandy, collecting hydrographic profiles. Data taken during Irene suggest that as the leading edge of the storm approached the coast, the hurricane-induced increase in the flow of water onto the shore was compensated by an offshore flow below the thermocline (the region of maximum temperature change in the water column) in a downwelling flow created by high winds. This phenomenon minimized the potential storm surge. Simultaneously, storm-induced mixing of the water layers broadened the thermocline and cooled the ocean surface ahead of Irene by up to 8 degrees in a few hours, shortly before the eye of the storm passed over. This cold bottom water potentially weakened the storm as it came ashore. When data from a glider that measured the colder surface water were retrospectively input into the storm forecast models, that adjustment eliminated the overprediction of Irene's intensity.

In contrast to Irene, Hurricane Sandy arrived in the late fall, after seasonal cooling had already decreased the ocean surface temperatures by 8 degrees. As



Glider data decode the complex dynamics of a deep-sea canyon in the western Antarctic Peninsula. Readings of water temperature (*top*) show an uplift of warm water, probably due to the coastward movement of the offshore circumpolar current. A chlorophyll map (*bottom*), from the same glider, indicates higher concentrations of phytoplankton where the warm water rises. This is the first hard evidence linking such upwelling with increased ocean productivity.

the storm came ashore, it induced mixing of cold water from the bottom to the surface—just as Hurricane Irene did—but because of the seasonal declines in temperature, the surface water temperature dropped by only around 1 degree. Such a small change did little to reduce the intensity of Hurricane Sandy as it approached the New Jersey and New York coastlines.

Robotic platforms have thus demonstrated their potential to sample storms and possibly aid future forecasts of hurricane intensity. The gliders operate effectively under rough ocean conditions that are not safe for people, and the mobility of gliders allows their positions to be adjusted as the storm moves. Their long deployment lifetime means these robots can be in place well before the storm's arrival until well after conditions calm down. Real-time data from the gliders should improve hurricane intensity forecast models and potentially help coastal communities proactively mitigate storm damage.

Heating Up Antarctica

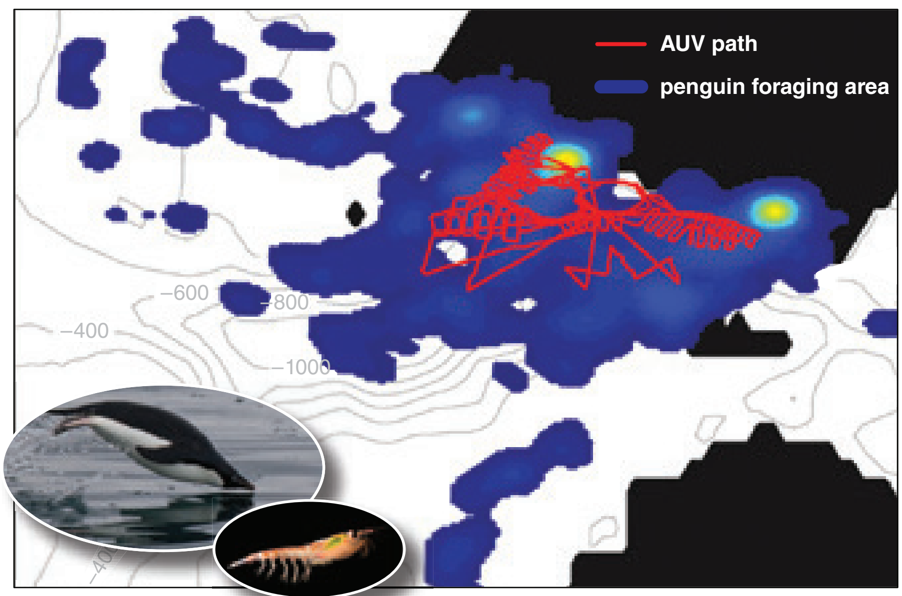
As complex as hurricane forecasting may be, it pales in comparison to interpreting changes in ocean physics on a global scale, and then connecting those changes with local effects such as sea ice coverage or species decline.

Many questions oceanographers face are so complex that they require the combined data of several robotic platforms that span the range of spatial and temporal scales of marine ecosystems. Linking global changes to local effects has been difficult to impossible using conventional strategies.

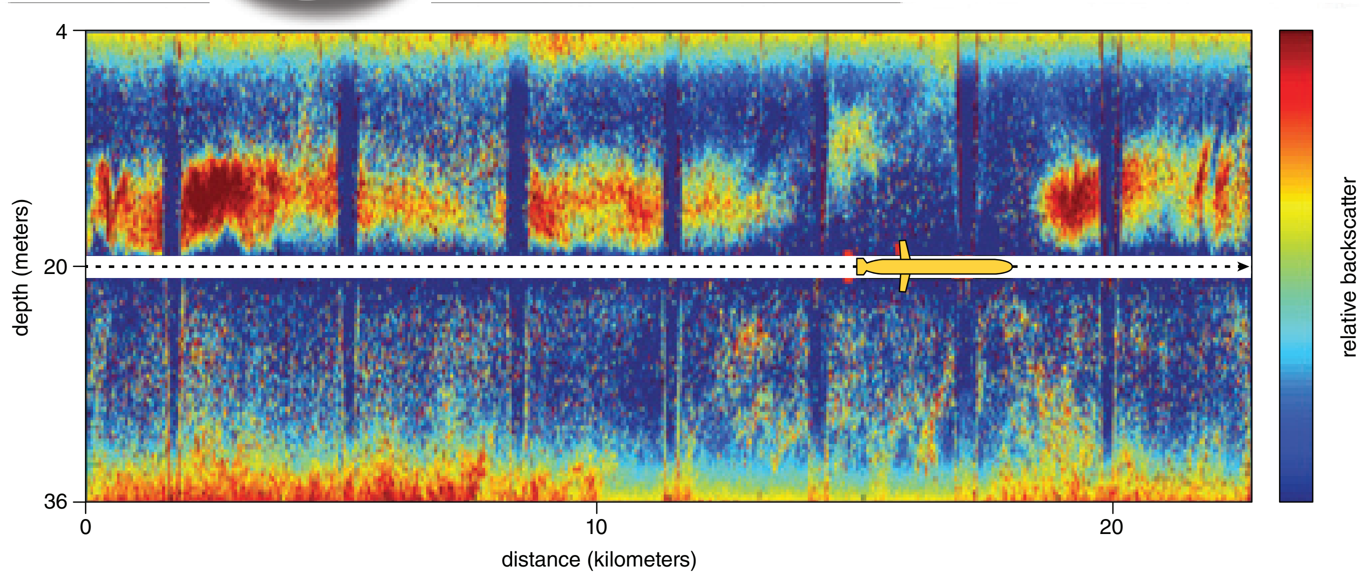
One setting that illustrates the importance of bridging these scales is the western Antarctic Peninsula, which is undergoing one of the most dramatic climate-induced changes on Earth. This region has experienced a winter atmospheric warming trend during the past half-century that is about 5.4 times the global average (more than 6 degrees Celsius since 1951). The intensification of westerly winds and changing regional atmospheric circulation, some of which likely reflects the effect of human activity, has contributed to increasing transportation of warm offshore circumpolar deep water onto the continental shelf of the peninsula.

This water derives from the deep offshore waters of the Antarctic Circumpolar Current, the largest ocean current on Earth, and is the primary heat source in the peninsula. The altered positions of this current are implicated in amplifying atmospheric warming and accelerating glacier retreat in the region. Monitoring and tracking the dynamics of the warm offshore deep current require a sustained global presence in the sea, which is now being accomplished via the Argo network of autonomous floats. Data from Argo suggest that the Antarctic Circumpolar Current has exhibited warming trends for decades.

The increased presence and changing nature of the deep-water circulation has



Penguin foraging locations (*left, blue areas*), identified by radio-tagged birds (*inset*), were used to guide a survey by a propeller AUV (*red lines*). The AUV was outfitted with an acoustic sensor that can detect Antarctic krill, the penguins' primary food source (*inset*). The resulting map of krill swarms (*below*), confirms the hypothesis that both krill and the penguins that feed on them congregate around canyons with warm-water upwelling.



implications for the local food web. The Western Antarctic Peninsula is home to large breeding colonies of the Antarctic Adélie penguin (*Pygoscelis adeliae*), which live in large, localized colonies along the peninsula even though food resources are abundantly available along the entire inner continental shelf. This concentration of the population has raised a persistent question: What turns specific locations into penguin "hot spots?"

The locations of the Adélie colonies appear to be associated with deep seafloor submarine canyons, which are found throughout the continental shelf of the peninsula. This colocation has led to a hypothesis that unique physical and biological processes induced by these canyons produce regions of generally enhanced prey availability. The canyons were also hypothesized to provide recurrent locations for *polynyas* (areas of open water surrounded by sea ice), giving penguins year-round access to open water for foraging. But linking the regional physical and ecological dynamics to test the canyon hypothesis had been impossible, because brutal environmental conditions limited spatial and temporal sampling by ships.

Robotic AUVs now offer expanding capabilities for observing those conditions. As part of our research, for the past five years we have been using a combination of gliders and propeller AUVs to link the transport of the warm offshore circumpolar deep water to the ecology of the penguins in the colonies. Gliders surveying the larger scale of the continental shelf have documented intrusions of deep, warm water upwelling within the canyons near the breeding penguin colonies. These intrusions of warm water appear to be ephemeral features with an average lifetime of seven days, which is why earlier, infrequent ship-based studies did not effectively document them. Associated with this uplift of circumpolar deep water along the slope of the coastal canyon, the gliders found enhanced concentrations of phytoplankton, providing evidence of a productive food web hot spot capable of supporting the penguin colonies.

Satellite radio tagging is being used to characterize the foraging dynamics of the Adélie penguin, and has shown the majority of their foraging activity was centered at the slope of the canyon. These more localized foraging patterns were used to guide sampling of the physical and biological properties with a propeller AUV, because strong coastal currents hindered buoyancy-driven gliders. The propeller AUV data were used to generate high-resolution maps, which revealed that penguin foraging was associated with schools of Antarctic krill. The krill in turn were presumably grazing on the phytoplankton at the shelf-slope front.

It took the integration of all three classes of robotic systems (profilers, gliders, and propeller AUVs) to link the dynamics of the outer shelf to the coastal ecology of the penguins. But in the end, that combination of techniques turned out to be just what was needed to settle a long-standing mystery of penguin biogeography. Better understanding of these processes is critical to determining why these penguin populations are exhibiting dramatic declines in number—for example, the colonies located near Palmer Station in Antarctica have declined from about 16,000 to about 2,000 individuals over the past 30 years. Ongoing and future robotic deployment will help address how climate-induced local changes in these deep-sea canyons might underlie the observed declines in the penguin populations, which themselves are serving as a barometer for climate change.

Many questions are so complex that they require the combined data of several robotic platforms.

Diving In

The pace of innovation for ocean technology is accelerating, guaranteeing that the next-generation robotic systems and sensors will make current crusty oceanographers green with envy. Some of that future direction is evident in recent advances such as AUVs with onboard data analysis, so they can make smart decisions at sea by analyzing their own data. Improved sampling will also be achieved by developing methods to coordinate the efforts of multiple AUVs, either by communicating directly among themselves or by downloading commands sent from shore.

These technical advances will dramatically improve our ability to explore the ocean. But the largest effect of these systems is likely to be a cultural shift stemming from real-time, open-access data. Ocean science has historically been limited to a small number of individuals who have access to the ships that can carry them out to sea, but the realization of Hank Stommel's dream now allows anyone with interest to become involved. This outcome will democratize the ocean sciences and ultimately increase overall ocean literacy, relevant for 71 percent of this planet.

This cultural shift in oceanography comes at a critical time, given that observations suggest that climate change is altering ocean ecosystems. Examining past large-scale changes in the ocean has revealed global scale alterations in the biota of Earth, suggesting life is more intimately linked to the state of the world's ocean than we knew. The greater our awareness of these intricate connections, the better chance we have of coping with a changing ocean planet.

***Abstract*— Ocean forecasting models are an extremely valuable tool for understanding Earth's oceans. Current ocean forecast models assimilate satellite sea surface height and temperature data as well as temperature/salinity profiles from the Argo network of over 3,000 drifters. Though assimilating datasets from these drifters is pertinent, it does provide some limitations. Observing System Simulation Experiments routinely indicate that additional profile data, especially profile data that crosses frontal features, are the most influential at reducing forecast uncertainty. Since Argos drifters cannot be controlled and are subject to the oceans currents, areas that would provide critical data to ocean forecasting models are often under sampled. A potential solution to this problem would be to implement datasets provided by Slocum Gliders into the ocean forecasting models. These Autonomous Underwater Gliders are not as limited by the conditions of the oceans as Argos drifters are. Through their ability to sample virtually anywhere in the ocean, they will be able to bridge the gap left by using Argos drifters. This project aims to show the validity of including glider data into forecasting projects by comparing temperature, salinity and surface current projections made by two different ocean models (RTOFS and MyOcean) to the in-situ datasets collected by two gliders: one in the North Atlantic (Silbo) and one in the South Atlantic (RU29). There was a larger variance found between the two models for temperature and salinity compared to Silbo at the 200 m level than the 800 m level. At 200 m there was also an interesting case of disagreement between the MyOcean model versus the RTOFS model and Silbo's observations. There was a considerable peak in values of salinity and temperature with the MyOcean that was not present with the other two sources of data. The results show that there is good reason for ocean forecasting models to incorporate glider data. As for the temperature comparison with RU29 at 200 m, the RTOFS model was typically 2°C too cold, while the MyOcean model was fairly accurate. For 800 m the RTOFS model was about 1°C too cold, while the MyOcean model was about 1°C too warm. The salinity projections made by both models at both depths were always consistently accurate with RU29. These results indicate that the models, while useful, are not free of error and can be improved by incorporating datasets from gliders. Improved ocean forecasting models will have many applications, most importantly the increased ability of predicting the paths of intense storms, especially hurricanes, which are heavily influenced by ocean conditions.**

I. INTRODUCTION

Autonomous Underwater Gliders have a long and successful history of regional deployments serving scientific, societal, and security need. Application areas range from pole to pole and include the range of water depths from shallow coastal seas to the deep ocean. Glider deployments covering the basin scale are much fewer, with some well-known exceptions including the Woods Hole to Bermuda line that crosses the Gulf Stream and the Atlantic Crossing line that follows the Gulf Stream (Figure 1). New technologies for extending glider endurance are making year-long deployments and regular basin-scale missions a new reality (Figure 2). The new technologies include the capacity for more on-board lithium battery power, lower power sensors and energy harvesting to extend duration, and biofouling protection to maintain flight control and sensor calibrations.

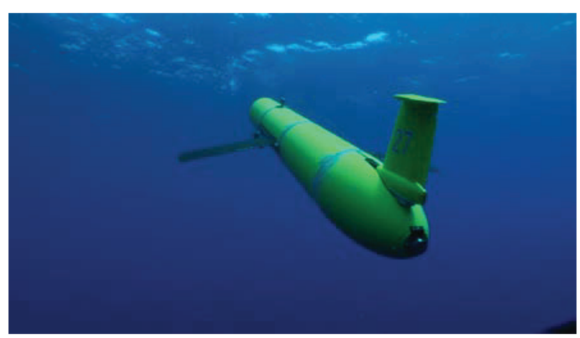

Figure 1: A photograph of RU27, an autonomous underwater glider that successfully crossed the Atlantic Ocean in 2009.

We have recently begun a globally coordinated underwater glider mission dedicated to research and education to demonstrate this new technological capability. The Challenger Glider Mission will include operation of a fleet of gliders on simultaneous basin-scale missions that revisit the historic track of the H.M.S. Challenger's first dedicated scientific circumnavigation. The scientific questions to be investigated focus on an assessment of the quality of the ensemble of available global-scale ocean models. The mission has already begun with one global-class G2 Slocum Electric glider deployed in the North Atlantic (Silbo) and a second deployed in the South Atlantic (RU29). These two gliders have already completed over 803 days at sea covering more than 15,000 km.

The goal is to match the 128,000 km distance covered by the H.M.S Challenger by 2016, the 140th anniversary of the research vessel's return to Great Britain. This goal can be achieved in 1 year with 16 gliders simultaneously flying 8,000 km legs following the gyre circulation around each of the 5 major ocean basins (Figure 3). Two additional Slocum Thermal gliders are scheduled to be deployed in the Pacific in 2013.

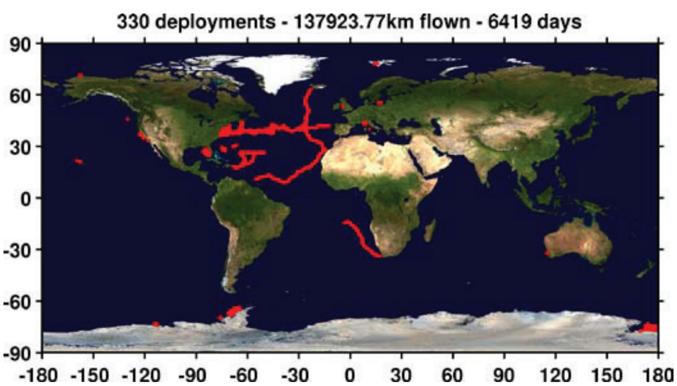

Figure 2: A map of the history of tracks covered by Rutgers Coastal Ocean Observation Lab's gliders. Basin scale missions, in collaboration with Teledyne Webb Research, Universidad de Las Palms de Gran Canaria.

The immediate scientific goals are to assess the current capabilities of the existing international suite of global ocean forecast models. The existing global ocean forecast models assimilate satellite sea surface height and temperature data as well as temperature/salinity profiles from the Argo network of over 3,000 drifters. Still, observing System Simulation Experiments routinely indicate that additional profile data, especially profile data that cross frontal features, are the most influential at reducing forecast uncertainty. Since the location of Argo drifters cannot be controlled after they are deployed, some regions are critically under sampled, and strong boundary currents are often unresolved.

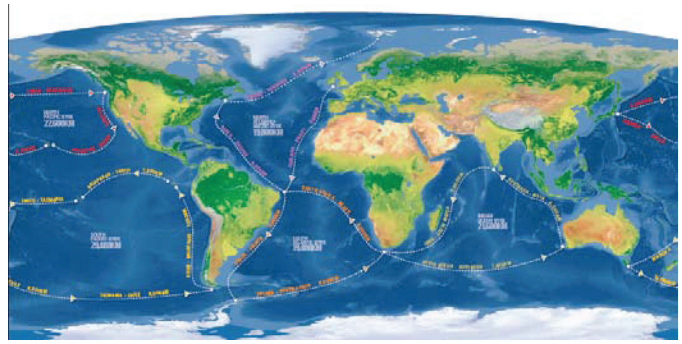

Figure 3: The projected paths of the Challenger Glider Mission.

This study will report the results of student investigations that compare the glider temperature and salinity profiles, along with depth-averaged currents, with the forecasts from the international ensemble of global ocean models. Preliminary student results indicate that the general structure of the model-generated temperature and salinity profiles agree well with the glider, but differ in the details. Much larger differences are found between the model and observed currents. Along the glider-tracks collected to date, the U.S. global model is found to compare more closely to the observations in the North Atlantic, while the European model is found to compare more closely in the South Atlantic. As an effort to improve the forecasting capabilities of ocean models, in-situ measurements of salinity, temperature, and currents, collected by gliders, were compared to conditions predicted by the models.

II. Methods

The first ocean forecasting model used in this comparison was the MyOcean model. This model is a product of Mercator and is a collaborative effort between European countries including the United Kingdom, France, Germany and Denmark. This model provides projected data for velocity, temperature, and salinity components of the water column in 5 m bins of depth, for the first 30m, and then in 10m bins for the next 70 m. The second ocean forecasting model used for comparison was the RTOFS (Real Time Ocean Forecast System) model. This model is a product of the National Center for Environmental Prediction (NCEP).

The primary oceanographic sensor on the G2 gliders is a SeaBird pumped Conductivity, Temperature and Depth (CTD) sensor. Temperature and salinity profiles are processed as described in Kerfoot et al. (2010), a process that includes correction for the thermal inertia of the conductivity sensor. RTOFS and MyOcean forecasts are harvested and archived each day in a 1000 km x 1000 km box surrounding the glider location. Glider data and model forecasts are compared every day to help determine new waypoints along paths with favorable currents, including new 3-D visualization tools developed at the Universidad de Las Palmas de Gran Canaria.

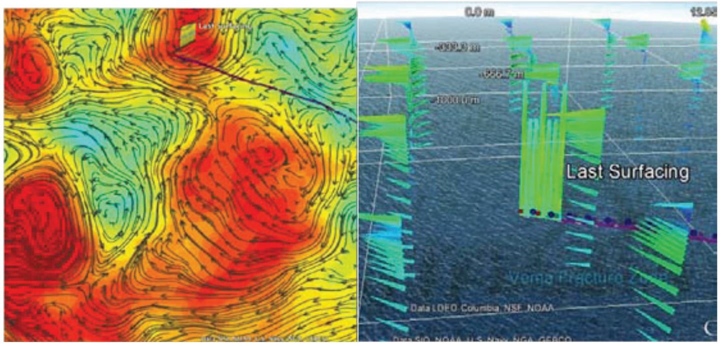

Figure 4: Example of the path planning tools that can be created using data from the ocean forecasting models RTOFS (left) and MyOcean (right).

The comparisons made between the glider data and the projected data formulated by the models were produced by analyzing estimates of temperature, salinity, and surface currents made by each. The data from the models was pulled the internet databases, while the glider data was collected by Silbo (Figure 5a) and RU29 (Figure 6a). The in-situ glider data was considered to be the ground truth conditions of the water column. The analysis was done by calculating the difference between conditions that the glider reported and the conditions that the models forecasted, as well as the differences between the two models. A series of MATLAB scripts allowed the data to be processed and various profiles to be made.

The plots for both Silbo and RU29 compare the 200 m and 800 m values of temperature and salinity as sampled from the gliders to the outputs from the RTOFS and MyOcean models. The 200 m level was chosen as a representation for the near surface layer of the ocean while the 800 m level was chosen to compare the deeper range of the gliders' approximately 1000 m maximum depth. There is a set of plots for each glider for each variable and depth level. To compare surface currents, the conditions reported by the glider were plotted against the conditions projected by the models, using Google Earth.

III. Results

A. Silbo

There is a 37 day period starting on April 9th, 2013 and ending on May 15th, 2013 that is plotted to compare the recorded values from Silbo to the two models on a daily basis (Figure 7). Beyond May 15th is when Silbo experienced its problems and was forced to abort so Silbo was no longer gliding and recording ocean profiles.

For the comparisons of salinity, at both 200 and 800 m the RTOFS model is more consistent with the data collected. At 200 m the salinity of the MyOcean model is seen to have a broad peak in which it diverges greatly from the observed temperatures from Silbo. By around the 24th of April the MyOcean model is shown to have recovered and then generally remains close in accuracy. The RTOFS model however is more accurate overall, especially with respect to the trends over the time period sampled. The fluctuations over time that Silbo recorded are also relatively well portrayed in the RTOFS salinity values at this level. The MyOcean model is off by about 0.6 PSU versus the Silbo observations and the RTOFS model during the MyOcean peak.

The consistency, accuracy and trends of the temperature plot for Silbo at 200 m are very similar to the 200 m plot for salinity. There is a jump or increase present in the MyOcean model approximately between the dates of April 10th and April 24nd where at the same time the RTOFS model shows one of its most accurate periods. The temperature between the MyOcean model and Silbo differ as much as 2-3°*C* between those dates. It is also evident from this plot that the RTOFS model is consistently cooler than the MyOcean model.

At 800 m the salinity differences of the models to the measurements from Silbo were considerably less than those found at 200 m. Both ocean models were found to be close in comparison to each other and any differences from either model rarely exceeded 0.1 PSU. The RTOFS is the better performer for the first half of the month time series but only by a small factor.

The temperatures at the 800 m level tell a different story than the 200 m level. Here the MyOcean model shows greater accuracy over the RTOFS model. Similarly to how the 800 and 200 m levels of salinity compared, the difference between the 800 m glider temperatures and the models did not have as great of a range as did the 200 m level. It is noticeable that the RTOFS model is about 0.5*°C* too cold at this 800 m level.

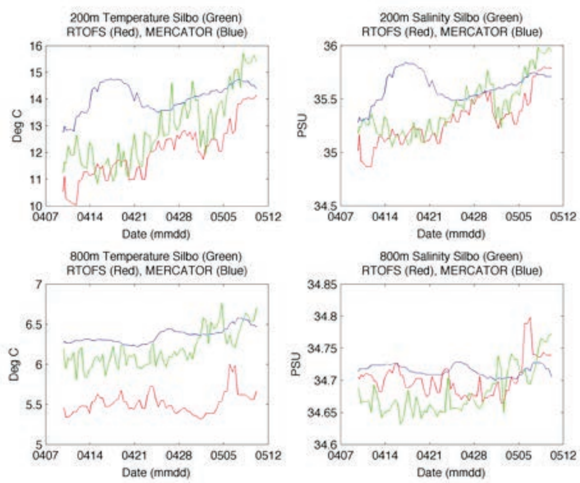

Figure 7: Comparisons of Silbo (green) with RTOFS (red) and MyOcean (blue) model data of temperature at 200m (top left), 800m (bottom left) and salinity at 200m (top right) and 800m (bottom right).

B. Silbo Case Study

Within Silbo's time series plots there is one feature that is most prevalent at the 200 m level which has been explored further here. As discussed earlier there is a period between 4/13/13 and 4/22/13 where there is a jump in the 200 m salinity and temperature as modeled by MyOcean. The RTOFS model however does not contain this feature and remains more accurate to the observations that Silbo recorded.

Figures 8a and 8b show two maps that display Silbo's path across a section of the Atlantic Ocean. There is a point labeled that represents the glider's surfacing location during the day of April 18th. This date was chosen because it falls near the MyOcean peak of temperature and salinity. The maps show the ocean temperatures and the ocean currents at 200 m with the upper being the RTOFS model run and the lower being the MyOcean model. Comparing the two vector fields alone on this same day show that there is a large amount of disagreement between the two and many of the eddy features are opposite in flow direction.

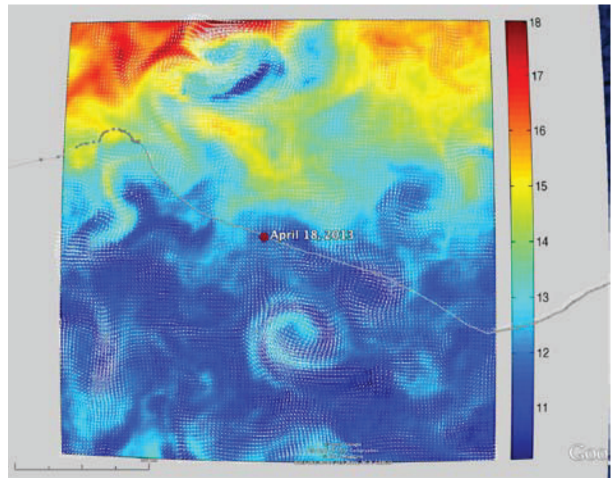

Figure 8a: RTOFS 200m temperature and currents on April 18th, 2013. The glider position is marked by the red dot.

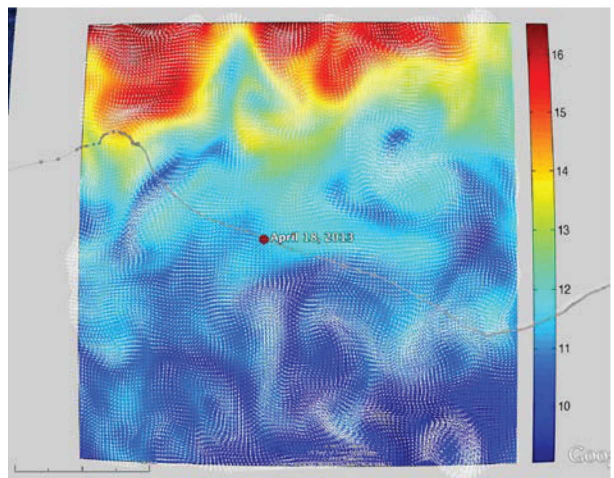

Figure 8b: MyOcean 200m temperature and currents on April 18th, 2013. The gliders position is marked by a red dot.

The RTOFS model displays currents at 200 m that are coming from the southeast at Silbo's location which would be providing cooler temperatures (Figure 8a). The MyOcean model however has currents at this level coming from the northeast towards Silbo and with them bringing comparatively warmer temperatures. The warmer area of water that MyOcean shows being pulled south is what it expected Silbo to fly through and would explain the broad peaked increase in temperatures (Figure 8b). At the surface, warmer water temperatures in the Northern Hemisphere would be to the south and closer to the equator. At 200 m, however, the warmer waters on the maps are shown to the north. This is the result of North Atlantic Gyre that creates a deeper layer of warm water which is visible at depth and is independent of what some of the surface solar-heated waters may be. In

Figure 9 two profiles, one for temperature and one for salinity show the entire depth range down to 1000 m. The warmer temperatures of the MyOcean model are visible here extending beyond the 200 m level (Figure 9).

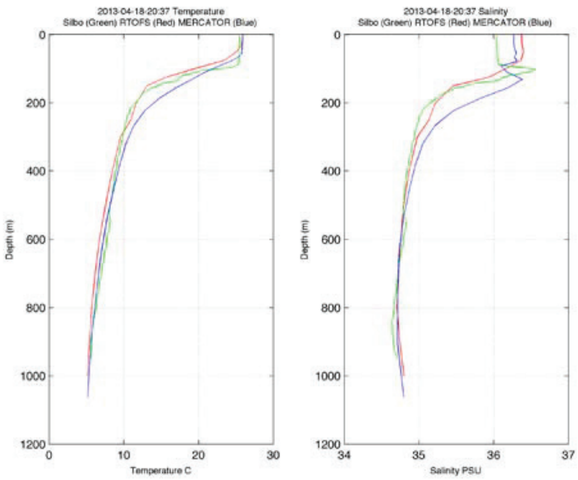

Figure 9: (Left) Profile of temperature comparison between Silbo (green), RTOFS (red) and MyOcean (blue) for 4/18/2013. (Right) Profile of salinity comparison between Silbo (green), RTOFS (red) and MyOcean(blue).

C. RU29

A time period consisting of 82 days, starting February 22nd, and ending May 15th was used for comparison with the two models (Figure 6a). These data sets were compared separately at 200m and 800m depths with respect to temperature and salinity. During this time period RU29 had begun to leave the coastal waters of South Africa and journey northeast towards the equator.

At 200m of depth, the RTOFS model was always about $2°C$ too cold, while the MyOcean model was quite accurate (Figure 10). As this time series progresses, the temperature reported by all three data sets show that the ocean is getting progressively colder. This corresponds to the transition of Summer to Winter in the Southern Hemisphere. Both models show an interesting spike in temperature around 3/25/13, but they are in different directions. The RTOFS model drops by about $1°C$ during this time, while the MyOcean increases by about $1.5°C$. The glider does show a slight decrease in temperature during this time, but not on the magnitude that the RTOFS model predicts.

At 800m depth, the RTOFS model was typically about $1°C$ too cold, while the MyOcean model was typically about $1°C$ too warm. As this time series progresses the three different datasets show a similar trend of a slight increase in temperature. This slight increase corresponds to the gliders approach to the equator. Neither model is ever off by more than $1°C$ during this time series.

At 200m depth, both models were very accurate in projecting salinity. The RTOFS model typically predicted low by about 0.2 PSU while the MyOcean model was pretty much spot on. Both models were also fairly accurate at projecting salinity at 800m depth. The RTOFS model typically over predicted but by only a very small margin. MyOcean again was pretty much spot on.

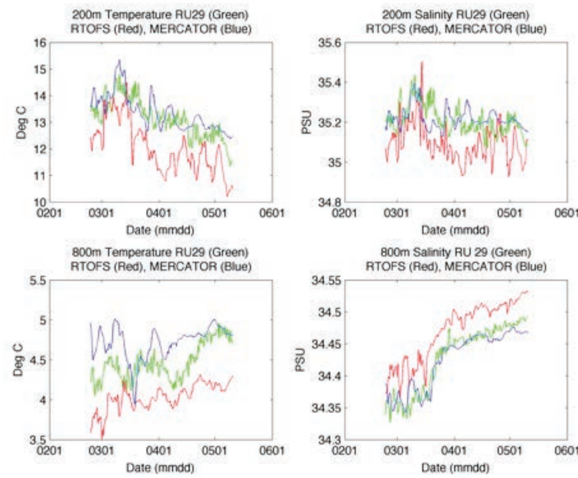

Figure 10: Comparisons of RU29 (green) with RTOFS (red) and MyOcean (blue) model data of temperature at 200m (top left), 800m (bottom left) and salinity at 200m (top right) and 800m (bottom right).

D. RU29 Case Study

Another day that provided results worth analyzing further was May 5th, 2013. On this day the MyOcean model depicted two different eddies, one north of RU29's location, and one south (Figure 11a). The eddy north of the glider was flowing in a counter-clockwise direction, and the eddy south of the glider was flowing in a clockwise direction. Since RU29 was located in the Southern Hemisphere, the southern eddy would be considered a warm eddy and the northern one a cold eddy. In order to verify that this phenomenon was actually occurring in the ocean, these projections were compared to both the RTOFS model and the glider data (Figure 11b).

RU29's location during this study is marked by yellow pins, and the currents it reported by red lines. The RTOFS model projections showed no sign of either eddy. The surface currents reported by the glider appear to be almost opposite of what the MyOcean model was predicting, and seem to agree more with the projections of the RTOFS model.

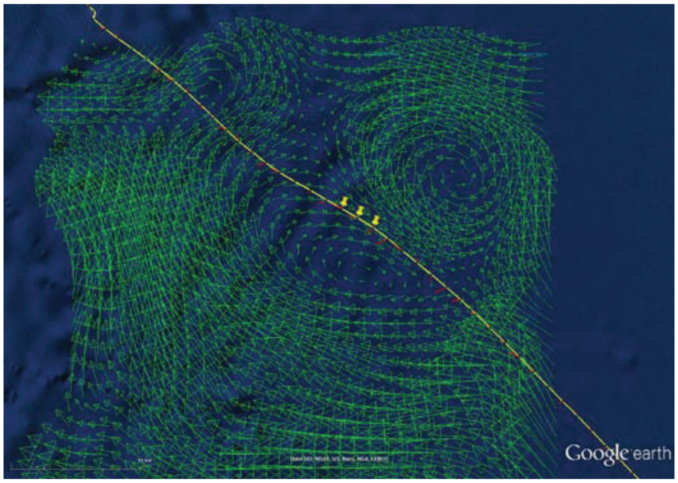

Figure 11a: MyOcean surface current projections and surface currents reported by RU29 for 5/06/2013.

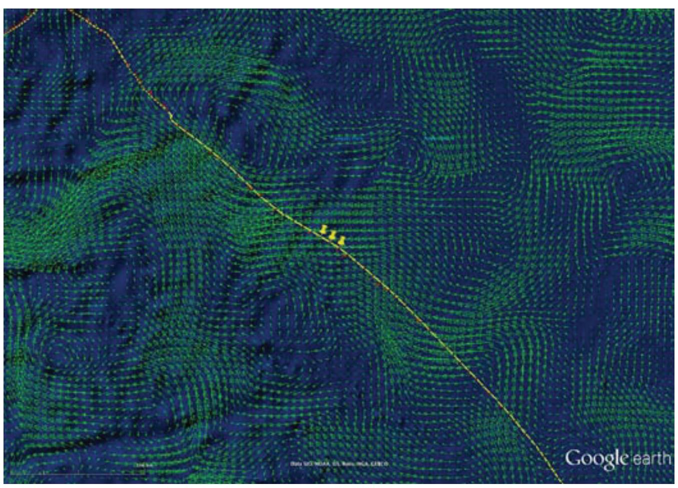

Figure 11b: RTOFS surface current projections and surface currents reported by RU29 for 5/06/2013.

In order to get a better understanding on whether the eddies were a valid feature or not, the salinity and temperature profiles of the models and RU29 were analyzed (Figure 12). According to these profiles, the data collected by RU29 agrees more with the MyOcean model for both temperature and salinity. So even though the surface currents experienced by RU29 were directly opposite of what the MyOcean model predicted, the MyOcean temperature and salinity projections were quite accurate.

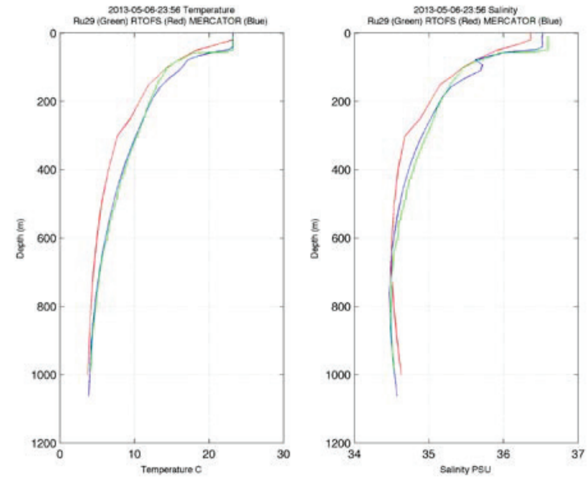

Figure 12: (Left) Profile of temperature comparison between RU29 (green), RTOFS (red) and MyOcean (blue) for 5/06/2013. (Right) Profile of salinity comparison between Silbo (green), RTOFS (red) and MyOcean(blue).

IV. DISCUSSION

The value of ocean forecast models has advanced well beyond scientific curiosity-driven research. The world's major forecast centers currently run operational global forecast models that are eddy-resolving, data assimilative, and are distributed free-of-charge to a wide variety of users. Global-scale ocean assimilation data include satellite-derived sea surface temperature and sea surface height, as well as the global array of Argo profiling floats and surface drifters. Forecast skill continues to improve, yet many offshore operators are faced with the same set of questions: (1) How good are the global ocean forecast models? (2) Can ocean forecasts for a specific area be improved through the use of nested regional-scale models? (3) Or can better improvements be obtained by locally enhancing the observations in either the global-scale or nested models?

Autonomous underwater gliders provide a means to test ocean models. Unlike drifters & floats, gliders also travel under their own power. They can be programmed to fly into areas with expected high forecast error and provide valuable assimilation data across fronts along the way. The model validation data includes not only the glider's subsurface temperature and salinity profiles, but also their depth averaged and surface drift velocity estimates. Depth averaged velocity profiles are a significant augmentation of the already invaluable Argo profile data. Model-derived temperature and salinity profiles often compare well to observed Argo and glider profiles, but as we see in the two case studies developed here, the model currents can be in opposite directions and the glider depth averaged velocity is required to discriminate.

At the surface, the two global ocean models compared here have very similar characteristics. This is not unexpected, since both are assimilating similar sea surface temperature and sea surface height products. Subsurface, the models look very different, especially at 200 m, near the seasonal thermocline. RTOFS contains many distinct and highly circular eddies at this level, while MyOcean exhibits many interconnected and meandering filaments wrapped around the same highs and lows. At times, the MyOcean filamental flow directions line up with the RTOFS eddy circulation, and at other times, they are in direct opposition. In the first case study presented here, the long filaments resulted in the advection of anomalous warm water from the southern edge of the North Atlantic gyre into the colder subsurface water to the south. The filament persisted for the full 10 days it took the glider to cross it, with no sign of the anomalously warm water in the glider data. In the second case study, surface currents from both models agreed well with the surface drift of the glider every time it surfaced to communicate. At 200 m depth, however, currents in the two models were exactly opposite, one generally in the direction of surface flow and one opposite. The glider depth averaged velocity indicates that one of the models did the better job of forecasting the observed temperature and salinity profiles, but that information was insufficient to decide which model produced the better velocity forecast. Neither model was in agreement with the observed currents at depth.

The two case studies highlight the need for a broader and more systematic validation study that could be conducted with a fleet of gliders with persistent coverage over a long period. In this paper we propose a global model skill assessment study focused on some of the more difficult to reproduce parts of the ocean, the edges of the major gyres. It is in these regions that glider observations may prove their greatest value in global model assimilation and validation by combining velocity profile observations with collocated standard CTD profiles. While surface parameters are important for many applications like Search and Rescue, vessel routing and floatable tracking, the fidelity of subsurface forecasts is required in other applications, in particular, understanding life cycles within pelagic ecosystems, subsurface pollutants, and upper ocean heat content for tropical storm intensity forecasting. Gliders provide the critical dataset to improve models below the surface, an area that is unseen from space, with a dataset that is not currently available from Argo CTD profilers or the global arrays of surface drifters.

V. Acknowledgements

The Challenger Glider Mission is growing global partnership of glider operators, scientists, educators and students coordinated by Rutgers University. The results presented in this paper were initiated in a Rutgers research course and completed by two undergraduate summer interns (Collin Dobson & Jeffrey Mart) supported by Teledyne Webb Research. Carlos Barrera teaches the companion course in the Canary Islands. Glider path planning and model/data comparison activities are led by Nilsen Standskov and Antonio Ramos. With cyber infrastructure support provided by John Kerfoot. Glider operators include Chip Haldeman, Dave Aragon, Tina Haskin (Rutgers) and Ben Alsup (TWR). Silbo was donated by Teledyne Webb Research and Challenger (RU29) by Rutgers. The RU29 deployment in South Africa was enabled by the University of Cape Town, The Nansen-Tutu Center, Sea Technologies, and the Department of Environmental Affairs. RU29 mission support is provided by U.S. IOOS. Support for the Pacific Basin Thermal Gliders is provided by ONR with path planning led by students in the U.S. Naval Academy.

Abstract

Penguin foraging and breeding success depend on broad-scale environmental and local-scale hydrographic features of their habitat. We investigated the effect of local tidal currents on a population of Adélie penguins on Humble Is., Antarctica. We used satellite-tagged penguins, an autonomous underwater vehicle, and historical tidal records to model of penguin foraging locations over ten seasons. The bearing of tidal currents did not oscillate daily, but rather between diurnal and semidiurnal tidal regimes. Adélie penguins foraging locations changed in response to tidal regime switching, and not to daily tidal patterns. The hydrography and foraging patterns of Adélie penguins during these switching tidal regimes suggest that they are responding to changing prey availability, as they are concentrated and dispersed in nearby Palmer Deep by variable tidal forcing on weekly timescales, providing a link between local currents and the ecology of this predator.

Introduction

The region surrounding Anvers Island, West Antarctic Peninsula (WAP) is a "hot-spot" for Adélie penguin activity. Adélie penguins (*Pygoscelis adeliae*) have been present in the Anvers Island region on millennial timescales [1,2]. The presence of a pronounced submarine canyon (Palmer Deep) near this area provides a conduit for warm Upper Circumpolar Deep Water (UCDW), locally increasing primary production, which supports a productive regional food web [3–5]. In addition, this region has warmed significantly [6,7] and has lost a significant amount of sea-ice [8,9]. The Adélie penguin population in this region has decreased dramatically since the 1970's [10], as climate conditions that support their chick rearing habitat have moved southward [11]. Understanding the interaction between the foraging behavior of the remaining Adélie penguins and physical dynamics in this historical "hot-spot" may provide insights into the future of this historic colony that has survived past warming and cooling events [12].

The effect of the tides on currents is most dramatic in coastal systems. Tidal forces interact with local geographic and bathymetric features that change sea level, cause water mass mixing, and create tidal fronts [13–16]. These features affect phytoplankton distribution [17–20], zooplankton aggregation [21–26], benthic grazers [27], fish behavior [28–30] and even marine mammal foraging activity [31–33]. Tidal fronts also influence seabird foraging timing and behavior by concentrating prey or providing favorable currents that regulate foraging trips. For example, short-tailed shearwaters (*Puffinus tenuirostris*) broaden their access to smaller euphausiids by foraging near recurrent tidal fronts in the Akutan Pass [34], while auklets coordinate their feeding behavior with peak tidal current velocities in the shallow passes in the Aleutian Islands [35]. In Vancouver Island, Canada, planktivorous diving birds prefer deep water with moderate to high tidal flow while benthic invertebrate feeders preferred shallow, tidally slack waters. Piscivorous diving birds feed in shallower water during moderate tidal flows and in a variety of water depths during slack water [36]. The impact of flood and ebb tidal forces has also influences the mode of transportation of Magellanic penguins (*Spheniscus magellanicus*), which avoid swimming against strong tidal currents by diving deeper or walking in San Julian Bay, Argentina [37]. Magellanic penguins also take advantage of tidal oscillations in the Beagle Channel, Argentina, to transport them to foraging locations maximize their foraging success [38]. The wide and varied exploitation of different tidal forces by sea birds show that tides produce regular and predictable concentrations of resources in an otherwise patchy coastal environment [39]. These local tidal concentrating mechanisms may become more ecologically important, as tides are not significantly affected by a changing climate.

In this study we test the hypothesis that tides are a significant predictor of Adélie penguin foraging locations in the Anvers Island region of the West Antarctic Peninsula (WAP). To do this, we used a combination of satellite-tagged Adélie penguins, historical tide records and currents derived from a Slocum glider autonomous underwater vehicle (AUV). We found a significant relationship between tidal regime and Adélie penguin foraging location during our field season and used an additional nine years of penguin location data to test the historical robustness of our results.

Methods

Penguin ARGOS Tags and Dive Recorders

From January 5–27, 2011, we tagged 11 Adélie penguins at the Humble Is. rookery near Palmer Station, Anvers Is., Antarctica (64° 46′ S, 64° 04′ W). This study area is characterized by large changes in bathymetry near shore, and narrow fjords characteristic of the WAP (Figure 1). Penguins selected for tagging were paired and had brood-stage nests containing two chicks. We use the brood stage as a "biological standard" to control for changes in parental foraging behavior that might be affected by chick age [40]. Tags were a custom mold based on SPOT and SPLASH tag configurations from Wildlife Computers (Redmond, WA, USA). Our tags had a sloped frontal area of 17×18 mm (306 mm^2), weighed 55 g and had an antenna length of 12 cm. Tag length was 86 mm. All tags in the 2011 season were equipped with pressure sensors to measure penguin dive depths (TDR, Lotek Wireless). Dive data was recorded at 1 Hz. Tags were fastened to anterior body feathers using double sided tape and small plastic cable ties. Tags were rotated to new penguins every 3–5 days depending on fair weather conditions allowing for access to the colony. The tag represents less than 2% of body mass of the lightest penguins that are typically tagged (range 3.2–4.7 kg). Some devices can affect foraging trip duration [41,42]; our study is focused on foraging location rather than trip duration. Furthermore, tags that have been shown to affect penguin foraging trip duration were in some cases up to three times heavier and had double the frontal area when compared with our custom tags [41,42]. Our tags are also among the lightest available and typically deployed for only 3–5 days before removal and rotation to other birds. We did not test explicitly for a "tag effect" on our penguins, but considering the size of the tag, we expect any effect to be small. Location-only data were collected from 103 Adélie penguins for ten breeding seasons (Dec–Feb) between 2002 and 2011 (Table 1) using similar tags and procedures.

Penguin Location Data Filtering

The quality of the location data depends on how many ARGOS satellites are in view while the tag is above the water. The porpoising and diving behavior of traveling penguins can result in poor quality location data. Location data qualities are classified as 3, 2, 1, 0, A, and B under the least-squares ARGOS algorithm. Class 3, 2, and 1 positions are accurate within 100 m, 250 m, 500 m−1500 m respectively. Class 0, A, and B positions are locations that have no error estimation [43]. We controlled the quality of our location data using three steps. First, we eliminated erroneous terrestrial positions using land masks from the National Snow and Ice Data Center, Atlas of the Cryosphere (http://nsidc.org/data/atlas/news/antarctic_coastlines.html). Second, we applied a sequential filter that considers location data quality flags and distance between successive locations based on maximum sustained swimming speed of the penguins [44] using the R argosfilter package [45]. Our threshold swimming speed was based on a maximum sustained swimming speed of 8 km hr^{-1} [40,46]. Finally, we visually inspected each track and manually removed

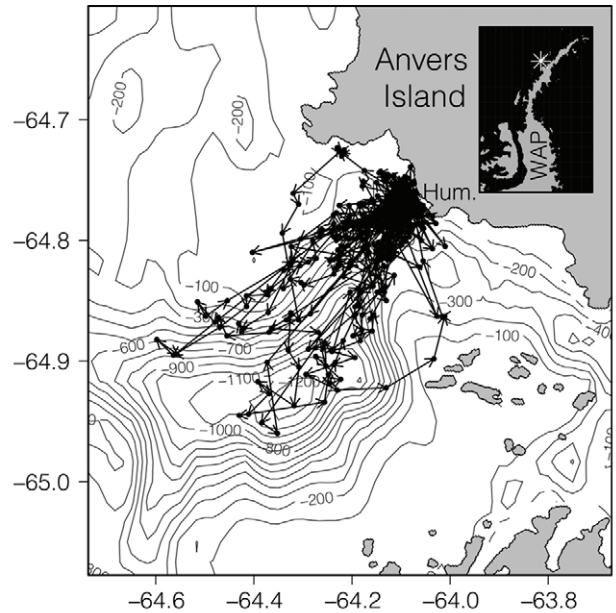

Figure 1. Filtered satellite tracks from Adélie penguins located at Humble Is. (Hum.), on the South coast of Anvers Island (white asterisk on inset) on the West Antarctic Peninsula (WAP) in January 2011. These birds also carried dive recorders. Arrows represent the path of foraging trips. Contours are bottom bathymetry (m) showing the location of Palmer Deep.
doi:10.1371/journal.pone.0055163.g001

any class B points that were unreasonable based on coastal geometry. For example, the distance filter considers only great circle distances and does not take into account geographic barriers such as islands, which would increase the travel time between points (Table 1).

Dive Records

Dive records from 2011 were zero-offset using the diveMove package in R [47]. Based on previous studies of penguin diving behavior, we considered dives deeper than 5 m to be foraging dives [48,49]. diveMove uses recursive filtering and a diving threshold to correct for drift in TDR depth sensors and identify diving behavior. This approach has been used to correct diving records of King penguins (*Aptenodytes patagonicus*) [50]. The dive records and penguin location data were then time merged. Location data within 150 seconds of a dive identified by the diveMove software were identified as foraging locations. Assuming a maximum swimming speed of 8 km hr^{-1} [40,46], diving must have occurred within one third of a kilometer of a location fix.

Tidal Measurements and Classification

A tide gauge mounted on the pier at Palmer Station, Anvers Island, Antarctica, recorded tidal amplitude during our experiment. The tide gauge is 1.7 km from Humble Is. We classified the tidal forcing regimes as diurnal or semidiurnal based on counting the number of high tides in a day. Time periods with one high tide per day were classified as a diurnal regime and all other tidal time periods were classified as a semidiurnal regime.

Depth Integrated Currents from a Slocum Glider

We deployed a Slocum electric glider AUV in two successive missions from January 10–14, 2011 for a 62 km mission and

Table 1. The deployment dates, number of ARGOS locations and mean range of the Adélie penguins tagged in each season.

Season	No. Birds	Dates Deployed	No. ARGOS locations (Post-filtering)	Mean range km (± s.d.)
2002	4	2002-01-19–2002-02-07	300 (256)	24.99 (±16.17)
2003	23	2002-12-28–2003 -02-11	2550 (1811)	11.29 (±7.56)
2004	22	2004-01-04–2004-02-08	2627 (1790)	7.72 (±5.12)
2005	19	2005-01-06–2005-02-07	1352 (991)	9.90 (±6.36)
2006	3	2006-01-18–2006-01-21	148 (119)	26.16 (±29.08)
2007	8	2007-01-11–2007-02-05	481 (340)	8.74 (±5.10)
2008	5	2008-01-19–2008-02-06	468 (367)	7.99 (±5.04)
2009	5	2009-01-06–2009-01-21	482 (445)	8.61 (±4.90)

*Birds that recorded dive information in addition to ARGOS location.
doi:10.1371/journal.pone.0055163.t001

January 15–31, 2011 for a 178 km mission. These vehicles have previously been used to provide environmental context for penguin foraging behavior [51]. Gliders are buoyancy driven and travel in an underwater "saw-tooth" pattern [52] between 1 m and 100 m, with surface GPS fix every 2 hours or upon reaching a waypoint. While underwater, the glider used internal compass heading corrected for declination to navigate to its next waypoint. Integrated currents between glider surfacings were estimated by the difference between where the glider surfaced based on a GPS fix, and the estimated location of the glider based on internal navigation. This method produced a 100 m depth integrated current estimate every two hours of the glider mission. During this experiment, the glider estimated currents in the general area of the Palmer Deep, which is a historically important location for penguin activity [3]. Twice, during a diurnal and a semidiurnal tidal regime, the glider was programed to remain near a station ("station keep") at the northeast edge of the Palmer Deep to resolve the temporal changes in currents over a diurnal and semidiurnal tide cycle.

Analysis of Penguin Foraging Location

We tested the hypothesis that Adélie penguins forage at different locations different tidal regimes (diurnal vs. semi-diurnal) by using a linear mixed model [53] on locations merged with dive information in the 2011 season. Because successive locations and dives for each penguin are spatially auto-correlated, we divided the location records associated with diving behavior into trips. Trips were defined as a set of locations separated by return (within 0.5 km) to Humble Is. We then treated each trip as a random effect and tidal regime as a fixed effect in a linear mixed model. We also developed models that included tidal amplitude and Julian day as fixed effects to account for influences of short term (flood and ebb tide) and possible intra-seasonal dependencies on penguin location We repeated this analysis for location-only data (2002–2011), even though we could not distinguish diving locations from non-diving locations. We expect qualitative similarity to results from the 2011 season where diving locations can be separated from non-diving locations, however quantitative differences in estimated fixed effects are expected. To visualize differences in penguin location between tidal regimes, we used a two-dimensional kernel density filter with a grid cell of 725 m. The size of the Gaussian smoothing kernel was ~3 km.

Results

Penguin Locations and Dive Records

The ARGOS filtering technique removed 24% of the ARGOS locations for all years (Table 1). In 2011, we collected 738 hours of dive depth records from 11 Adélie penguins. We classified 201 locations as diving locations and 467 locations as non-diving locations. The 2011 record was separated into 30 trips, while the historic record was separated into 603 trips. The Adélie penguins from Humble Is. frequently forage over the northeast edge of Palmer Deep (Figure 1) and follow noticeably different trajectories during the diurnal and semidiurnal tidal regime are evident (Figure S1).

Palmer Tide Records

The tides at Palmer station are mixed, and switch between diurnal (one high and one low tide per day) and semidiurnal (two highs and two lows per day) (Figure 2). The principal tidal constituents are the diurnal K_1 and lunar O_1 and the semidiurnal K_2 and M_2 [54]. Mean tidal amplitudes during our study were 1.23 m and 0.93 m during diurnal and semidiurnal tidal regimes respectively. During the 2011 season, 32% of the penguin trips were during the diurnal tidal regime, while 68% were during the semidiurnal tidal regime. For all penguin trips from 2002–2011, 46% were during diurnal and 54% were during semidiurnal tide regimes.

Currents in Palmer Deep

In 2011, the AUV made 130 and 122 estimates of 100 m vertically integrated currents during diurnal and semidiurnal tides respectively. The mean current speed was 0.13 m s^{-1} with a range of 0–0.41 m s^{-1}. Currents directed toward the northeast, southeast, southwest and northwest quadrat were 59%, 19%, 11%, and 10% of all current observations, indicating a general flow towards the northeast edge of Palmer Deep (Figure 3). Mean current velocities during diurnal and semidiurnal regimes were 0.14 (s.d. ±0.09) and 0.11 (s.d. ±0.08) m s^{-1} respectively. A t-test showed that currents during diurnal tides were significantly stronger than currents during semidiurnal tides ($t = 3.10$, d.f. = 247.84, $p = 0.002$). During diurnal tides, current bearings

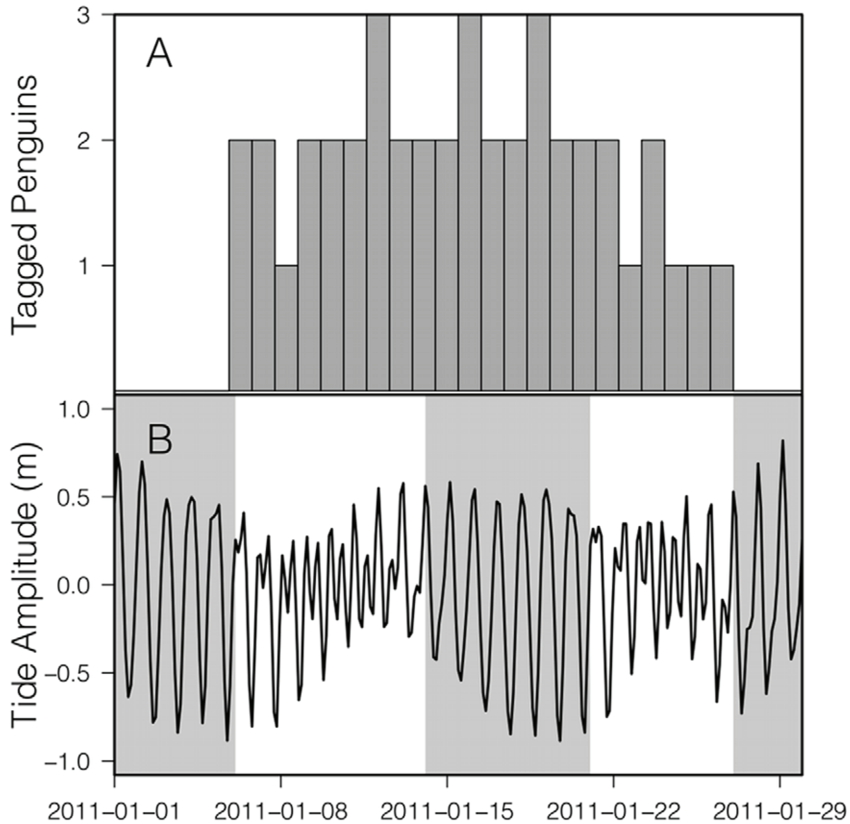

Figure 2. The number of tagged Adélie penguins deployed each day over the course of the 2011 experiment compared to the tidal record at Palmer Station. The number of penguins tagged was between 1 and 3 during the 2011 experiment (A). Mixed tide cycles at Palmer Station during the field season showing the shift from diurnal to semidiurnal tides. Diurnal tides are shaded in grey (B).
doi:10.1371/journal.pone.0055163.g002

were toward the northeast, southeast, southwest and northwest quadrats 68%, 16%, 7%, 9% as compared to 50%, 22%, 14%, 11% during semidiurnal tides indicating stronger flow toward the northeast edge of Palmer Deep, near Humble Is. more often during diurnal tides. The distribution of current bearings between the two tidal regimes was significantly different according to a Mardia-Watson-Wheeler test ($W = 13.988$, $p << 0.001$) [55]. The non-parametric Mardia-Watson-Wheeler test was necessary to test for differences in current bearing between the tidal regimes because the current bearing distribution did not follow a von-Mises (circular normal) distribution. During one diurnal tidal regime, and one semidiurnal tidal regime, the glider maintained its position ("station-kept") to measure currents over a tidal cycle at the northeast edge of Palmer Deep (Figure 4). During semidiurnal tides, the tidal currents are asymmetric over a tidal cycle with stronger currents directed up the canyon. However, during diurnal tides, there is no current to the southwest, indicating that the direction of flow is steady towards the northeast edge Palmer Deep and Humble Is. throughout the tidal cycle. The current bearings between the tidal regimes during the station-keeping missions were significantly different according to a Mardia-Watson-Wheeler test ($W = 21.009$, $p << 0.001$). Wind speeds at Palmer Station while station keeping were weak (mean 2.92 ± 1.45 m s^{-1} and 6.35 ± 2.41 m s^{-1} during the diurnal and semidiurnal tides respectively) and uncorrelated to the vertically integrated currents measured by the AUV during both the diurnal ($t = 1.0$, d.f. = 11, $p = 0.34$) and the semidiurnal ($t = -0.04$, d.f. = 15, $p = 0.96$) tidal regimes. This indicates that wind speed had little effect on the 100 m depth integrated currents during the station-keeping experiments of the AUV. The significant difference of tidal current bearing between the diurnal and semidiurnal regime provide justification for treating the two tidal regimes as factors in our statistical models.

Analysis of 2011 Penguin Diving Locations

We used a linear mixed effects model fit by maximum likelihood to estimate the relationship between tidal regime and the penguin locations relative to their rookery on Humble Is.:

$$DHI_{ijk} = tide\ regime_i \times \beta + tripID_j + \varepsilon_{ijk} \tag{1}$$

where DHI is the distance of the penguin location to Humble Is., tide regime ($i = 1, 2$) is a fixed effect factor that corresponds to the diurnal or semidiurnal regime, β is an estimated coefficient, tripID ($j = 1, 2, 3\ldots$) is a random effect and ε_{ijk} is the residual error, assumed to be normally distributed ($k = 1, 2, 3\ldots$). This model showed that locations associated with diving behavior were significantly farther from Humble Is. during the semidiurnal tide regime compared to a diurnal tide regime (Figure 5) in 2011. The mean ($\pm$ S.E.) distance to diving locations from Humble Is. was 5.4 ± 1.4 km during the diurnal tidal regime while the mean distance to diving locations from Humble Is. was 9.1 ± 1.5 km during the semidiurnal tidal regime ($AIC = 1284$, $t = 2.50$, $p = 0.015$). The residuals of this model satisfied the assumption of normality. Since non-diving locations are generally co-located with diving locations (Figure 5), we repeated the analysis on the

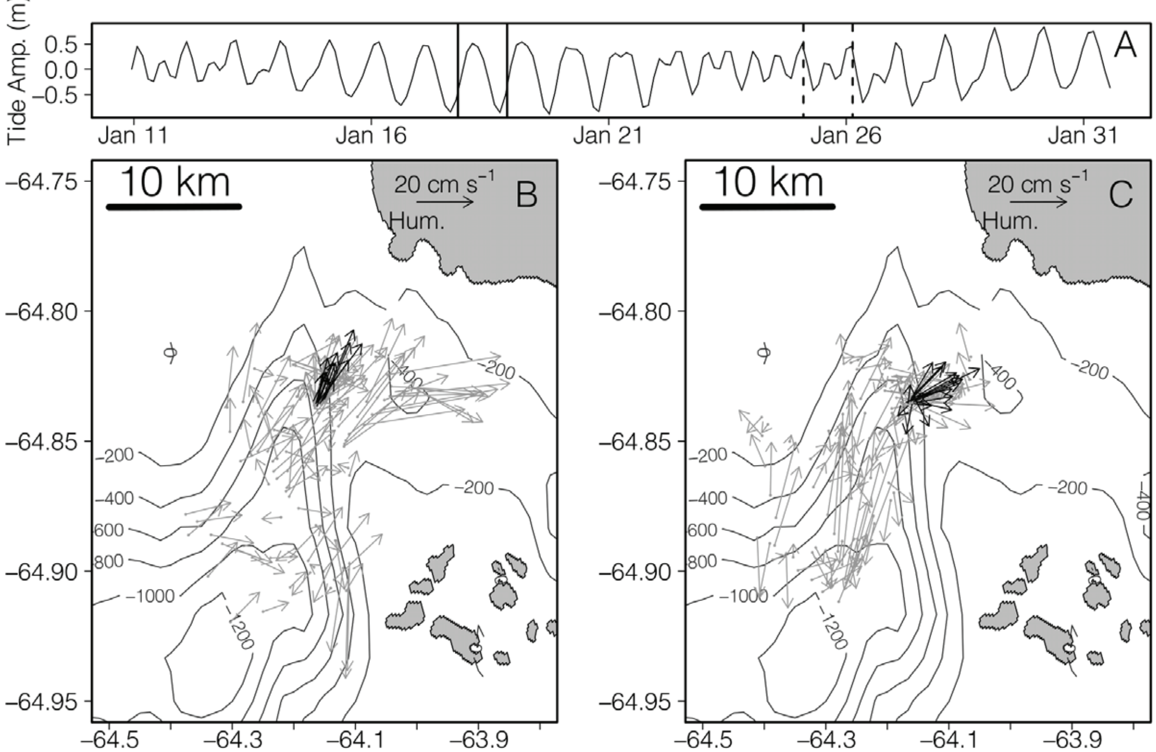

Figure 3. Depth integrated currents measured by a Slocum Glider AUV deployed for the month of January 2011 (arrows). Flow in both tidal regimes is complex, but onshore toward the northeast edge of Palmer Deep in both tide regimes throughout the glider mission. The two separate "station-keeping" periods during strong diurnal tides (station keeping between black lines) and semidiurnal tides (station keeping between dashed lines) are shown in panel A. Black arrows represent the currents measured while station keeping during diurnal and semidiurnal in panels B and C respectively. During the diurnal tides, flow was always toward the northeast edge of the canyon showing no reversals. During the semidiurnal tide, flow oscillated between shoreward and offshore flow, however the shoreward flow was much stronger.
doi:10.1371/journal.pone.0055163.g003

2011 data, for all diving and non-diving locations. The residuals of a linear mixed model that included all locations from 2011 indicated that the data were not normally distributed. Therefore, we $\log_{10}$ transformed DHI, after which model residuals were nearly normal. We found that penguin locations, irrespective of diving behavior, were significantly farther from Humble Is. during a semidiurnal tide compared to a diurnal tide (AIC = 345.3, t = 2.99, p = 0.004). The mean (±SE) distance to Humble Is. during a diurnal tide was 2.7±0.5 km and the mean distance to Humble Is. during a semidiurnal tide was 4.4±0.3 km. Mean distances are closer to Humble Is. when all locations are considered, compared to the diving-only locations. This is likely a consequence of not separating locations that are associated with diving behavior.

Changes in penguin foraging distance and location have been observed to vary with the season [56,57], and with daily flood and ebb tides [38]. To test for intra-seasonal changes or changes related to flood or ebb tides in the penguin location distance from Humble Is. we also included Julian day and tidal amplitude as additional fixed effects in the linear mixed effects models:

$$DHI_{ijk} = X_{ijk,l} \times \beta_l + tripID_j + \varepsilon_{ijk} \qquad (2)$$

where DHI is the distance of the penguin location to Humble Is., X is a three column (l = 1, 2, 3), fixed effects design matrix of the tide regime (i = 1, 2), tidal amplitude (m) and Julian Day (d) and β is a vector of three estimated coefficients of the fixed effects. tripID (j = 1, 2, 3…) is the random effect and ε_{ijk} is the residual error, assumed to be normally distributed (k = 1, 2, 3…).

Similar to Eq. (1), model fits of Eq. (2) showed that penguin diving locations (AIC = 1284, t = 2.68, p = 0.008) and all penguin locations in 2011 (AIC = 345, t = 2.75, p = 0.003) during the diurnal tide regime were significantly closer to Humble Is. compared with the semidiurnal tidal regime. Neither tidal amplitude nor Julian day were significant predictors of DHI for diving locations alone (tidal amplitude t = 1.19, p = 0.235; Julian Day t = −0.75, p = 0.941), nor all penguin locations (tidal amplitude t = 1.14, p = 0.254; Julian day t = −1.18, p = 0.237) in 2011. An AIC comparison of the model fits of Eq. (1) and (2) showed they were not significantly different for penguin diving locations (d.f. = 2, χ^2 = 1.41, p = 0.495), or for all penguin locations (d.f. = 2, χ^2 = 2.490, p = 0.288), indicating that there is not an effect of tidal amplitude or Julian day on penguin foraging location in 2011.

Analysis of 2002–2011 Penguin Locations

Location-only data from 2002–2011 also show a difference between penguin locations between tidal regimes. Contours containing 95% of observations showed that penguins used a smaller area to forage during diurnal tides (40.6 km^2), compared to semidiurnal tides (101.4 km^2) (Figure 6). A linear mixed effects model the same form as Eq. (1) on $\log_{10}$ transformed distance data showed that penguins were significantly farther from Humble Is. during semidiurnal tides, compared to diurnal tides (AIC = 13263, t = 2.054, p = 0.04). The mean distance (±SE) from Humble Is.

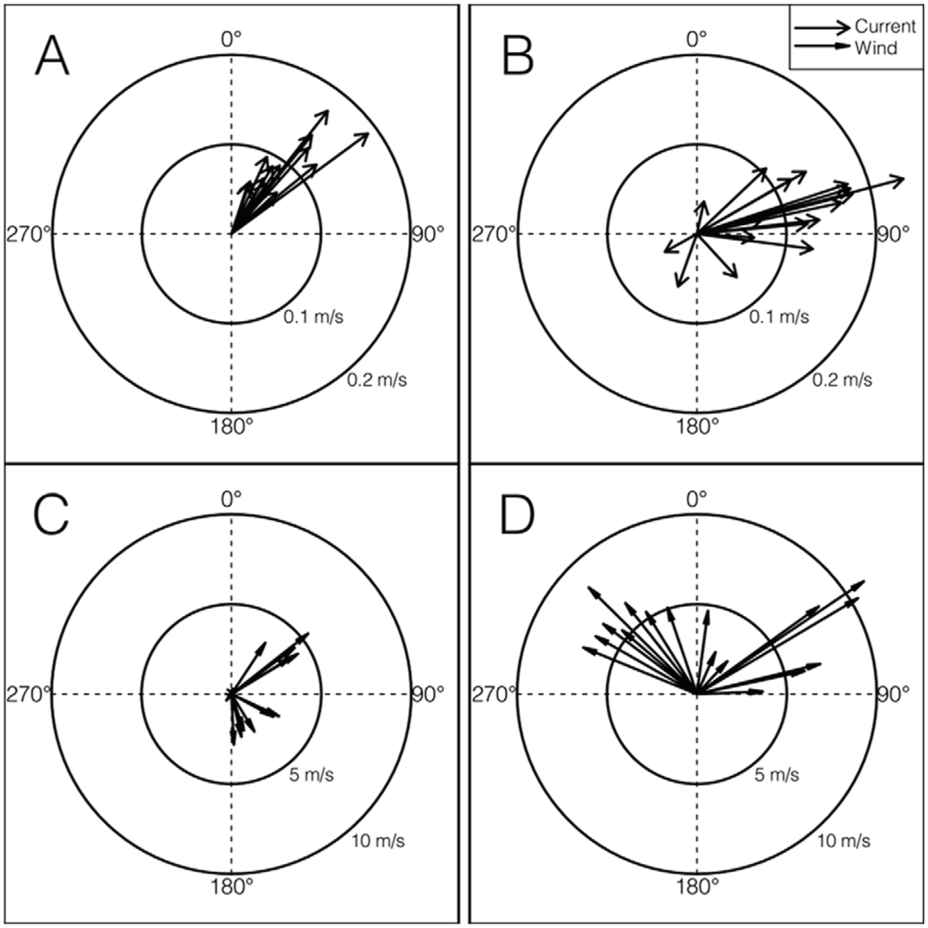

Figure 4. Depth integrated currents and surface winds during AUV station keeping. During diurnal (A) tidal regime, currents never reversed. Currents during a semidiurnal tidal regime reversed for part of the tidal cycle (B). Winds during the diurnal (C) and semidiurnal (D) tidal regimes were uncorrelated to current flow during while the AUV was station keeping.
doi:10.1371/journal.pone.0055163.g004

during diurnal tides was 2.02±0.11 km and 2.34±0.08 km for semidiurnal tides. Although significant differences in penguin distance from Humble Is. are observed (Figure 6), the inability to identify diving locations in seasons prior to 2011 likely occludes the true spatial separation of penguin diving behavior across tidal regimes.

We also tested the effect of tidal amplitude and Julian day on DHI for the 2002–2011 location data using Eq. (2) as the model. Neither tidal amplitude ($t = -0.524$, $p = 0.601$) nor Julian day ($t = -0.195$, $p = 0.845$) was a significant predictor of DHI. An AIC comparison of Eq. (1) and Eq. (2) using location-only data from 2002–2011 showed that the inclusion of tidal amplitude or Julian day as a predictor of DHI did not significantly change AIC (d.f. = 2, $\chi^2 = 0.303$, $p = 0.859$), indicating that tidal regime alone was the best predictor of penguin location.

Discussion

Our results show that weekly switching in tidal regimes, but not daily changes in tidal amplitude, is a significant predictor of Adélie penguin foraging locations near a historic penguin "hot-spot" that is characterized by deep submarine canyons and fjords. By comparison, the foraging location of Magellenic penguins that also inhabit the fjord rich environment of southern Chile, is best predicted by daily changes in tidal amplitude and current direction [38]. The contrast in response to tidal forces between these two penguin groups can only be understood in the light of the hydrography of their respective locations. An AUV consistently occupied the general foraging area of Adélie penguins, and showed that the bearing of the tidally driven flow patterns over Palmer Deep did not follow a daily oscillation, but rather oscillated between weekly tidal regimes (Figure 4). The link between both penguin diving and non-diving location and tidal regime switching is strongly supported statistically for both the 2011 field season (Figure 5), and for historical observations of Adélie penguin location (Figure 6) indicating that the weekly switching of tidal regime in our region plays a strong role in organizing the local coastal ecosystem near Palmer Deep.

The interaction of nutrient rich UCDW with switches in tidal regime has already been observed in primary producers near Palmer Deep. Phytoplankton concentrations are much higher near the Adélie penguin colonies during diurnal tides compared to semidiurnal tides [20], indicating that both the presence of the Palmer Deep and tidal regime switching impact the base of the food web. While we did not have direct krill observations during our 2011 field experiment, our observations of current magnitude and direction suggest that krill may also be differentially concentrated during different tidal regimes. During our experiment, the 100 m depth integrated flow measured by

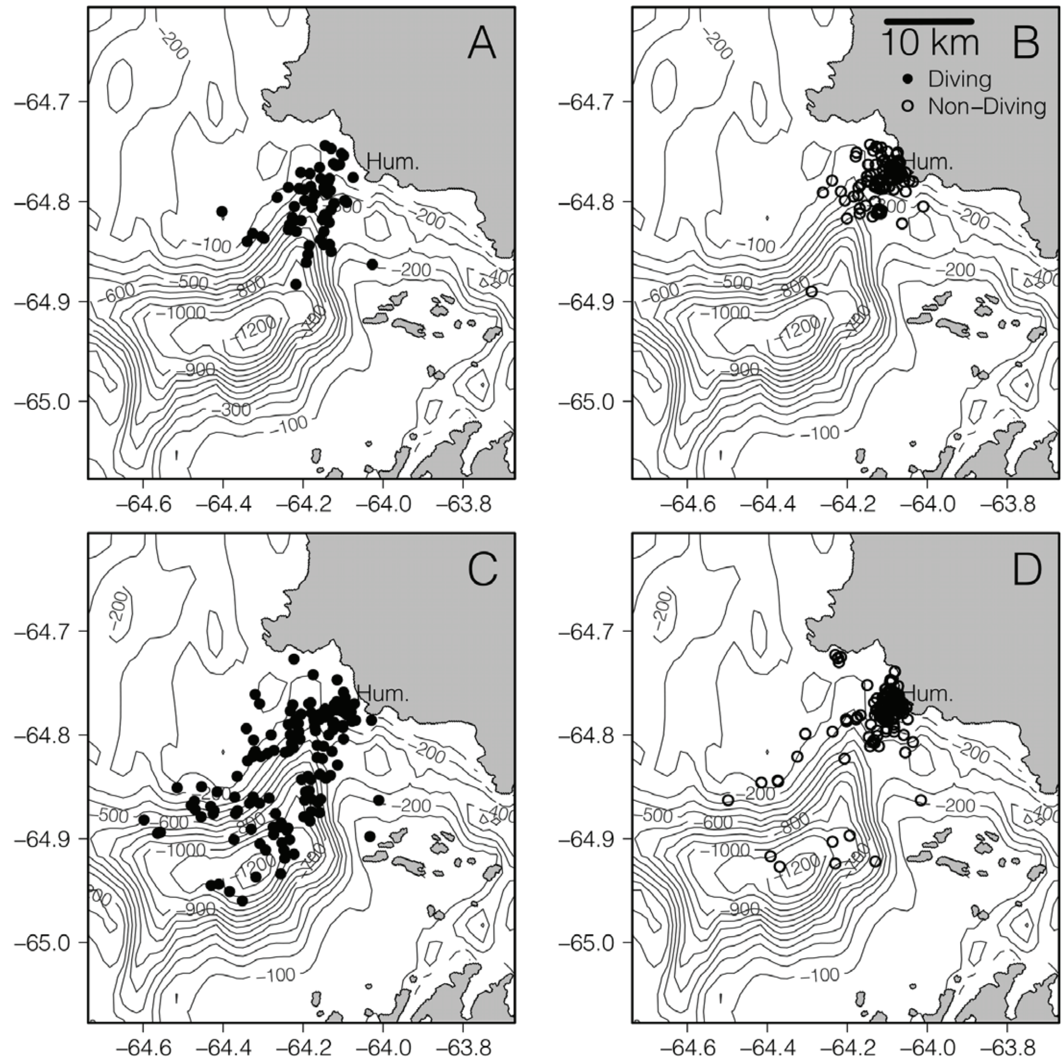

Figure 5. Penguin locations corresponding to diving and non-diving behavior during the 2011 season. Panels A and B are during the diurnal tidal regime and diving panels C and D are during the semidiurnal tidal regime.
doi:10.1371/journal.pone.0055163.g005

the AUV was predominantly northeast (59% of all depth integrated current measurements) toward the head of Palmer Deep suggesting water in our study area is continually being replaced by water from the continental shelf. The mean speed of depth integrated currents was 0.13 m s^{-1}, which is about half of the normal swimming velocity for krill [58], the predominant prey item in the region [59]. Also, in the summer season, krill are generally located in the upper 100 m of the water column [60]. Therefore the direction of the flow regime would influence the location of krill populations over Palmer Deep. During the diurnal tidal regime the flow towards the northeast edge of Palmer Deep never reversed, while there was only weak reversal during semidiurnal tides (Figure 4). Because tides in this region may stay in a diurnal or semidiurnal regime for up to a week, the diurnal tide regime would continually concentrate krill and other prey items at the northeast edge of Palmer Deep, near Humble Is. During the semidiurnal tide regime, the currents over Palmer Deep reverse for a portion of the tidal cycle, reducing this proposed concentration mechanism near the northeast edge of the canyon. We speculate that the reason Humble Is. Adélie penguins do not travel as far from Humble Is. during the diurnal tide compared to the semidiurnal tide is because krill are concentrated near Humble Is. by currents during the diurnal tidal regime.

It is difficult to tell from our data if the differences in Humble Is. Adélie penguin foraging locations are due to a physiological or behavioral constraint on the penguins, or if the penguins are following changing prey fields over Palmer Deep. Physiological and behavioral constraints seem unlikely, since the foraging distances of these particular Adélie penguins are short in comparison to other known breeding colonies that have foraging ranges of up to 100 km [40]. Also, the difference in mean current speeds between tidal regimes is only ~1% of the penguins' maximum sustained swimming speed indicating the direction of tidal currents are unlikely to have a large effect on the distance Adélie penguins forage from Humble Is.

Understanding the interaction between Palmer Deep and tidal regime switching as a potential prey concentrating mechanism has significant implications for understanding the future of Adélie penguins in this region. The climate driven southward translocation of Adélie penguin chick rearing habitats on the WAP [11] could be ameliorated by predictable, hydrographically concen-

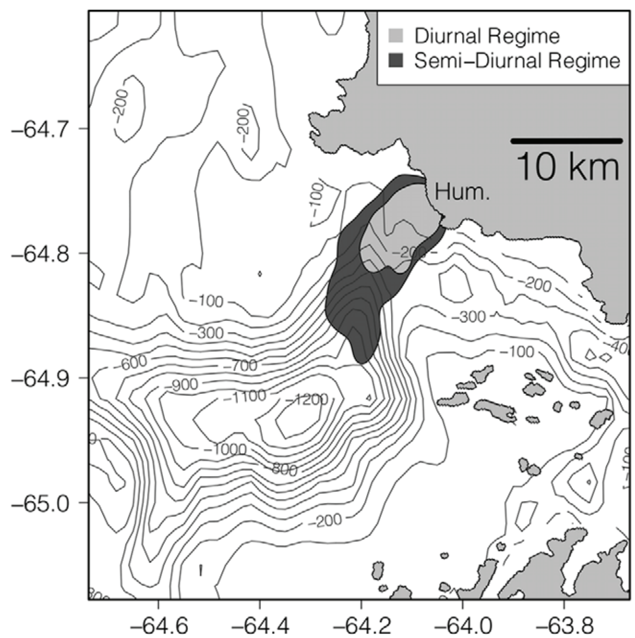

Figure 6. The locations of Adélie penguins during the diurnal and semidiurnal tidal regimes or ten seasons (2002–2011). Ninety five percent of Adélie penguin locations were within the light grey contour during diurnal tides and within the dark grey contour during semidiurnal tides indicating that Adélie penguins tended to be farther from Humble Is. during semidiurnal tides.
doi:10.1371/journal.pone.0055163.g006

trated food resources that allow Adélie penguins to persist in this region despite climactic change [12]. However, because the proposed concentrating oscillates with roughly weekly switches of tidal regime, and not daily scales of tidal amplitude, successive Adélie penguin breeding seasons do not have equal proportions of diurnal and semidiurnal tides. For example, in January 2003, 60% of the tides were during the diurnal regime, while in January 2008, 40% of the tides were during the diurnal regime. Uncovering the mechanics of this effect on krill will require more detailed surveys of local currents and krill densities to determine if the seasonal heterogeneity of tidal regime is a significant factor for Adélie penguin foraging in this region. Whether or not local hydrographic processes that concentrate prey items will provide local a refuge for Adélie penguins in a changing climate is unknown. A path forward could include the interaction between foraging and local hydrography in climate models, however downscaling these models to capture local dynamics present significant challenges [61,62].

Supporting Information

***Abstract*— The coastal northeast United States was heavily impacted by hurricanes Irene and Sandy. Track forecasts for both hurricanes were quite accurate days in advance. Intensity forecasts, however, were less accurate, with the intensity of Irene significantly over-predicted, and the rapid acceleration and intensification of Sandy just before landfall under-predicted. By operating a regional component of the Integrated Ocean Observing System (IOOS), we observed each hurricane's impact on the ocean in real-time, and we studied the impacted ocean's influence on each hurricane's intensity.**

Summertime conditions on the wide Mid-Atlantic continental shelf consist of a stratified water column with a thin (10m-20m) warm surface layer (24-26C) covering bottom Cold Pool water (8-10C). As the leading edge of Irene tracked along the coast, real-time temperature profiles from an underwater glider documented the mixing and broadening of the thermocline that rapidly cooled the surface by up to 8C, well before the eye passed over. Atmospheric forecast sensitivity studies indicate that the over prediction of intensity in Irene could be eliminated using the observed colder surface waters. In contrast, Hurricane Sandy arrived in the late Fall of 2012 after seasonal cooling had already deepened and decreased surface layer ocean temperatures by 8C. The thinner layer of cold bottom water still remaining before Sandy was

978-1-4799-0002-2/13/$31.00 ©2013 IEEE

forced offshore by downwelling favorable winds, resulting in little change in ocean surface temperature as Sandy crossed and mixed the shelf waters. Atmospheric sensitivity studies indicate that because there was little ocean cooling, there was little reduction in hurricane intensity as Sandy came ashore. Results from Irene and Sandy illustrate the important role of the U.S. IOOS in providing the best estimate of the rapidly evolving ocean conditions to atmospheric modelers forecasting the intensity of hurricanes. Data from IOOS may enable improved hurricane forecasting in the future.

I. Introduction

Tropical storms are some of the most destructive and deadly weather phenomena on Earth, and have killed more people than any other natural catastrophe (Keim et al. 2006). For example, in the United States during the 20th-century, ten times as many deaths and >three times as much damage occurred from these extreme weather events as compared with earthquakes (Gray, 2003). The impacts are magnified given the human population density found along the coastlines that are prone to hurricanes. Despite the potential devastation, advances in technology, communication, and forecasting have resulted in significant declines in hurricane-related mortalities between 1900 and present day (Walker et al. 2006). Most recently these declines reflect the developments in global atmospheric models and an ensemble forecasting approach that have successfully reduced hurricane track forecast errors by factors of 2-3 over the last two decades, allowing communities sufficient time to proactively prepare for the storms and evacuate prior to their arrival. Despite the progress in predicting hurricane tracks, the predictive skill for hurricane intensity forecasts has remained “flat” over the last twenty years (Pasch & Blake, 2012).

This current state of the science was illustrated by the two recent hurricanes Irene and Sandy that devastated many communities along the Mid-Atlantic coastline spread over dozen states. Hurricanes Irene and Sandy struck dense population centers, and as a result, the National Hurricane Center’s list of costliest hurricanes in United States history ranks Sandy second with over $60 billion and Irene eighth with over $15 billion in damages. Despite the epic scale of devastation, the loss of life was greatly minimized due to accurate forecasts of the hurricane tracks days in advance. Unfortunately, forecasts of hurricane wind intensity were less accurate, impacting efforts to proactively mitigate the damage. For Irene, the wind intensity was significantly over predicted, and for Sandy, the rapid acceleration and wind intensification just before landfall were under predicted. The over prediction of Irene’s intensity in 2011 led to skepticism of the storm surge warnings for Sandy in 2012. To further complicate matters, the under predicted intensity of Sandy resulted in an under predicted storm surge that in some cases led to insufficient preparation.

The Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS), one of eleven Regional Associations comprising the regional component of the U.S. Integrated Ocean Observing System (IOOS), operates a Regional-Scale Coastal Ocean Observatory that includes coastal weather mesonets, satellite data ground stations, a 1000 km long High Frequency (HF) Radar network (Roarty et al., 2010), and a distributed fleet of autonomous underwater gliders (Schofield et al., 2010). Observatory data is assimilated into global and regional-scale ocean models, and an ensemble of regional atmospheric models beginning to use the ocean surface conditions as a boundary condition. The Regional-Scale Coastal Ocean Observatory was fully operating during both hurricanes. In this paper, we discuss selected highlights of real-time ocean data acquired by the MARACOOS regional-scale network during Irene and Sandy, and how the ocean forecasts faired. Through a series of atmospheric model sensitivity studies, the potential impact of accurate real-time ocean data and forecasts on hurricane intensity forecasts in the Mid-Atlantic is demonstrated.

II. Hurricanes Irene & Sandy

The Mid Atlantic Bight of North America was recently struck by two hurricane landfalls that devastated dense population centers and communities spread over a dozen neighboring states (Figure 1). Hurricane Irene, a category 1 storm offshore, tracked rapidly northward along the eastern seaboard in August of 2011, resulting in significant flooding on inland waterways due to torrential rains. Fourteen months later, Hurricane Sandy, a much larger category 2 storm offshore, made an uncharacteristic left turn and approached perpendicular to the coast in October of 2012, causing significant damage to coastal communities due to the extreme storm surge.

Fig. 1. National Weather Service tracks for hurricanes Irene (purple) and Sandy (orange).

Data from the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS), one of eleven regional associations in the U.S. Integrated Ocean Observing System (IOOS), monitored the ocean response, and used that data to study the influence of the ocean on the intensity of both hurricanes.

Hurricane Irene approached the Mid Atlantic's regional ocean observatory from the south. The real-time observations of the evolving ocean are described in the MARACOOS blog (Glenn et al., 2011). Irene's size was similar to the 1,000 km length scale of the region's HF Radar network (Figure 2) Strong storm-related winds were experienced for only 1 day. Winds initially came from offshore, turned to an alongshore direction as the eye passed, and continued turning to come from the coast after the eye moved north into New England. Most atmospheric models in the ensemble converged on the track forecast days in advance, but unfortunately, the wind intensity was over-predicted by the ensemble. Because of the short duration of hurricane-forced winds, the relative timing between the high tide and the time of the most severe onshore currents for this rapidly moving storm were critical to determine the severity and location of the maximum storm surge. The severe damage from Irene instead occurred inland, where winds that picked up moisture over the warm ocean resulted in heavy rains and flood conditions along the Delaware, Hudson and Connecticut Rivers.

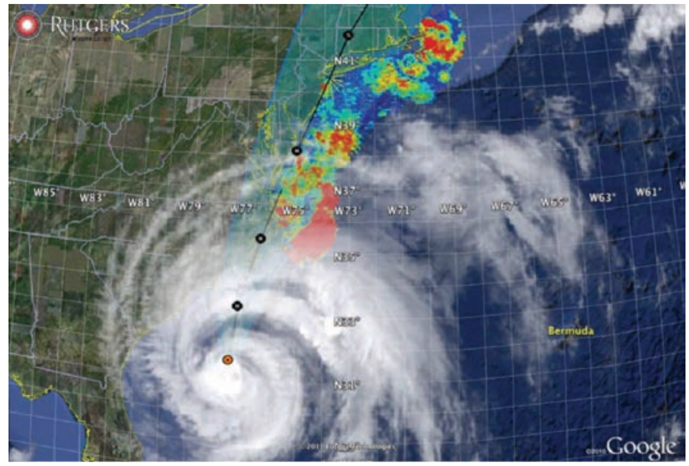

Fig. 2. Spatial extent of Hurricane Irene, August 27, 2011.

Hurricane Sandy approached the Mid-Atlantic's ocean observatory from offshore, perpendicular to the alongshore track of Irene. Real-time ocean observations were again described in the MARACOOS blog. The diameter of Sandy was twice as large as Irene, larger than the scale of the observatory (Figure 3). The approach direction had a significant impact on the areas with severe storm surge damage. North of the eye on the right hand side of the track, the counterclockwise circulation is in the same direction as the propagation. Here sustained winds from offshore that transported water towards the coast were experienced for multiple tidal cycles. South of the eye, winds blew from the coast and water was transported offshore. Compared to Irene, the relative timing between hurricane forcing and high tide was much less important for determining damage. More important for Sandy was your location north or south of the eye.

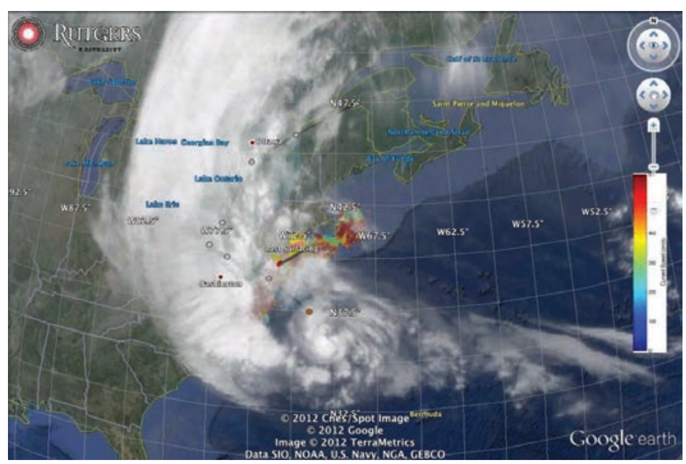

Fig. 3. Spatial extent of Hurricane Sandy, October 28, 2012.

III. Water Column Mixing in IRENE

The eye of Hurricane Irene made landfall in southern New Jersey near Atlantic City at 0900 UTC on August 28, 2011. Irene was moving rapidly northward, fully crossing the state of

New Jersey in about 6 hours. The rapidly evolving surface current response as Irene propagated along the New Jersey coast was observed (Figure 4) using the Mid-Atlantic's High Frequency (HF) Radar network (Roarty et al., 2010). At 0600 GMT, Irene's eye is still over water, with its location observed in the CODAR currents offshore southern New Jersey. Strong onshore currents over the entire width of the shelf are observed north of the eye. At 1200 GMT, the eye is over land in central New Jersey. The ocean currents have rotated to be along the coast to the northeast, and are reduced in speed. By 1800 GMT, the eye is over northern New Jersey. Currents behind the eye are again strong and offshore. The transition from strong onshore flow to strong offshore flow occurred over a short 6 hour period.

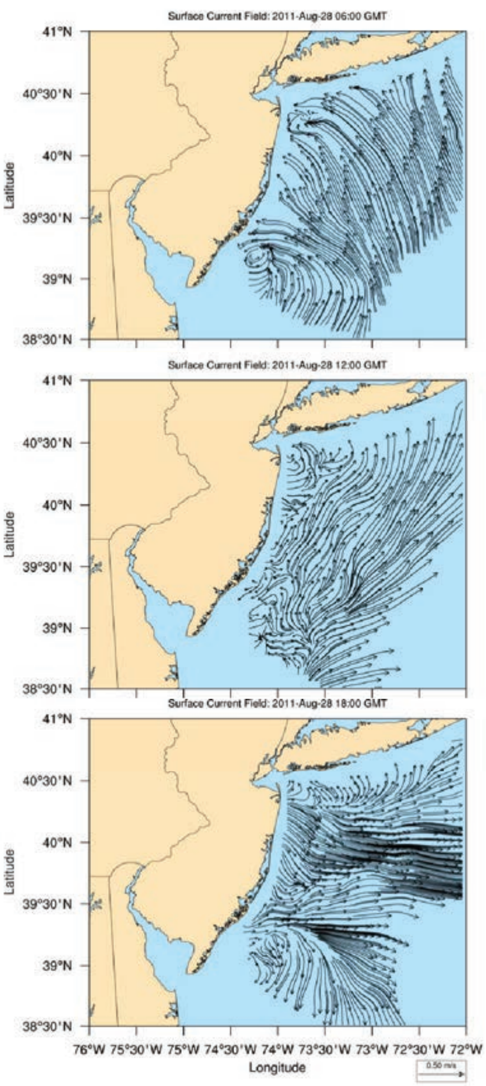

Fig. 4. CODAR-derived surface current spatial response as Irene tracks along the New Jersey coast.

Glider RU16 was deployed on the New Jersey shelf on a coastal survey mission well ahead of and independent of the hurricane. As Irene approached, the glider was purposely left at sea, but was moved offshore to the 40 m isobath to ride out the storm (Figure 5a) The 40 m isobath is an area of relatively uniform sandy sediment, and was considered far enough offshore that even strong hurricane currents faster than the glider's flight speed would not blow the glider onto the beach.

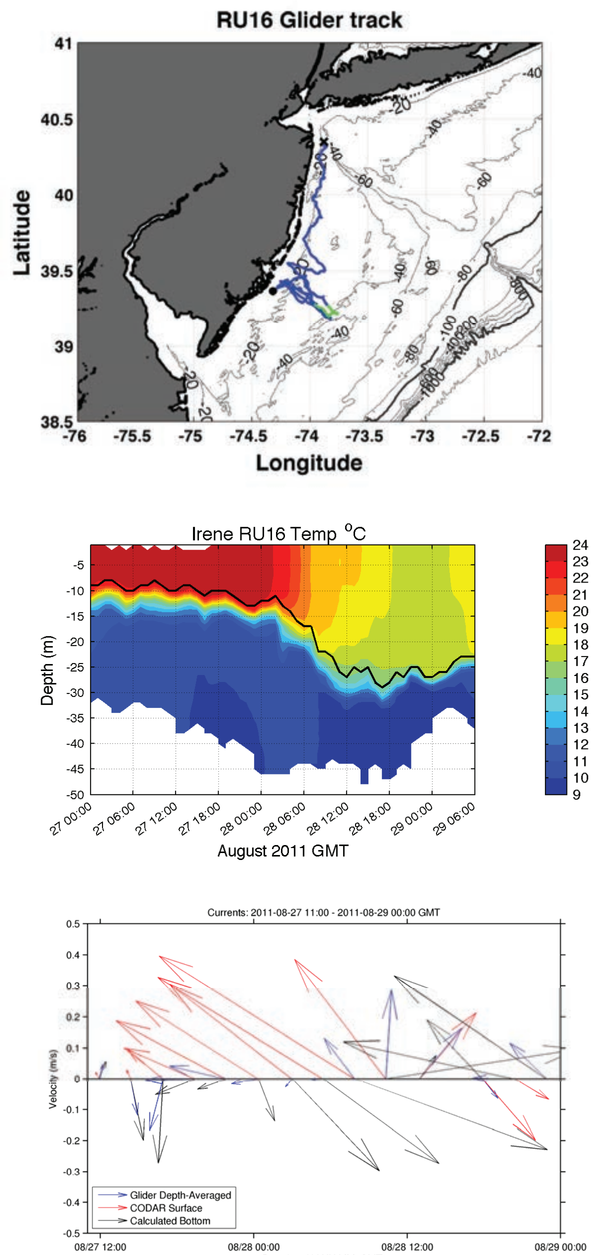

Fig. 5. (a) Glider track in Hurricane Irene. (b) Glider temperature section for the portion of the glider track marked in green. Black line is the depth of the surface mixed layer. (c) Glider depth averaged currents (blue), CODAR surface currents along the glider track (red), and inferred bottom layer currents (black).

The temperature section collected by the glider near the 40 m isobath during Irene (Figure 5b) indicates that on

August 27, the Mid Atlantic shelf was near its peak summer stratification, with a thin 10 m thick layer of warm surface water near 22-25C, and a thicker layer of bottom “Cold Pool” water near 8-10C. The summer thermocline was typically sharp, with the transition from warm surface waters to bottom Cold Pool waters occuring in a few meters. As Irene approached, mixing within each of the surface and bottom layers made each layer more uniform and tightened the thermocline. On August 28, between 0000 GMT and 1200 GMT, as the northern edge of Irene passed over the location of the glider, the thermocline broadened (from less than 5 m to over 15 m) and deepened (from 10 m to 28 m), and the surface layer cooled (from 24C to 18C). After 1200 GMT, as the backside of the hurricane passed over the glider, the deeper thermocline remained near 25 m. Both the surface and bottom layers continued to cool independent of each other as the thermocline reintensified.

Gliders report the depth averaged current over the previous segment with each surfacing. The depth averaged current is estimated by comparing the dead reckoned surface location with the actual surfacing location, and assuming the difference is due to advection of the glider by the depth averaged current. During the hurricane, depth averaged currents are initially southward at 20 cm/sec before the storm, drop to near zero during the approach of the storm, and transition to northward at 30 cm/sec on the backside of the storm (Figure 5c). The important observation is that the depth averaged current is near zero between 0000 GMT and 1200 GMT on August 28 when the thermocline deepening and surface layer cooling is observed. Plotting the CODAR surface currents at the location of the glider, shows how the surface layer is being forced directly onshore to the northwest by the hurricane winds starting on August 27 and peaking during the deepening event. After 1200 GMT on August 28, the CODAR surface currents rotate clockwise to alongshore and then to offshore as noted in the spatial maps (Figure 4). Using the observed CODAR surface current to represent the average current above the thermocline, the average current below the thermocline was estimated based on the requirement that the weighted average of the surface and bottom layers equal the observed glider depth averaged current. Based on the estimated bottom layer current, the onshore transport in the surface layer begins midday on August 27 and for the first 12 hours, there is little response in the bottom layer. During this time the storm surge is expected to grow. Between 0600 GMT and 1200 GMT, as the onshore currents in the surface peak, the offshore currents in the bottom layer accelerate, resulting in zero net transport towards the coast. This time interval when the greatest shear between the surface and bottom layers is expected is precisely the time when the thermocline is observed to deepen. The zero net transport also implies that the storm surge that would have resulted from the shoreward transport of surface water is compensated by the offshore transport of bottom water.

The Regional Ocean Modeling System (ROMS) was operated in forecast mode during the storm. The model was rerun here using the same forecast parameters for more in depth studies. The ROMS forecast/hindcast of the ocean response has several features consistent with these observations that enable further definition of the physical processes responsible for the surface layer cooling. But there are also several differences between the observations and the model. The initial state of the ocean in the ROMS model (Figure 6a) has a 10 m thick surface warm surface layer near 24 C, and bottom Cold Pool layer near 9C, but the initial thermocline is wider than observed, extending over 15 m thick instead of less than 5 m. So the initial condition has a less extreme thermocline that would be more easily mixed than observed. The model was driven by the North American Mesoscale (NAM) model winds. Despite the weaker thermocline, significant mixing does not begin in the model until 6 hours later than the observations. The initial response is an acceleration of the alongshore currents to over 60 cm/sec to the northwest at 0000 GMT on August 28 (Figure 6c). The cross-shore currents, in the onshore direction at the surface and the offshore direction in the bottom, spin up simultaneously and peak at 0600 GMT. At this peak in shear, the thermocline starts deepening and the surface water starts cooling. In the model, this process ends in 6 hours, with the surface water cooling 5C and the bottom water warming 1C. At 1200 GMT, the alongshore surface current reverses direction consistent with the CODAR observations, the bottom jet relaxes in the cross-shore current but remains present in the alongshore current. The glider observations indicate that the bottom jet should have remained in the cross-shore direction.

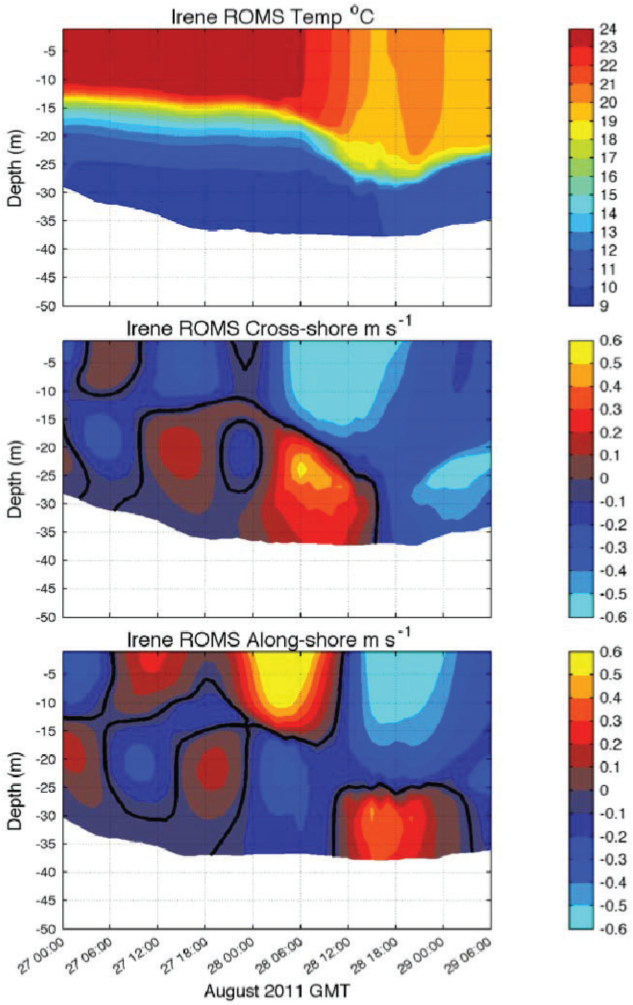

Fig. 6. Regional Ocean Modeling System (ROMS) hindcast of temperature, cross-shore (+offshore) and alongshore (+northeast) current sections along the green portion of the glider track in Figure 5a. Black lines indicate 0 cross and alongshore currents.

While the exact details of the deepening of the thermocline and the cooling of the surface layer do not exactly match those observered, model diagnostics indicate that the vertical diffusion in the surface layer dominate advective changes in the model. This points to improvements in the mixing parameterizations as a place to look to improve the model. Even with a weaker thermocline and stronger winds, the mixing is insufficient to cool the upper layer as much as observed.

Satellite-derived Sea Surface Temperature (SST) maps of the Mid-Atlantic Bight just after Irene indicate that the cooling was widespread (Figure 7). The locally generated SST product (Figure 7a) indicates that surface temperatures dropped to as low as 14C on the shelf, with the greatest cooling observed over the historical location of the Cold Pool and concentrated on the mid to outer shelf, shoreward of the shelfbreak. The cooling was so significant, even though skies were clear after the storm, the cloud detection algorithms rejected the data as being too cold, removing it from the Real Time Global (RTG) SST updates (Figure 7b). As a result, the RTG SST map is essentially unchanged before and after Irene. Since the RTG map is the SST used by several atmospheric forecast models as a bottom boundary condition, the ocean used in the Irene forecasts was too warm. The difference between the RTG and the actual sea surface temperatures after the storm is as large as 10C (Figure 7c).

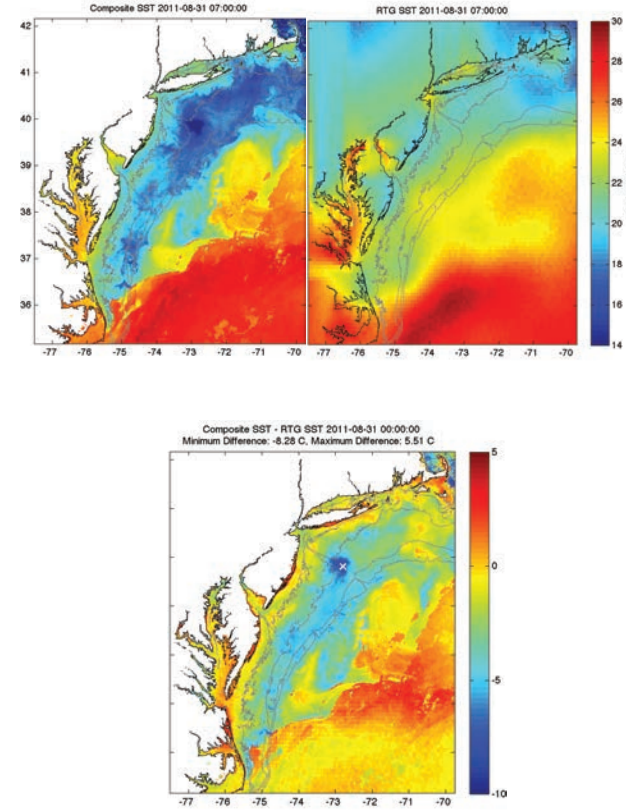

Fig. 7. Post-Hurricane Irene Satellite-derived Sea Surface Temperature (SST) products for August 31, 2011. (a) Locally composited SST showing the surface cooling. (b) Operational global SST product with the cool pixels incorrectly identified as clouds. (c) Difference.

The impact of the rapidly cooling SST on the Weather Research and Forecasting (WRF) model hindcast sensitivity studies of Hurricane Irene illustrates the significant impact of the cooler water. The glider data indicates that the cooling occurred ahead of the eye as the high winds of the outer wind bands approached. Thus the eye of the hurricane passed over cool water as it propagated northward. Since the RTG SST does not cool, it was used as the base case for comparison (Figure 8a). At the time of landfall, the hurricane intensity is over predicted. Since the ROMS model cools late and insufficiently, the locally composited SST product was used to simulate the change in SST as the storm passed. Starting with the warm pre-storm SST, the cold post-storm SST was applied everywhere at the time of peak mixing observed in the glider transect. The resulting WRF forecast is lower by 5-10 knots. (Figure 8b).

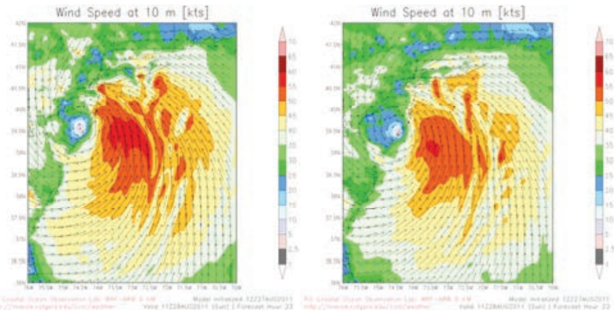

Fig. 8. Weather Research Forecast (WRF) atmospheric hindcasts of Hurricane Irene with different ocean boundary conditions. (a) Using the warm SST throughout the run. (b) Switching to the cold SST in Figure 7a when the cooling is observed in the glider data.

IV. Sandy

Hurricane Sandy followed Hurricane Irene by 14 months. Forecasts made by the European Center for Medium-range Weather Forecasting (ECMWF) alerted researchers to the possibility of a signficant storm hitting New Jersey a full week in advance. The importance of the glider observations in Irene prompted the deployment of glider RU23. Based on the lessons learned in Irene, the glider payload bay with its standard CTD was further equiped with optical sensors to look at the sediment concentrations as a tracer for mixing. A Nortek Aquadopp Acoustic Doppler Current Profiler (ADCP) was attached externally to examine the shear across the thermocline during the event. The glider was deployed nearshore with a small boat, and, as in Irene, was directed to fly to the 40 m isobath to ride out the storm (Figure 9).

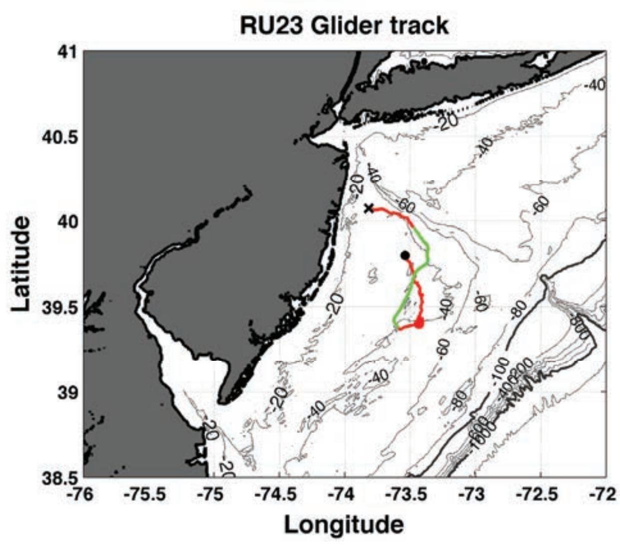

Fig. 9. Glider track during Hurricane Sandy.

Glider RU23 revealed that the initial ocean conditions for Hurricane Sandy were quite different than 14 months ago before Irene (Figure 10). The peak summer thermocline intensity observed in Irene was already 2 months into the fall transition. The two-layer structure was still present, but the surface layer had already cooled to 16C-17C, and thickened to a depth of 30 m. As usual, the bottom Cold Pool temperatures where observed to be around 9C-10C. Like Irene, the thermocline is again observed to be only a few meters thick. As Sandy approaches the coast, the increase in the thermocline depth is even more rapid than Irene, occuring within a few hours near 0600 GMT on October 29. After the deepening event, the water column is filled with a single surface layer, but the layer cooling is only 1 C from 16 C to 15 C. The glider data indicated that Sandy was going to make landfall propogating over SSTs that changed little from the pre-storm conditions. No ohterwise unobserved cooling to reduce intensity was expected.

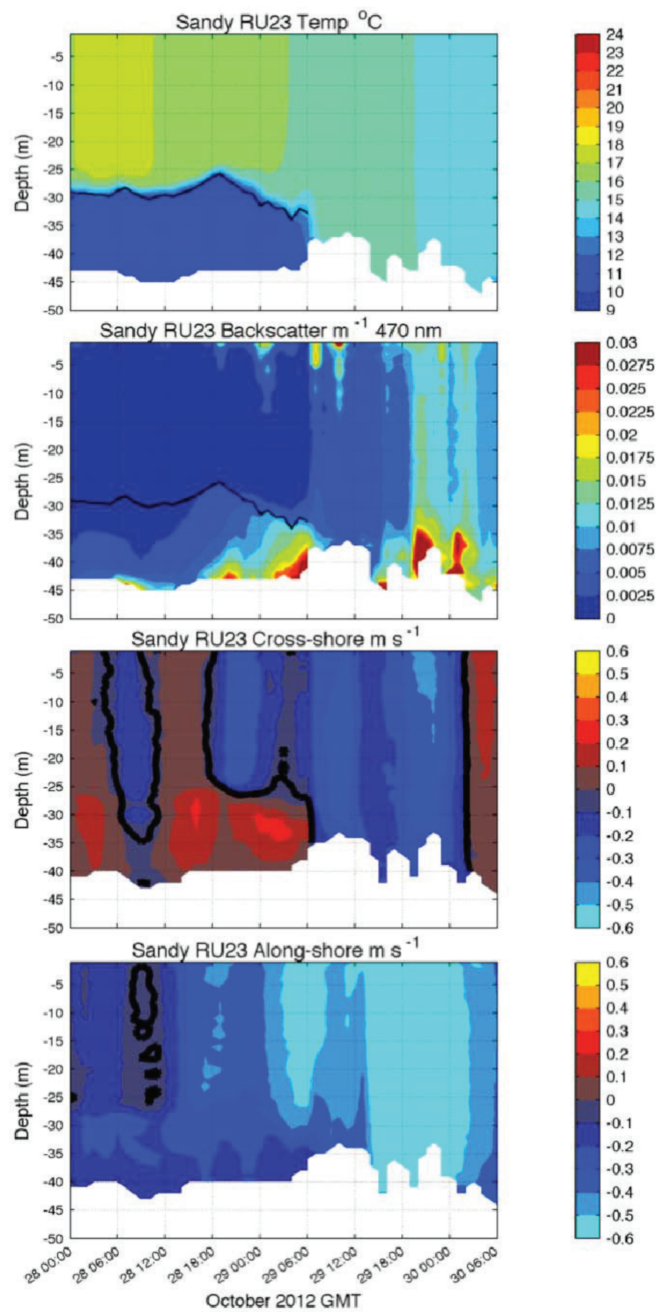

Fig. 10. Glider-derived temperature, backscatter, cross-shore (+offshore) and alongshore (+northeast currents for Hurricane Sandy.

The ocean model in Irene indicated the deepening and cooling of the surface layer, while inadequate, was dominated by a mixing processes. More extensive glider observations in Sandy indicate the layer deepening was likely dominated by an advective processes. Optical backscatter in Sandy indicates that before the transition to a fully mixed water column, sediment suspended from the bottom did not cross the thermocline. After the transition to one layer, optical sensors indicate that sediment resuspension filled the water column, with a single mixed layer going from surface to bottom. Currents measured by the glider-mounted ADCP indicate that before the transition, a two layer flow was observed, especially in the cross-shore direction. A strong offshore jet formed in the bottom layer and persisted for over 18 hours before the transition as the water in the bottom layer thinned and moved offshore. Once the transition was complete, the water column responded as a single layer. Most significantly, the cross-shore current was onshore throughout the water column and persisted for two tidal cycles as the alongshore current accelerated to the southwest.

The same two SST products used in Irene were also examined in Sandy for August 27 (Figure 11). There is little pre-storm difference between the two SSTs, both maps have shelf temperatures in the 16C-18C range before the storm. Because Sandy was so extensive, and it was followed several days later by a northeaster that dropped snow on the damaged area, new SST products were not available for 11 days after the storm.

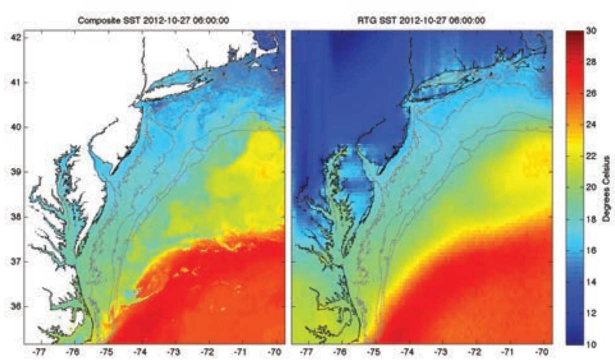

Fig. 11. Pre-Hurricane Sandy Satellite-derived Sea Surface Temperature (SST) products for October 27, 2012. (a) Locally composited SST. (b) Operational global SST product.

The Sandy observations indicated that there would be no significant cooling of the ocean surface layer as Sandy propagated shoreward. The WRF winds based on the conditions used in the real-time WRF forecasts, with atmospheric boundary conditions supplied by NCEP and ocean boundary conditions supplied by the locally composited SST are in Figure 12a. There is little sensitivity to the source of the SST, either the RTG or composite. Both result in an intensification of the storm as it makes landfall. The main sensitivity is the timing of landfall that is adjusted based on which NCEP atmospheric model is used for boundary conditions. WRF embedded within the North American Mesoscale (NAM) model captures the acceleration of Sandy during the last 6 hours before landfall better than WRF embedded in the Global Forecast System (GFS) model. The acceleration and intensification is significant, since the mean storm surge using operational products was under-predicted by 1 m in the hardest hit areas. Using the WRF model run in Figure 12a with the proper intensification and acceleration gains back the missing meter in the mean storm surge as predicted by the New York Harbor Ocean Prediction System (NYHOPS) run by Stevens Institute of Technology.

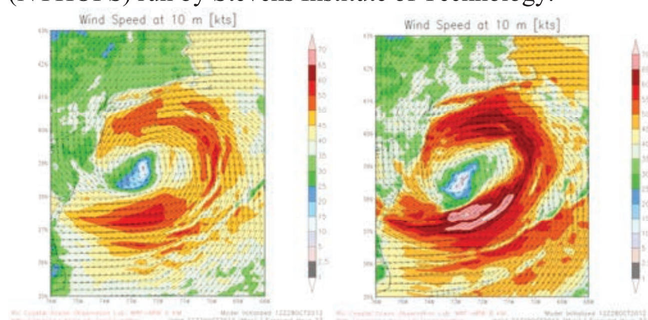

Fig. 12. Weather Research Forecast (WRF) atmospheric hindcasts of Hurricane Sandy with different ocean boundary conditions. (a) Using the cold SST from Figure 11a. (b) Using a warm SST characteristic of August conditions on the Mid-Atlantic continental shelf.

This series of model runs, while producing a hindcast that accurately recreates the observed storm surge, leaves unanswered the question of forecast sensitivity to SST in Sandy. If Sandy had hit earlier in the hurricane season during the peak summer stratification, would the forecast be sensitive to rapid changes in SST? As a test case, Sandy was rerun with typical August SSTs where, as in reality, it was assumed that no satellite updates to SST were available for over a week. The increase in forecast intensity at landfall is evident in Figure 12 b. Using these higher winds to force the NYHOPS storm surge model results in another meter increase in the predicted storm surge.

V. Conclusions

The back-to-back landfalls of hurricanes Irene and Sandy along the coast of New Jersey have hightened awareness of hurricanes and their potential impacts in the Mid-Atlantic. Irene’s alongshelf track was accurately forecast but the intensity was over-predicted. Ocean observations by U.S. IOOS provide guidance as to why. Operational SST products did not pick up the 8-10C cooling caused by Irene even several days after the weather had cleared. An autonomous underwater glider that flew through the storm indicated that the cooling occurred rapidly as the leading edge of the hurricane approached and well ahead of the eye. Even if the operational SST products were reconfigured to pick up the cooling after the storm, they could not be applied in time to impact Irene. A more useful SST mapping product that accurately captures the timing and spatial extent of the cooling can only be supplied by an ocean forecast model. The ocean observations indicate what processes the ocean model must capture. Specifically, the initial thermocline must be better represented as the starting point. Second, the model must be 3-D, with a coast and a bottom. An infinitely deep 1-D model, one potential option for coupled atmosphere-ocean modes, will not capture the processes observed here. These include the initial onshore transport in the surface layer towards the coast, and the delayed response of the bottom layer to produce an offshore transport that limits the net shoreward transport. When there are two layers, the water transported onshore has an escape route through the bottom layer that appears to limit the storm surge. It also appears that the bottom layer also should be sufficiently thin for the offshore transport to produce a large shear across the interface. It is when this large shear is present that the mixing and cooling occurs.

Sandy occurred later in the year than Irene, after the fall transition was well on its way. Real time ocean observations during Sandy provided different guidance on what to expect when Sandy came ashore. The surface layer was already much thicker and cooler, so significant additional cooling was not expected. Advection moved what remained of the bottom Cold Pool offshore, removing the midshelf source of cool water. The water column responded as a single layer as Sandy came ashore, with mixing from surface to bottom, no cooling to reduce the intensity, and no bottom layer for the water in the growing storm surge to escape offshore.

The U.S. IOOS observations of hurricanes Irene and Sandy as implemented by MARACOOS for the Mid-Atlantic provided unprecedented real-time views of the evolving coastal ocean as the hurricanes made landfall in New Jersey. The observations led to new process studies in the ocean using numerical ocean models to examine the role of shallow topography, stratification and mixing that ultimately will lead to better ocean forecasts in extreme forcing conditions. New atmospheric sensitifivity studies further indicate that the rapid evolution of the ocean's surface layer temperature can have a significant impact on hurricane intensity. These results provide further evidence that one step towards inrpoving hurricane intensity forecasting is to provide atmospheric modelers a better forecast of the rapidly changing coastal ocean beneath hurricanes.

ACKNOWLEDGMENT

Base support for this research was provided by the U.S. Integrated Ocean Observing System (IOOS) through the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS). The Department of Homeland Security National Center for Secure and Resilient Maritime Commerce provided additional support for the HF Radar network. New Jersey Board of Public Utilities further augmented the satellite data products, the HF Radar network, and the atmospheric forecasting. The deployment and operation of Glider RU16 in Irene was funded by the Environmental Protection Agency and the New Jersey Department of Environmental Protection. The deployment and operation of Glider RU23 in Sandy was funded by graduate student grants from Teledyne Webb Research and Nortek.

Penguin Biogeography Along the West Antarctic Peninsula

Testing the Canyon Hypothesis with Palmer LTER Observations

BY OSCAR SCHOFIELD, HUGH DUCKLOW, KIM BERNARD, SCOTT DONEY, DONNA PATTERSON-FRASER, KRISTEN GORMAN, DOUG MARTINSON, MICHAEL MEREDITH, GRACE SABA, SHARON STAMMERJOHN, DEBORAH STEINBERG, AND WILLIAM FRASER

The West Antarctic Peninsula (WAP) is home to large breeding colonies of the ice-dependent Antarctic Adélie penguin (*Pygoscelis adeliae*). Although the entire inner continental shelf is highly productive, with abundant phytoplankton and krill populations, penguin colonies are distributed heterogeneously along the WAP (Ducklow et al., 2013, in this issue). This ecological conundrum targets a long-standing question of interest: what environmental factors structure the locations of Adélie penguin "hot spots" throughout the WAP?

Penguin colonies appear to be located in association with deep submarine canyons that are found all along the WAP continental shelf (Figure 1). These deep troughs extend from the shelf break to the land margin. Marine canyons are hypothesized to provide a cross-shelf conduit for warm (> 1°C), modified, Upper Circumpolar Deep Water to the coast. This water mass is the primary heat source within the WAP, and the observed warming of Upper Circumpolar Deep Water (Martinson et al., 2008) is driving regional atmospheric warming (Ducklow et al., 2012) and the observed declines in sea ice in this region (Stammerjohn et al., 2008). In the past, when annual and perennial sea ice dominated these coastal waters, canyons were hypothesized to drive the recurrent formation of polynyas (areas of open water surrounded by sea ice) that provided penguins year-round access to open-water foraging areas. Proximity of reliable foraging areas to breeding colonies is important given the energy costs for breeding parents needing to travel to forage and return to provision and protect chicks.

Close association of major WAP penguin colonies with marine canyons led to a long-standing hypothesis that unique physical and biological processes induced by these canyons produce regions of enhanced prey availability that are predictable over ecological time scales (decades to centuries). Linking the regional physical and ecological dynamics to test the "canyon" hypothesis has in the past been restricted by harsh environmental conditions that limit Zodiac and ship sampling. However, the Palmer Long Term Ecological Research (LTER) network recently expanded its observational efforts by incorporating autonomous underwater sampling and satellite tagging of penguins to increase sampling capabilities at two large Adélie penguin colonies along the WAP.

Anvers Island is a focal site of Palmer LTER efforts (Figure 1). Here, Palmer Deep is a cross-shelf canyon bathymetrically similar to others in the WAP that are also associated with large penguin populations. Satellite-tagged Adélie penguins breeding at Anvers Island appear to forage exclusively within Palmer Deep. A majority of Adélie foraging activity is centered over the canyon edge where the bathymetry rapidly shoals, and around which the spatial variability in foraging is strongly influenced by tides (Oliver et al., 2013). These foraging patterns were used to guide sampling of physical and biological properties using autonomous Webb Slocum gliders. Gliders revealed the uplift of

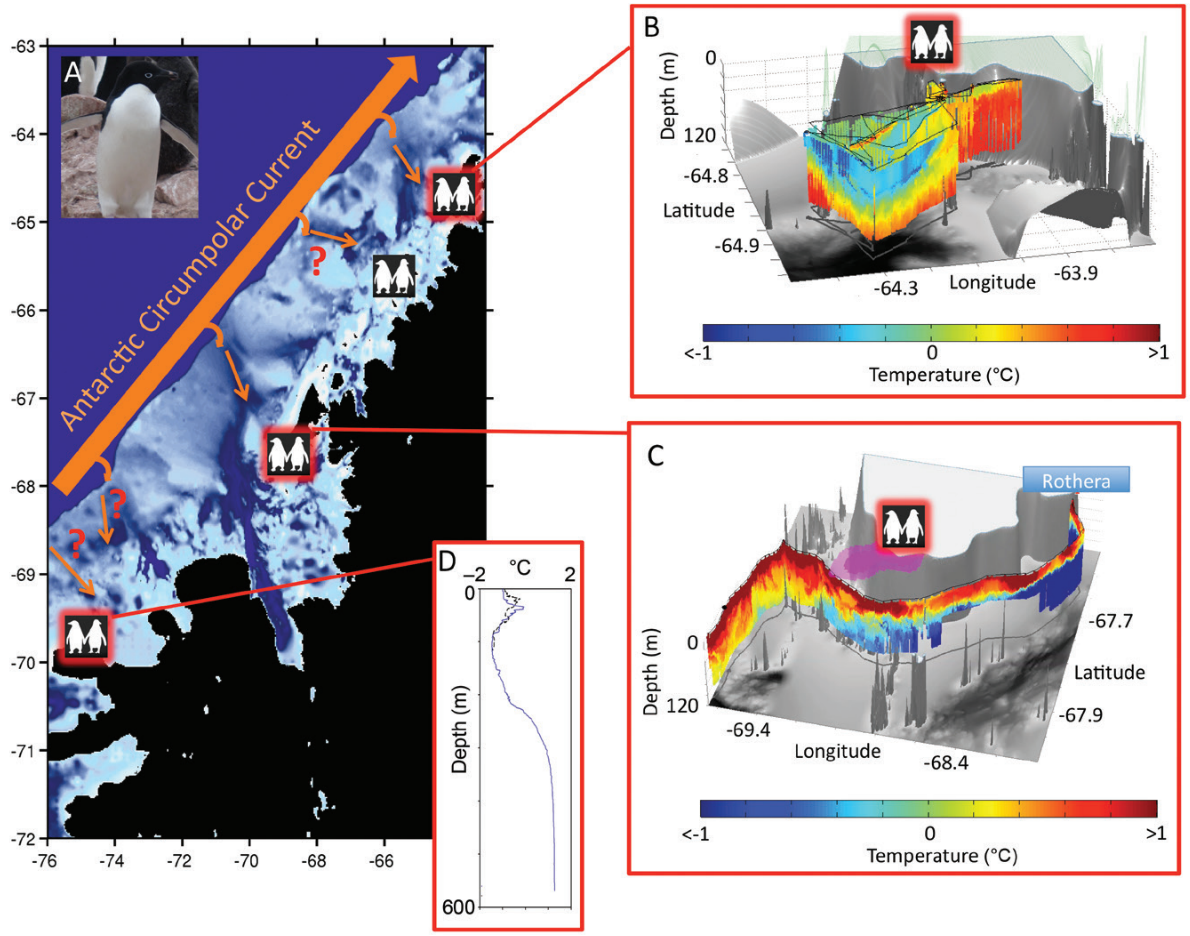

Figure 1. The 1,000 km sampling domain of the Palmer Long Term Ecological Research (LTER) program. (A) Bathymetry of the spatial sampling domain of the Palmer LTER. Orange arrows indicate the Antarctic Circumpolar Current and potential transport to coastal regions. Arrows with question marks indicate hypothesized routes requiring more data. Penguin breeding colonies are indicated by the paired-penguin symbols. For three of the penguin colonies (outlined in red), subsurface data have been collected with an effort to identify the presence of warmer deep waters of the modified Circumpolar Current near the penguin colonies. (B) Slocum glider temperature data collected offshore Palmer Station and its resident penguin colonies, showing the uplift of warm water along the canyon. (C) Glider temperature and penguin foraging data, collected by radio-tags at Avian Island near Rothera Station. The foraging locations are indicated by the surface purple shadow. It is associated with areas where warm water occurs at both surface and at depth. (D) Two temperature profiles measured by ship over the seafloor canyon adjacent to the penguin colony at Charcot Island, showing warm water at depth consistent with the presence of modified Upper Circumpolar Deep Water.

warm deep water along the slope of the canyon (Figure 1B), a hydrographic feature associated with enhanced concentrations of phytoplankton. Furthermore, glider-based measurements of phytoplankton health using a bio-optical measure, Fv/Fm, the quantum yield for photosystem II activity (Falkowski and Raven, 2007), indicated algal cells at the canyon edge were the healthiest in the region. Net tows and acoustic survey data indicate the presence of abundant krill near the canyon slope.

A second major Adélie breeding colony is located on Avian Island in Marguerite Bay (Figure 1), where chlorophyll and krill concentrations are high. Based on available satellite tag data, penguin foraging is concentrated on the southern flank of Avian Island (Figure 1C). This region is located near the seafloor canyon at the mouth of Marguerite Bay, where gliders revealed shoaling of warm bottom water. In contrast, on the inner reaches of Marguerite Bay by Rothera Base, gliders revealed high chlorophyll but no shoaling of warm bottom water. Penguin foraging does not appear to be significant at the inshore location, further suggesting the importance of warm deep water for foraging at Adélie colonies.

As the WAP warms, it might be expected that conditions surrounding breeding colonies in the south may become more favorable as sea ice and perennial land-fast ice continues to decline. This situation motivated the Palmer LTER program to expand its regional sampling grid to the south. Charcot Island, newly accessible following the collapse of the Wilkins Ice Shelf in 2008, borders the southern boundary of the new Palmer LTER regional grid. During our first exploration in 2009, the Palmer LTER team conducted only the third known landing on Charcot Island in the last century. We discovered the continued presence of a rarely documented breeding colony of Adélie penguins (Henderson, 1976). Consistent with our canyon hypothesis, a previously unmapped 800 m deep seafloor canyon was discovered adjacent to the penguin colony. Conductivity-temperature-depth (CTD) profiles within the canyon revealed warm (> 1.2°C) water at depth (> 200 m), consistent with the presence of modified Upper Circumpolar Deep Water (Figure 1D). The canyon was first located by the presence of a polynya, consistent with the hypothesis that canyons result in predictable access to open water for penguin foraging.

Shipboard measurements at the Charcot Island canyon revealed high concentrations of phytoplankton, bacteria, and krill. Satellite tags confirmed penguin foraging near the canyon. Subsequent visits also confirmed the sustained presence of the Charcot penguin colony; however, poor-quality bathymetric data requires future surveying to map the link between the nearshore seafloor canyon and the outer shelf. We discovered that navigational charts have Charcot Island misplaced by 5 km in this previously inaccessible region.

In conclusion, major WAP Adélie penguin colonies appear to be located in close proximity to the heads of seafloor canyons (although the presence of seafloor canyons does not assume an association with a penguin breeding colony). This connection may in part reflect that marine canyons can provide a conduit for warm Upper Circumpolar Deep Water near the coast. Taken together, these results emphasize the importance of geology in structuring the spatial heterogeneity of ecosystems.

Abstract
The ocean is a complex and difficult sample, and our understanding of how it operates and its future trajectory is poor. This has implications for humanity as increasing numbers are living in coastal zones. To better understand the ocean, it is necessary to adopt new sampling strategies that consist of coupling new observational technologies with numerical ocean models. New observational technologies are becoming available to oceanographers. Fixed assets include moorings, sea floor cables, and shore-based radars. These fixed assets are complemented with mobile platforms that provide spatial maps of subsurface data. The mobile platforms include profiling floats, gliders, and autonomous underwater vehicles. The observational data is complemented with numerical models. Many simulation models are becoming available to the community and the appropriate model is a function of the specific need of the user. Increasingly, observational data are used to constrain the models via data assimilation. The coupled observational and modeling networks will provide a critical tool to better understand the ocean.

INTRODUCTION

The oceans cover the majority of the Earth's surface and despite centuries of exploration they remain relatively unexplored. This gap of knowledge reflects the difficulty of collecting physical, chemical, and biological data in the ocean, as it is a harsh and unforgiving environment in which to operate. Despite centuries of ship-based exploration, the immense size and hazards associated with wind, waves, and storms limit the ability of humans to sustain a coherent global sampling network. Satellite and aircraft remote sensing approaches provide powerful tools to map global synoptic properties (Fig. 1); however, satellite systems largely provide information on the surface ocean. Fixed and mobile sensors deployed in the ocean can provide subsurface data, however, their numbers, while expanding, are limited and the technology still struggles with issues related to the onboard power availability and the number of available robust sensors. These sampling shortcomings have significant implications for human society especially as there is increasing evidence that the physics, chemistry, and biology of the ocean have changed over the last few decades. These changes reflect both natural cycles and the anthropogenic forcing from human activity.

Quantitatively understanding the relative importance of the natural and anthropogenic forcing in the ocean remains an open question, which needs to be resolved as the environmental impacts associated with human activity will increase, reflecting the growth of human populations.[1] The current projections suggest that human population growth at coastlines will be the most rapid and largest on the planet.[2] This will increase the importance of marine systems in national economies around the world making managing coastal systems critical. The close proximity of large populations will expose them to potential natural and man-made disasters associated with the oceans. These disasters include tsunamis, hurricanes, offshore industrial accidents, and human health issues such as outbreaks of waterborne disease. Our current capabilities to predict, respond to, manage, and mitigate these events is astonishingly poor. Improving our ability to observe and predict changes in the ocean will require technical improvements combined with an increased fundamental understanding of physical, chemical, and biological processes.

WHAT IS THE PATH FORWARD?

Improving our understanding and management of the ocean system will require an improved ability to map ocean properties in the present and improving our ability to forecast future ocean conditions. The ability to map ocean

Encyclopedia of Natural Resources DOI: 10.1081/E-ENRW-120048087

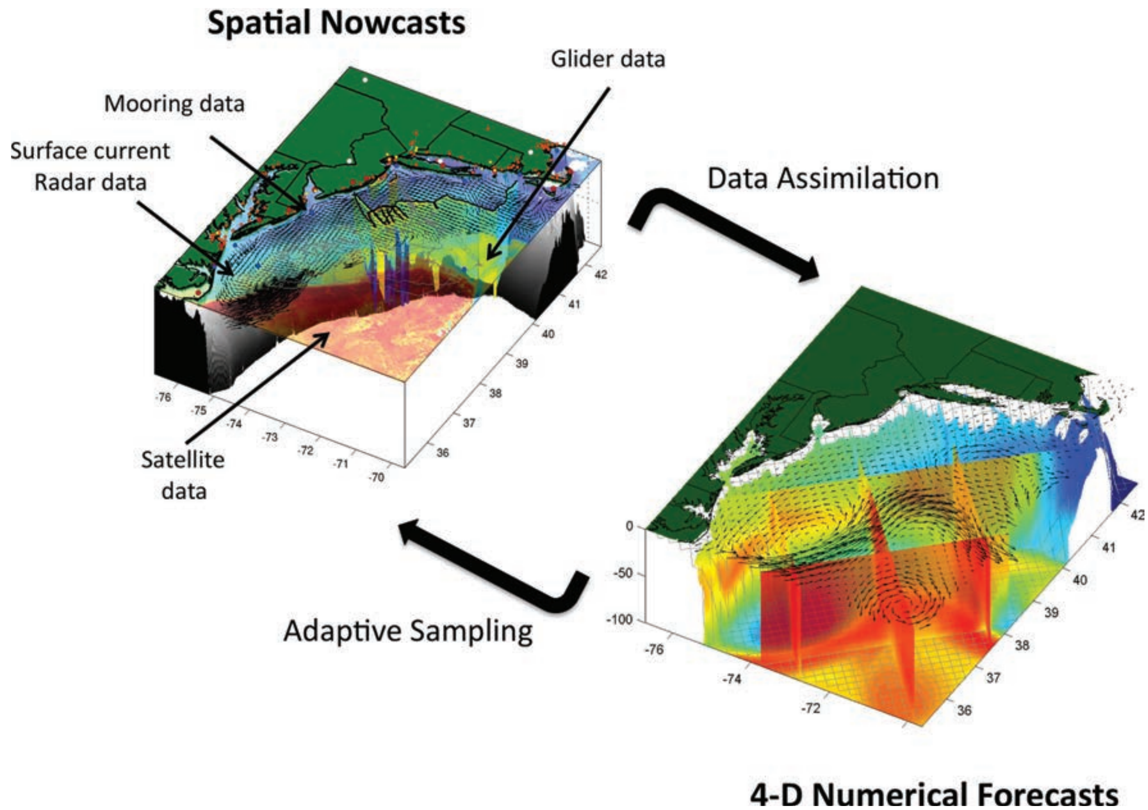

Fig. 1 An example of a coupled ocean observation and modelling network along the East coast of the United States. The spatial nowcast consists of observational data delivered in near real-time to shore. The nowcast consists of satellite data (sea surface temperature is shown), surface current radar (black arrows on the ocean), mooring data (black dots), subsurface data collected from gliders (water temperature shown here), and weather data collected by shore based stations (small white dots). The nowcast provides data to simulation models via data assimilation. The simulation model provides a 48-hour forecast, which is used to redistribute observational assets to provide an improved data set before the next forecast cycle.

properties will require a distributed portfolio of ocean infrastructure that will be linked together through an increasing number of ocean models.[3] The observation networks will collect quantitative data about the current status of the ocean. The forecasts are driven by numerical models that use current scientific understanding to project how the ocean will evolve. The combined observatory and numerical modelling capacity will improve our fundamental understanding and ability to respond to changes in the physics, chemistry, and biology of the marine systems.

The observations will assist the modelling efforts in several ways. Observations will provide data required to parameterize processes within the models. If the data are delivered in real-time they will be assimilated into the model to improve the predictive skill of the forecast. Finally, as new data are collected, they will be used to validate the predictive skill of the model. In turn the model forecasts will assist the observational efforts by providing forecasts that will allow scientists to adjust the spatial configuration and sampling rates of sensors to better sample future ocean conditions. These coupled systems are a rapidly maturing technology and builds off the more mature science of weather forecasting, which has its roots in the early 19th century. The fundamental approaches are based on the seminal work of Lewis Fry Richardson who is considered the father of numerical weather prediction in the 1920s. These approaches are computationally intensive and it was not until the advent of electronic computers that the science moved forward to become an indispensable tool for humanity. Modern computer models use data as inputs collected from automated weather stations and weather buoys at sea. These instruments, observing practices and timing are standardized through the World Meteorological Organization.

Oceanographic efforts are evolving in a similar fashion where observations inform operational models. The weather and ocean models, most often run by federal agencies, provide forecasts that are used by scientists, the maritime industry, state and local communities. Most often they are used to issue warnings of unsafe conditions due to storms and high waves. The motivation for global standardized ocean forecast systems can be traced back to the sinking of the Titanic in 1912, which prompted the international community to call for development of systems to improve safety at sea. Modern approaches and forecasting tools for the ocean did not mature until the 1980s and are rapidly evolving as the computing and ocean observation technologies are rapidly improving.

HOW ARE OBSERVATIONS MADE IN THE OCEANS?

Many platforms are available for making ocean measurements and, although the list below is not exhaustive, it provides a snapshot of the major platforms. The platforms carry sensors that can measure physical, chemical, and biological properties of the sea; however, most new novel sensors can only be carried on ships. A smaller number of sensors can be deployed on autonomous platforms and the discussion in this entry is focussed on those sensors that can be deployed on a variety of ocean platforms.

The most mature sensors are those that measure physical and geophysical variables, such as temperature, salinity, pressure, currents, waves, and seismic activity. Except for seismic variables, most of the physical sensors can be deployed on most of the platforms listed below. Many of the physical properties are the key variables in ocean numerical models. Currently, chemical sensors can measure dissolved gases (primarily oxygen) and dissolved organic material; however, recently the sensors capable of measuring nutrients (primarily nitrogen) are becoming commercially available. Biological sensors currently consist of optical and acoustic sensors. The optical sensors are used to provide information on the concentration, composition, and physiological state of the phytoplankton. Acoustic sensors can provide information on zooplankton to fish depending on the acoustic frequency band that is chosen.

Ships

The primary tool for oceanographers for centuries has been ships and will remain a central piece of infrastructure for the foreseeable future.[4] Ships are ideal as they are extremely flexible and allow teams to conduct experiments at sea. Ships are expensive to operate and must avoid hazardous conditions, such as storms, which limit the ability to make sustained measurements.

Satellites

Satellites are the most important oceanographic technology in modern times (beyond the ships).[5] Satellite observations have resulted in numerous advances in our fundamental understanding of the oceans[6] by resolving both global features associated with the mesoscale circulation of physical and biological properties. Satellite datum is fundamental to weather and ocean state prediction. Physical parameters available from space-based sensors include ocean surface temperature, wind speed and direction, sea surface height and topography, and sea ice distribution and thickness. Biological and chemical parameters can be derived from ocean colour radiometers.

High-Frequency Radar

High-frequency radar measures ocean surface current velocities over hundreds of square miles simultaneously. Each site measures the radial components of the ocean surface velocity directed towards or away from the site[7,8] and the estimated velocity components allow surface currents (upper meter of water column) to be estimated.[9] These systems are cost effective and have many applied uses.

Ocean Moorings

The modern ocean moorings grew out of the weather stations established in the 1940s. Since the 1960s, modern buoys have enabled a wide range of studies addressing the ocean's role in climate, weather, as well as providing insight into the biogeochemistry of the sea. Moorings provide the backbone to many of the global ocean networks studying ocean–atmosphere interactions and are the foundation for the global tsunami warning system network. They will continue to be a key element of ocean observing infrastructure for the foreseeable future.

Seafloor Cables

Scientists often require high bandwidth and power for sustained periods of time. Seafloor electro-optic cables provide a means for maintaining a sustained presence in the ocean. Cables have been deployed off the east and west coasts of the United States, Canada, Japan, and Europe. Many other countries are planning to deploy seafloor cables.

Drifters and Floats

Passive Lagrangian platforms are tools for creating surface and subsurface maps of ocean properties. These platforms are relatively inexpensive and thus allow thousands of these platforms to be deployed. Drifters have historically been a key tool for oceanography as evidenced by the important works by Benjamin Franklin[10] and Irving Langmuir.[11] The drifters can carry numerous sensors to create global maps of surface circulation. The first neutrally buoyant drifters were designed to observe subsurface currents.[12] The subsurface profiling drifters were enabled in the early 1990s with communication capabilities[13] and now anchor the international ARGO program, which has over 3000 floats deployed in the ocean.

Gliders are a type of autonomous underwater vehicle (Fig. 2) that use small changes in buoyancy in conjunction

Fig. 2 A Webb underwater glider being deployed in the Ross Sea Antarctica in February 2011.
Source: Photo credit Chris Linder.

with wings to convert vertical motion to horizontal motion, and thereby propel itself forward with very low-power consumption.[14] Gliders follow a saw-tooth path through the water, providing data on large temporal and spatial scales. They navigate with the help of periodic surfacing for Global Positioning System (GPS) fixes, pressure sensors, tilt sensors, and magnetic compasses. Using buoyancy-based propulsion, gliders have a significant range and duration, with missions lasting up to a year and covering over 3500 km of range.[15–17]

Propeller-driven autonomous underwater vehicles (AUVs) are powered by batteries or fuel cells and can operate in water as deep as 6000 m. Similar to gliders, AUVs relay data and mission information to shore via satellite. Between position fixes and for precise maneuvering, inertial navigation systems are often available onboard the AUV to measure the acceleration of the vehicle, and combined with Doppler velocity measurements, it is used to measure the rate of travel. A pressure sensor measures the vertical position. AUVs, unlike gliders, can move against most currents nominally at 3–5 knots, and can therefore systematically and synoptically survey a particular line, area, and/or volume.

WHAT NUMERICAL OCEAN MODELS ARE AVAILABLE?

Over the last 30 years, there have been significant developments in three-dimensional numerical models for the ocean.[18] Many models exist spanning from global ocean scales down to the scale of individual estuaries. Models vary in their coordinate system (linear, spherical, and others), resolution in space and time, complexity (i.e., number of state variables), and the parameterization of key processes within the model. There are several excellent texts that outline many of the details of numerical ocean modelling[19,20] and one key lesson is that the choice of particular modelling approach depends on its intended application and on the available computational resources. Although an exhaustive list of the ocean models is beyond the scope of this text, several classes are described in the following paragraphs.

Mechanistic models are simplified models used to study a specific process, and are used to provide insight into the underlying processes influencing the physics, chemistry, and biology of the ocean. These models are most often constructed as a learning tool in order to assess processes and feedbacks within marine systems.

Simulation models are complex and describe three-dimensional (3-D) ocean processes using the continuity and momentum equations. For this reason they are called the primitive equation models. These models can be used to simulate many processes, including ocean circulation, mixing, waves, and responses to external forces (such as storms). All these models are constructed using different assumptions. Additionally, the resolution of the models requires that the trade-offs of the computation burdens be measured against the processes that need to be simulated. For example, if the model must resolve mesoscale eddies, it will require the resolution of a few tenths of a degree of latitude and longitude. In contrast, most primitive equation climate models have much coarser horizontal resolution as they were designed to study large-scale hydrographic structure, climate dynamics, and water-mass formation over decadal time scales; however, for a specific question, there are climate models with sufficient resolution to resolve mesoscale eddies if one is willing to accept the computation cost. Simulations are also constructed for coastal systems and can resolve coastal currents, tides, and storm surges. Increasingly the biological and ocean chemistry models are being coupled into these 3-D simulation models. Although these biogeochemical models are rapidly improving, there is unfortunately no set of "primitive" equations yet capable for describing biological and chemical systems in the ocean; however, as these models evolve, they will be increasingly useful tools for managing living resources and water quality in the ocean.

Often models of varying resolutions are combined. Coarser-scale global or basin-scale models provide outer boundary inputs to higher resolution nested models, which allows a myriad of processes to be modelled with a lower computation burden but allow a range of processes to be simulated even if they require high resolution. This is often the case for coastal and continental shelf models. The advantage of this downscaling approach is that it allows basin scale models to resolve large-scale forcing that drives the regional to local-scale processes that are effectively modelled by a higher resolution model. The approach by which one links these models is a difficult problem and remains an area of active research.

Data assimilation is an approach by which model simulations are constrained by observations. For example, model calculations and observations of temperature and salinity can be compared, and then the model can be "adjusted" based on the mismatch. This is a difficult problem as 1) it represents an inverse problem (where a finite number of observations are used to estimate a continuous field), 2) many of the ocean processes of interest are non-linear, and 3) the observations and models both have unknown errors. Descriptions of data assimilation approaches for oceanography have been reviewed.[21,22] These approaches allow modellers to increase the forecast skill of their models by essentially keeping the models "on track" if the observations and data assimilation approaches can be provided in a timely fashion. Many in the ocean modelling community are focusing on using these approaches to increase model forecast skill as it determines how well these approaches will serve a wide range of science, commercial, and government needs.[23]

CONCLUSIONS

Ocean observation and modelling capabilities are rapidly diversifying and improving. These systems are increasingly linked by data assimilation approaches that when combined, provide a coupled observing and forecasting network. These approaches will increase the predictive skill of forecast models that in turn can serve a wide range of applications spanning from basic research to improving the efficiency of the maritime industry. The combined technologies will be critical to improving our understanding of the ocean today and the potential trajectory in the future.

Halifax, N.S. Canada

Abstract— Gliderpalooza represented a grass-roots coordinated field demonstration of ocean observing technologies spanning the eastern seaboard of North America. The overarching goal was to coordinate disparate ocean research efforts, funded by disparate programs from a variety of agencies to demonstrate continental scale coordination of various ocean observing technologies to sample ecologically relevant scales.

The coordinated data from satellites, HF-Radar surface currents [1], moorings, drifters and models was focused on and around the distributed deployment of Slocum gliders. The seven science and technical goals were to:

1) provide a unique data set the modelers can use for years to come (real-time & hindcast),
2) provide a standardized dataset over ecological scales and information on fish/mammal migrations,
3) provide a 3-D snapshot of the MAB cold pool,
4) provide an extensive distributed instrumented network through the peak period of fall storms, demonstrating a community "surge" capacity,
5) provide one, of many demonstrations, of the potential U.S. national glider network,
6) proof of data flow throughput to the Global Telecommunications System (GTS) via DMAC and,
7) engage undergraduates in ocean observing efforts.

During the summer and fall of 2014, the Gliderpalooza team will once again work together, but with several additions to the group, the geographical scope will cover Texas to Newfoundland. There will be more than 30 glider deployments that will be assimilated by seven numerical ocean models. Acquisition of this massive data set of water column profiles will permit evaluation of the accuracy of the models, especially in the coastal zone. Additionally, new online educational tools developed through the NSF's Ocean Observatory Initiative (OOI) will be used to by students in the undergraduate classroom to analyze, compare and contrast the glider data in real-time during the fall 2014 semester.

Keywords — ocean glider, ocean modeling, data assimilation, physical oceanography, optics, mixing storm, cold pool, fish/mammal migrations, U.S. IOOS, MARACOOS.

I. Introduction

The research performed during Gliderpalooza grew out of the U.S. Integrated Ocean Observing System's (U.S. IOOS) Mid Atlantic Regional Association Coastal Ocean Observation System (MARACOOS) and Ocean Tracking Network's science priorities. Ten universities, one corporation and the US Navy worked together to perform 17 glider deployments along the eastern coast of the U.S. and Canada (Table 1 and Figure 1). Many of the deployment locations were determined by an ocean continuously well sampled by satellites, surface current data provided by the MARACOOS HF-Radar Regional Network [2] and drifters. Much of this data was assimilated into dynamical ocean models which were then used to direct the location of a handful of the deployments in the Mid-Atlantic bight. Upon completion of the project, full resolution data sets from almost all deployed gliders were shared amongst all researchers.

In late February of 2014, the Gliderpalooza team met in Honolulu during the Ocean Sciences meeting to plan research papers focusing on the seven program goals. This paper will summarize the seven science and logistical goals and elaborate on early results from initial data analysis performed during 2014. It will then discuss plans for Gliderpalooza 2 (aka Modelpalooza) which will occur during July-November 2015 but will now span from Texas north to Newfoundland and east to Bermuda.

Fig. 1. Gliderpalooza deployments in summer and fall 2013.

II. Gliderpalooza Goals & Early Results

A. Goal 1: Provide a Unique Dataset for Ocean Modelers

A shelf wide subsurface perspective for the North American east coast was collected through a coordinated range of regional combined with coastal surveys. All gilders provided an extensive survey for the hydrographic and optical data as well as acoustically tracked animal locations. The database spans from the upstream condition of Canadian waters through the South Atlantic Bight. The database is enabling studies to improve data assimilative forecast models.

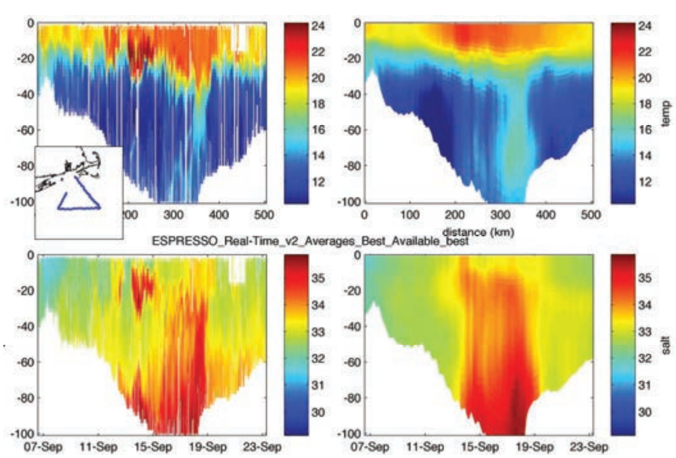

Fig. 2. Observed (left) and ROMS ESPRESSO model (right) temperature (top) and salinity (bottom) following glider BLUE. Inset shows the glider path south of Providence, RI (blue).

Moving forward, the goal is to support the improvement of the ensemble of ocean models through assimilation and validation. Figure 2 highlights a time series of temperature and salinity from a glider and compares it to the identical locations virtually sampled within the ROMS ESPRESSO model [3], [4].

B. Goal 2: Tracking Fish/Mammal Migrations

The glider survey was focused on collecting a broad environmental dataset to provide a map of the hydrography in which to interpret major migration patterns. The Ocean Tracking Network (OTN) is augmenting current capabilities to provide the foundation for a listening network. The collection of gliders provided a subsurface spatial snap shot of a Large Marine Ecosystem (LME) during the fall migration that was mined by scientists in both real-time and in hindcast mode as nine of the gliders were fitted with Vemco trackers. This effort is motivated as the region is home to some of the most migratory fish communities in the eastern United States and Canada. These data from multiple gliders are currently being combined by OTN. Species locations will be analyzed against the subsurface glider data as well as available satellite and CODAR assets and models of subsurface physical/biological parameters to provide a perspective of the northeast United States/Canada ecological domains.

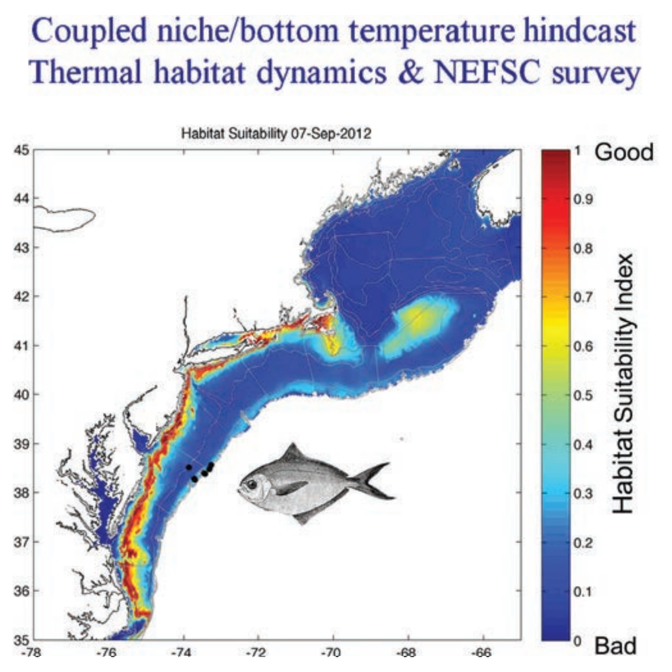

Fig. 3. A habitat sustainability model showing likelyhood of butterfish bycatch with likely areas shown in red. Block dots indicate in situ fishign surveys which tested the accuracy of this early model from 2012. Gliderpalooza data will help to improve these models in the future. Early funding for this work was from the NOAA NEFSC and Fisheries Habitat Program.

Sponsors of this work include NOAA's U.S. IOOS, Ocean Tracking Network Canada, N.J. Department of Environmental Protection, U.S. EPA, U. of Delaware, NASA, ONR, U. of Maine, College of William and Mary, U. of Georgia, Teledyne Webb, US NMFS, NSF Ocean Observatories Initiative and the U.S. Navy. Additional sponsors in 2014 will include Memorial University and Texas A&M U.

The data are also being used to improve fisheries bycatch models. Rutgers and NOAA's Northeast Fisheries Science Center (NEFSC) conducted in situ surveys in 2012 where forecast models were tested that predicted the butterfish bycatch amounts in the mid-Atlantic bight (Figure 2). Subsurface water column profile data, especially geographically distributed bottom temperatures, are key to these forecasting models, and the glider data sets will both aid in improving the models through assimilation and verifying the model's accuracy.

C. Goal 3: Mapping the Mid-Atlantic Cold Pool Water

During summer, a distinctive, bottom-trapped, cold water mass called the Cold Pool Water (CPW) resides as a swath over the mid to outer continental shelf throughout much of the Middle Atlantic Bight (MAB) [3]. This evolving CPW is important because it strongly influences the ecosystem, including several important fisheries. Thus there is a priority to better understand the relevant ocean processes and develop a CPW forecast capability.

Seven gliders crossed the area of Cold Pool during Gliderpalooza. The path of RU23 is show in red in figure 4 overlaid on a ROMS ESPRESSO modeled bottom temperature hindcast off of the New Jersey coast. Cold Pool water sits on the shelf between approximately 35m to 100m. Temperature and salinity glider transects are compared to a 2d version of this this model hindcast in figure 5.

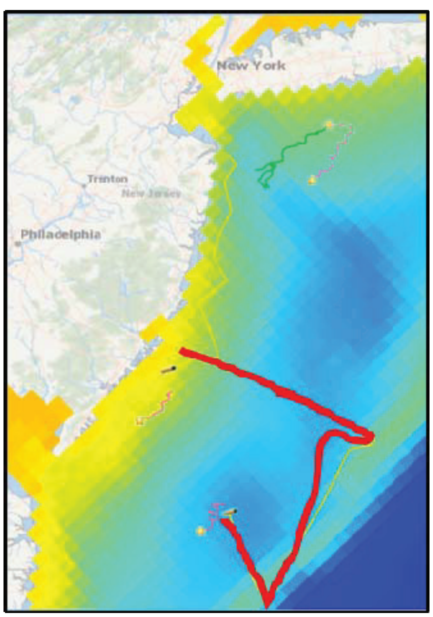

Fig. 4. A habitat sustainability model showing likelyhood of butterfish bycatch with likely areas shown in red. Black dots indicate in situ fishing surveys which tested the accuracy of this early model from 2012. Gliderpalooza data will help to better inform these models in the future through assimilation. Early funding for this work was from NOAA's Norteast Fisheries Science Center and Fisheries Habitat Programs.

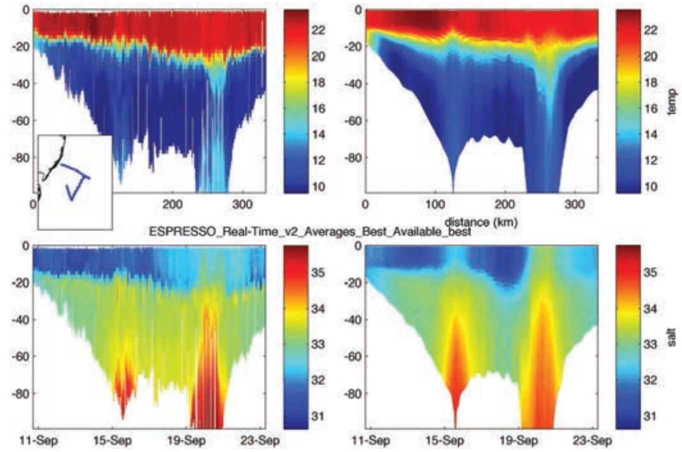

Fig. 5. RU23 glider temperature and salinity on the left are compared to modeled temperature and salinity on the right from ROMS ESPRESSO.

D. Goal 4: Analysis of Fall Mixing Storms

September is the peak month for tropical storm and hurricane landfall along the Eastern coast of North America. The regional array provided a comprehensive sampling of the continental shelves, which are the most undersampled with regards to subsurface temperatures. This subsurface temperature data is increasingly being viewed as valuable in potentially improving the ability to better predict hurricane intensity [6]. The 2013 Gliderpalooza dataset will serve as a baseline as it was a quiet tropical storm season. In 2014-2015, the Cooperative Institute for the North Atlantic Region (CINAR) is providing funding to support deployments of four storm gliders, rapid profile drifters and rapid deployable buoys into both tropical storms and winter Nor'easters. Storm gliders will be equipped with an acoustic Doppler current profiler, a full range of optical instruments, and accelerometers in addition to the standard CTD package. A preliminary in water test of these new storm gliders was performed during Hurricane Arthur in July, 2014 (figure 6).

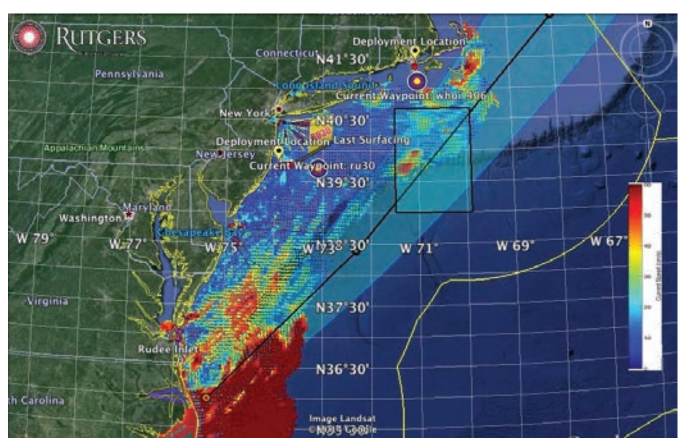

Fig. 6. Hurricane Arthur forecasted storm track from July 4, 2014. Locations of CINAR funded gliders RU30 and WHOI_406 are shown with target icons. HF-RADAR surface currents are shown, highlighting the counterclockwise circulation around the eye of Arthur just north of Cape Hatteras and the forecast track.

E. Goal 5: Demonstration of a National Glider Network

During the summer of 2012 a workshop funded by U.S. IOOS was held at Scripps Institute of Oceanography to discuss plans for a national glider network. As a result, multiple partners from federal agencies, IOOS Regional Associations (RAs) of coastal ocean observing systems, and universities were assembled to develop a National Glider Network Plan for a viable, sustainable, and reliable network that delivers timely monitoring and distribution of coastal subsurface glider data to federal, state, and local governments, as well as the general public. The plan is structured to develop an initial network that includes maintaining existing long term glider sampling lines, acquiring additional glider lines to fill high priority gaps, and improving data management, product development, and data/product delivery. The national plan was released in January 2014 and available at http://www.ioos.noaa.gov/glider/strategy/welcome.html.

Gliderpalooza enabled a first example of a multi-regional coherent effort to deploy, monitor and access glider data in real time through a central site at Rutgers University. The ultimate national goal is to attain funding for long term sustainability of deployments on all U.S. coasts (Figure 7).

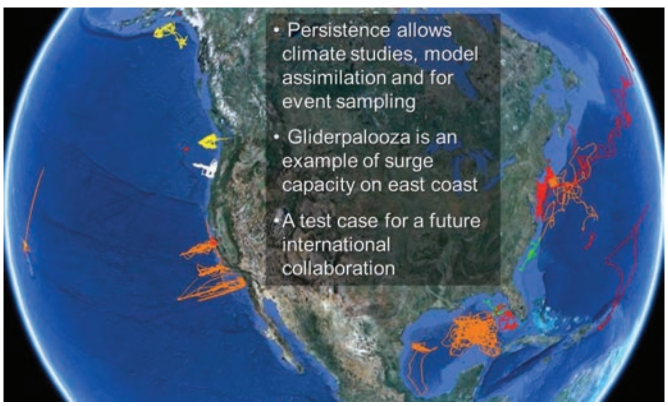

Fig. 7. U.S. glider deployments from 2000 through early 2013.

F. Goal 6: Data Throughput to the GTS

In 2013 IOOS secured funding to begin construction of a Data Management and Communications System (DMAC) specifically for glider data distribution. A successful goal of Gliderpalooza was to have real-time throughput of raw data from the gliders to Dockservers to the DMAC where it was converted to Climate and Forecast (CF) compliant NetCDF files and then sent to the National Data Buoy Center and finally to the Global Telecommunications System. This mission to make glider data available to modelers and forecasters worldwide will continue to expand outside the east coast region to the U.S. and eventually global throughput of glider data to NDBC and GTS.

Fig. 8. Schematic of glider data throughput from acquisition to the GTS.

G. Goal 7: Undergraduate Education

In addition to having undergraduate students assist with glider deployments and recoveries, the Gliderpalooza data were made available to undergraduate classrooms in real-time during the fall semester of 2013. During fall 2014, both real-time and archived glider data are going to be used by numerous Community and 4-Year college professors in the undergraduate classroom through cooperation with the NSF's Ocean Observatory Initiative's Education and Public Engagement team's (OOI EPE) newly developed online educational tools (Figure 9). This software can be used by undergraduate educators to build and share online lessons using ocean data from both the OOI and outside resources, including global glider deployments.

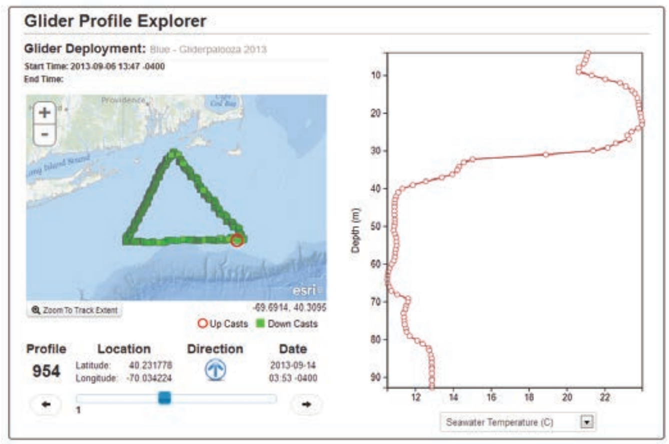

Fig. 9. Newly developed glider profile explorer tool that allows users to search and display glider profiles through the OOI EPE's website at: http://education.oceanobservatories.org/.

III. Next Steps: Gliderpalooza 2 – Modelpalooza!

The success of Gliderpalooza 2013 built on a collaborative community which was a great start, and one the team wishes to build on for the coming year. Gliderpalooza 2 will begin during the summer of 2014 but this time with a focus of using the real-time data for ocean model assimilation and validation in several models and, in turn, using model output to help drive sampling locations throughout the east coast, not just the mid-Atlantic bight. At least seven ocean models are going to be used for this effort (table 2). A new glider tool that will support comparison of the glider profiles to any of these ocean models is shown in figure 10.

The list of groups involved with glider deployments and models is expected to expand to include Memorial University of Newfoundland, Dalhousie University (Ocean Tracking Network), University of Maine, Woods Hole Oceanographic Institute, University of Massachusetts Dartmouth, Stevens Institute of Technology, Rutgers University, University of Delaware, University of Maryland, College of William and Mary, North Carolina State University, University of Georgia, Texas A&M University, the US Navy and the Bermuda Institute of Ocean Sciences.

TABLE II. MODELS TO BE USED FOR ASSIMILATION AND VALIDATION TESTING DURING GLIDERPALOOZA 2: MODELPALOOZA.

	Models	Affiliation
1	Regional Ocean Modeling System 1 (ROMS)	North Carolina State University
2	ROMS Experimental System for Predicting Shelf and Slope Optics (ROMS HOPS)	Rutgers University
3	Harvard Ocean Prediction System (HOPS)	University of Massachusetts Dartmouth
4	New York Harbor Ocean Prediction System (NYHOPS)	Stevens Institute of Technology
5	Real Time Ocean Forecast System (RTOFS)	NOAA National Centers for Environmental Prediction
6	MyOcean	European Union
7	Mercator Ocean	Europe (France)

In addition to the science and technical goals outlined in this paper, additional goals for Gliderpalooza 2 include; 1) Improved data flow of all gliders to the World Meteorological Organization's GTS, 2) Visualization of all data in the NOAA U.S. IOOS National Underwater Glider Network Map portal, 3) Data assimilation by four ocean models and validation testing of at least seven ocean models (hence the name Modelpalooza), 4) Using the ocean models to assist in planning glider sampling activities, 5) Building an active community blog, 5) Improving coordination between distributed teams, 6) Strengthening science working groups thereby accelerating the publishing of potential products/manuscripts/articles for the ocean science community and general public, and 7) Improving the existing web portal tools that link the community.

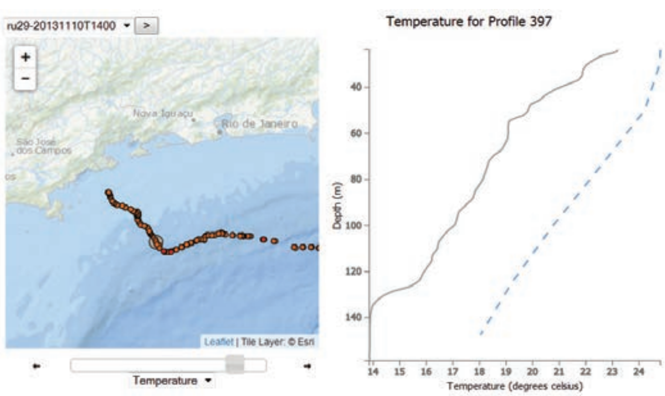

Fig. 10. Newly developed NSF OOI visualization tool that will enable researchers to compare glider profiles to model output. This example highlights a single profile from glider RU29 located just south of Rio de Janerio on the outer edge of the continental shelf (145 meters). The temperature data is compared to RTOFS and highlights that RTOFS is significantly warmer (~3C) throughout much of the water column. Development of this tool leveraged both NOAA US IOOS funds and NSF OOI funds.

ACKNOWLEDGMENTS

There were dozens of co-authors to this work from the numerous groups involved with the Gliderpalooza effort. They include J. Kerfoot, C. Haldeman, D. Aragon, A. Comeau, R. Davis, J. Pye, N. Beauchamp, K. Morton, S. Iverson, N. Fisher, M. Neary, N. Pettigrew, L. St. Laurent, J. Reilly, K. Decoteau, C. Jones, C. DeCollibus, C. Jacubiak, J. Kohut, T. Miles, T. Haskins, J. Wilkin, N. Strandskov, M. Breece, M. Oliver, D. Haulsee, G. Kuska, C. Thoroughgood, W. Boicourt, D. Gong, R. He, W. Woods, C. Edwards and the U.S. Navy Glider Team headed by C. Szczechowski

Funding for this work came from the National Oceanographic and Atmospheric Administration's U.S. Integrated Ocean Observing System (much of which came through the Mid Atlantic Regional Association Coastal Ocean Observation System Regional Association), Ocean Tracking Network, New Jersey Department of Environmental Protection, U.S. Environmental Protection Agency, U.S. Department of Environmental Protection, University of Delaware, National Aeronautics and Space Administration, U.S. Office of Naval Research, University of Maine, College of William and Mary, University of Georgia, Teledyne Webb Research Corporation, NOAA National Marine Fisheries Service, the National Science Foundation's Ocean Observatories Initiative and the U.S. Navy.

In addition to the funding agencies and partners listed here, the authors would like to thank Doug Webb for his futuristic vision, and, leading us one step at a time toward 'changing the world'.

Enabling Shallow Water Flight on Slocum Gliders

Clinton D. Haldeman III, David Aragon, Hugh Roarty, Joshua Kohut, Scott Glenn
Institute of Marine and Coastal Sciences
Rutgers University
New Brunswick, New Jersey 08901

Abstract— **Underwater gliders are a disruptive technology capable of transforming our understanding of the ocean. Efficient vehicle flight is critical for proper data collection, allowing successful completion of project goals. Slocum glider flights in less than 15 m of water have been only marginally successful, as use of deep water flight coefficients disables proper inflection at shallow depths. Groundings can damage sensors, degrade data, halt progress, and ultimately endanger the vehicle. To correct poor flight performance, sensor parameters responsible for inflection were individually analyzed and adjusted. Tests were conducted on repeated flights in the shallow state waters of New Jersey with glider RU28 while conducting dissolved oxygen surveys for the New Jersey Department of Environmental Protection (NJDEP) and the United States Environmental Protection Agency (USEPA); further verifications were conducted off the shoaling areas of Delaware with glider OTIS while searching for tagged sturgeon and sand tiger sharks. As a result of these tests, flight performance has been drastically improved, with efficient flight in 8 m of water, including several promising instances in water as shallow as 6 m. Prior to adjustments, gliders would make little forward progress and spend 50-100% of a flight segment grounded. With the new parameters loaded, groundings have been eliminated from coastal missions. Enabling shallow water flight for Slocum gliders allows vehicle operations in an area largely unexplored by this type of platform, opening up coastal areas to new project ideas and sampling schemes. Shallow water flight parameters can be shared with the community to increase sampling density in areas previously off limits to these vehicles**.

Keywords—Gliders; Slocum gliders; Shallow water; AUV operations; Glider flight parameters

I. INTRODUCTION

In 1989, Henry Stommel penned a science fiction article published in the journal Oceanography entitled "The Slocum Mission"[1]. In it, he elaborated on an idea conceived by Douglas C. Webb about a fleet of autonomous underwater vehicles driven by buoyancy changes, dubbed Slocums, that traversed the oceans while profiling in a sawtooth pattern, surfacing at regular intervals and sending data back to a control center via satellite. Today the Slocum glider is no longer a myth, but a reality with purposed missions, monitoring both deep ocean basins [2] and shallower coastal regions [3]. While the former presents its own suite of challenges, the latter has presented glider operators with a unique set of issues to overcome merely to enable continuous flight in a limited water column. Standard flight coefficient settings work well in depths of 15 meters or greater, but often fail in depths below that, causing the vehicle to strike the bottom. Several separate factors can lead to these groundings with differing severity. Short duration groundings are affectionately termed "bottom sampling" (Fig.1), while longer duration groundings are referred to as "dredging" (Fig. 2). Both are capable of degrading the data set, and can cause damage to the vehicle and payload sensors. As work in these regions expands, finding a solution becomes imperative.

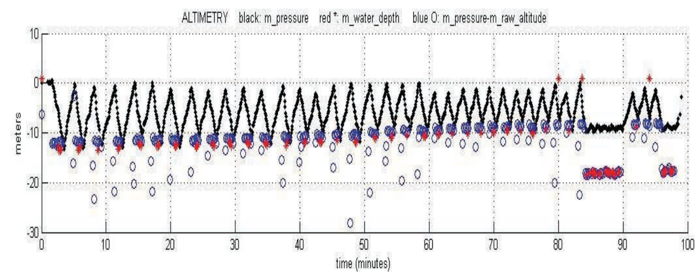

Fig. 1. *Pressure record from University of Delaware glider "OTIS". Towards the end of this segment, the otherwise uniform sawtooth pattern is interrupted by " bottom sampling"..*

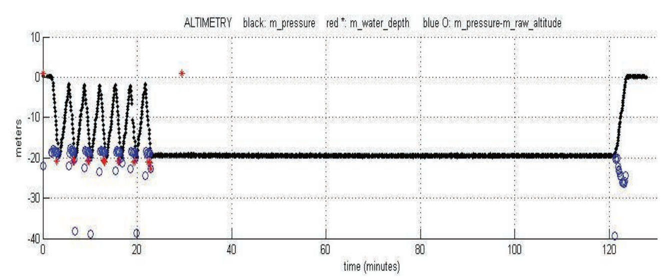

Fig. 2. *Pressure record from Rutgers University glider "RU28". In this example of "dredging", once the glider strikes the bottom, it is unable to recover and stays on the bottom for the remainder of the segment.*

II. Background

A. Glider Configuration

The Slocum glider, manufactured by Teledyne Webb Research Corporation (TWRC), is modular in design and available in several different configurations [4]. Aside from the payload bay that can be configured with a variety of different sensors, the primary differences lie in the depth rating of the buoyancy pump – currently 30 m, 100 m, 200 m, and 1000 m, with others well on the way. For very shallow coastal areas, the 30 m pump configuration is ideal, with a theoretical operational depth of between 4 m and 30 m of water. With the standard flight coefficients, the 30 m pump has not performed any better in shallower water than the deep rated 100 m pumps.

B. Applicaitons Requiring Efficent Shallow Water Flgiht

1) New Jersey Dissolved Oxygen Monitoring

With the arrival of the warm summer weather, the coastal waters of New Jersey often experience areas of low dissolved oxygen at depth. [3] These areas are of interest to and are occasionally monitored by the New Jersey Department of Environmental Protection (NJDEP) and the United States Environmental Protection Agency (USEPA), often leading to an "impaired" classification for the coastal waters of the region. Rutgers University has since partnered with these agencies to pilot a Slocum glider through the state's coastal waters, monitoring dissolved oxygen at a much higher spatial resolution than previous shipboard surveys. Data collected for the USEPA has a previously specified resolution and format, specified in a Quality Assurance Project Plan (QAPP), and state waters lie within three nautical miles from shore. The convergence of these constraints require reliable operation and data collection of a glider in very shallow water, in this case approaching as near to the seabed as possible without risking the glider.

2) University of Delaware Shark Tagging Project

The University of Delaware pioneered the integration of a Vemco VR2C hydrophone into a Slocum glider, effectively allowing the glider to receive information from sand tiger sharks, sturgeon, and other tagged species in the area while mapping out the physical properties of the associated preferred water masses [5]. Rutgers University partnered with the project team to pilot the glider, primarily in the shallow coastal region off Delaware, known for its shoaling. A glider in this area can often find itself operating in 6-8 m of water while winding its way through the navigable waters between shoals. Flight dynamics adjustments are necessary to successfully gather data in these regions.

III. Methods

Two gliders were flown for separate projects off the coasts of New Jersey and Delaware – RU28 to monitor areas of low dissolved oxygen off New Jersey, and OTIS in a search for tagged sharks and sturgeon off Delaware. While instances of bottom sampling and occasionally even dredging have been seen before, both became common occurrences during these flights. Glider pilots were not able to coerce the gliders to make headway, and the project data sets were in jeopardy. It was at this point that in-depth analyses of flight data were conducted in an attempt to pinpoint the root cause of the issues.

"Live" plots that update with the newest flight data after every surfacing were poured over time and time again, as were higher density datasets transferred directly from the glider representing suspect segments. Several plots began to point toward altimetry issues, both in the collection and processing of the sonar returns. The master file containing all sensors aboard the glider, masterdata was scoured for all sensors and settings related to the altimeter. Upon reasoning through the default settings, the root cause of bottom sampling had been found.

A rather specific set of criteria applies to altimeter returns to be considered "good", and thus be accepted by the glider. As the glider begins a dive in shallow water, a good altimeter return may be received and rejected, as the glider is still considered to be "on surface", or it may still be too soon after an inflection. As the glider continues its dive, it reaches a window where an altimeter return is recognized as "good", and that value is stored. The glider continues its dive, and receives another good return, but it may be rejected because the glider is too close to the bottom. The glider requires two valid altimeter returns to determine height above bottom and then inflect, but in very shallow water, it may only receive one, which is then ignored, and the glider strikes the bottom. (Fig. 3.) Fixing the bottom sampling issue requires taking multiple flight parameters into consideration at once, with an understanding of their interactions between each other and the glider. The initial step is to disable the filtered altimetry:

```
sensor:  u_alt_reqd_good_in_a_row(nodim)      1
sensor:  u_alt_filter_enabled(bool)           0
sensor:  u_alt_reduced_usage_mode(bool)       0
```

This step disables the built-in filter, turns off the standard reduced usage mode, and requires only one "good" return in a row to register as a valid altimeter return. Otherwise, valid returns are rejected. The second step requires changing parameters that effectively increases the size of the water column to the glider's altimeter.

```
sensor:  u_reqd_depth_at_surface(m)              2
sensor:  u_alt_min_post_inflection_time(sec)   4.0
sensor:  u_alt_min_depth(m)                    1.0
sensor:  u_min_altimeter(m)                    1.5
```

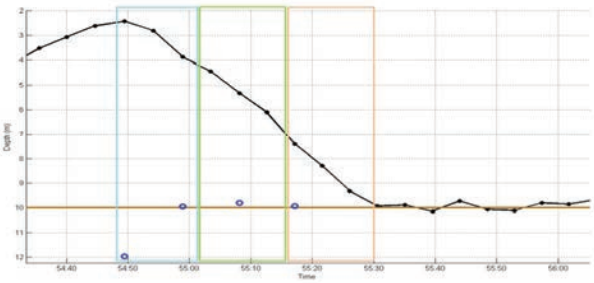

Fig. 3. Obtaining returns in very shallow water. The 2 initial returns are rejected, one valid return is accepted, and another later hit is rejected, causing the glider to ground.

The depth at which the glider considers itself on surface is reduced to 2 meters instead of 4, immediately increasing the depth in which valid returns can be obtained. The post-inflection time filter is reduced to 4 seconds, letting the glider take readings earlier after it inflects. The minimum depth the glider must obtain before taking altimeter readings is reduced to 1 meter, effectively keeping the altimeter on for the majority of the flight. The minimum reading the altimeter may return is then reduced to 1.5 meters, allowing the glider to reach as low as 1.5 meters above bottom prior to inflecting. Below this altimeter readings can be unstable, spiking up into unrealistic values. So the general summary of steps to avoid bottom sampling is to a) disable the filtering of valid altimeter returns and b) increase the depth of the water column in which the glider is able to receive returns. Should these fail, an additional safety can be added:

sensor: u_max_water_depth_lifetime(yos) 2

Setting this sensor allows the glider to use the measured altimetry from the last dive should it fail to obtain a valid measurement on the current dive. While not accurate, it can serve as a safety if the depth hasn't changed drastically.

Further refinements can be made to increase altimeter accuracy and nullify false hits:

sensor:	u_sound_speed(m/s)	1510.0
sensor:	u_max_bottom_slope(m/m)	3.0
sensor:	u_min_water_depth(m)	0
sensor:	u_max_water_depth(m)	2000

The speed of sound can be set to match as closely as possible the physical properties of the water mass in which the glider will be flying. Although the difference may not appear drastic, all attempts to increase altimeter accuracy had to be taken into consideration. The maximum slope of the seabed can be adjusted; this value is presented in vertical meters per horizontal meter. Strong caution is urged in reducing this value, as it may be acceptable where topography is generally flat, but can filter out valid returns in an environment with a more dynamic terrain, such as rocky coasts, reefs or wrecks. The final two sensors listed above are included as an altimeter fix for a very specific situation; their inclusion here will be clarified later in this section. Several glider flights have produced false altimetry hits, causing the glider to inflect up in the water column instead of down near the seabed. Although this has been seen occasionally off New Jersey in the shelf waters, it is primarily an issue in the colder waters of Antarctica. General speculation points towards masses of krill acting as a false bottom, giving the glider false returns. Setting the minimum water depth deeper than the false returns filters out any returns prior to the preset depth. Again caution must be used, especially if entering shallow water. This can inadvertently trigger a grounding. Setting the maximum water depth avoids null returns from the altimeter; i.e. generic placeholder values such as 9999. This is not an issue, as this is the default setting, and is included here only for completeness.

Preventing dredging, although related, is a separate issue. When bottom sampling, the groundings occur due to a lack of altimetry, but the glider can typically recover. When dredging occurs, the glider not only grounds, it remains on the bottom for extended periods of time, typically the remaining duration of the segment. On occasion, a trigger will cause the glider to recover, but the safeties in place often aren't enough to overcome the dredging. For example, the glider should attempt to surface if it has been at the same depth for a specified period of time, which seems plausible, as the glider is stuck on the bottom. However, in dynamic shallow water environments, the surge of the waves moving the glider around often creates enough of a pressure change that the glider's logic does not realize it is generally at the same depth. The underlying cause of dredging is yet another altimeter issue – surface reflections. When the glider is on the bottom, the ping of the altimeter reflects immediately off the seafloor, and again off the surface before returning to the glider. The glider registers these as valid returns, and continues trying to dive through the seafloor to reach the depth registered by the altimetry (Fig. 4). To circumvent this, one sensor is set:

sensor: u_max_altimeter(m) 6.0

The maximum value allowed to be returned by the altimeter is set to less than the actual water depth. This is considered to be a workaround rather than a final solution, as it prevents the glider from dredging, but also limits altimeter returns in deep water to the same value; e.g. if the glider is flying to 80 m in 100 m of water, no altimetry will be returned, as 20 > 6, even though the altimeter is easily capable of measurement at that depth.

Throughout the initial troubleshooting process, the above sensors were individually adjusted and tested to gain better understanding of how the glider's flight behaviors changed with each setting, and how the sensors interacted with one another. Once a best-practice set of parameters was decided upon, the sensors were collected and placed into a mission file that is now included in Rutgers' default software version. Using a simple "loadmission" command via short-range

Freewave communications or even through TWRC's dockserver over the Iridium network, shallow water flight parameters can quickly and easily be loaded on a glider at sea, preventing nearly all groundings.

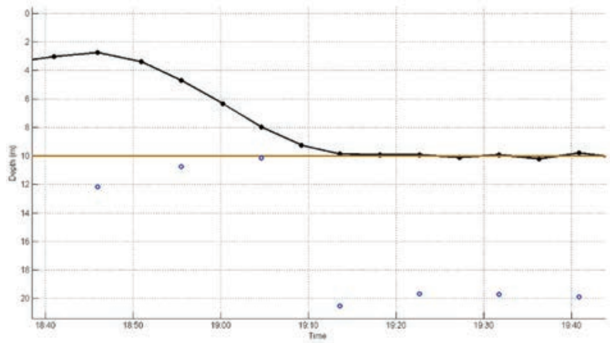

Fig. 4. Altimetry surface reflections during a grounding event. The glider remains grounded as it attempts to dive to the values returned by the altimetry.

IV. DISCUSSION

Slocum gliders are a powerful tool capable of sampling the marine environment with very high resolution, both vertically and horizontally. A standard suite of software included from the manufacturer generally enables glider flight across a range of pump configurations, providing the water depth is sufficient. This "one-size-fits-all" approach breaks down in shallow water, causing the glider to strike the bottom on multiple occasions, or strike the bottom and remain there for the duration of the segment. While adjusting sensors onboard the glider has lead to a software fix, not everything can be blamed on the software configuration.

A. Causes of grounding

Splitting the glider into two separate systems, denoting a hardware system and a software system, both have their faults that can result in groundings.

1) Hardware

Sonar altimeters, although used for decades and generally trustworthy, are not without their own idiosyncracies. As the physical properties of seawater (temperature, salt content) change, the speed of sound in that water mass changes, causing the altimeter's calibration to differ as well. Although this difference is typically small, it is still present.

In glider altimeters, as in many other lowered instrumentation packages, the altimeter will begin reporting erratic values when the altimeter reaches approximately one meter above bottom. Without filtering, the glider's logic would simply continue to send the glider on its dive, resulting in grounding.

Although less common, there have also been instances where the altimeter calibration has been incorrect, and an offset occurs. This calibration offset has been seen in both the positive and negative direction, causing one glider to ground while another could not seem to find the bottom.

While calibration issues can often be survived at sea and solved in the lab, some are intrinsic issues that cannot be resolved.

2) Software

The standard altimetry settings onboard the glider allow flight in sufficient water, but can cause grounding in water depths less than 15 meters. This is a direct result of the glider's cycle time and ability to obtain altimeter returns combined with its filtering logic ignoring valid returns. Unlike the hardware system, the user has control over the software system, and these settings can be adjusted to enable shallow water flight. By disabling the standard altimetry filters, more altimeter returns are considered for inflection determination. By decreasing the top and bottom boundaries for altimetry data, more of the water column becomes available to obtain valid altimeter returns. The culmination of these changes result in enough valid altimetry to inflect effectively and continue to collect data in very shallow water.

B. Detriments of groundings

1) Vehicle/platform risk

Groundings present a series of risks to gliders and the sensors they carry. Striking the seafloor - or any number of objects on the seafloor – has the potential to scratch, break, or otherwise damage attached sensors such as the external CTD (Conductivity, Temperature, Depth) sensor and the exposed faces of integrated fluorometers and backscatter meters. As the glider is pushed around by the surge, sediment can build up in the nosecone, resulting in a loss of buoyancy. With enough additional sediment, it is possible this could lead to the inability to surface, eventually resulting in the glider releasing its ejection weight. At that point, the glider's mission is over and a typical recovery becomes a rescue. On one occasion, University of Delaware's glider OTIS had gathered enough sand in the nosecone during a bottom sampling segment that small pieces of gravel became lodged between the buoyancy pump and the diaphragm. As the pump moved during inflection, the small pieces of gravel ground against the diaphragm, eventually ripping through and causing a leak. This put the vehicle in immediate risk of total loss.

2) Data quality risk

Aside from the obvious physical dangers presented by groundings, data quality can be affected as well, even jeopardizing projects. Deployments monitoring dissolved oxygen for the NJDEP and USEPA require a predetermined and preapproved glider path, horizontal, and vertical data resolution. Groundings halt forward progress, thereby wasting battery and possibly jeopardizing the path. Horizontal resolution is reduced, often drastically, as the glider cannot make expected progress. Vertical resolution is also affected, as the glider may still be sampling and taking high resolution data, but at a single point on the seafloor rather than monitoring the water column.

C. Summary/results

The software solution outlined above allows a quick, easy method for loading shallow water flight coefficients on a deployed Slocum glider. The end result is confident flight and data collection in 8 meters of water, with examples of successful flight in as little as 6 meters of water (Fig 5.).

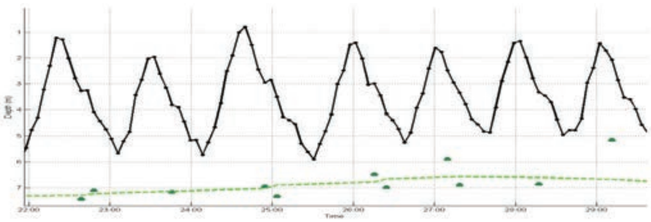

Fig. 5. Successful flight in 6-7 m of water after applying shallow water flight coefficients.

The ability to operate Slocum gliders in shallow water environments presents a new monitoring tool to the community. No longer are shallow coastal regions off limits to endurance sampling schemes. Future implications point towards the possible monitoring of harbors and bays, with the ability to transit to areas of interest, as opposed to single point moored arrays that require vessel intervention to reposition. Regions shallower than 6 meters currently pose flight mechanics issues, but shallower flight may be possible with further adjustments of flight characteristics such as pitch, pump flow rates, and stability. As the vertical speed of the platform is slowed, the ability to obtain altimeter returns is increased, possibly allowing full flight in the designed inflection range of 4 meters for the 30 m shallow pump configuration.

Abstract— Autonomous Underwater Gliders have over a decade long history of successful regional deployments serving scientific, societal and security needs in application areas ranging from pole to pole and including the full range of water depths from shallow coastal seas to the deep ocean. Glider deployments covering the basin scale are much fewer, but are a growing capacity as demonstrated by the Woods Hole to Bermuda line that crosses the Gulf Stream, the Atlantic Crossing line that follows the Gulf Stream, and the basin circling flights now being conducted as part of the Challenger Glider Mission.

The next step in the evolution of the global Challenger mission is to enable an ensemble of modelers from different institutions and agencies to participate in a meaningful way. This process with be formalized in 2014 by leveraging the data management tools of the U.S. Integrated Ocean Observing System (IOOS) and the education tools of the U.S. National Science Foundation's (NSF) Ocean Observing Initiative (OOI). The Education Visualization (EV) tools developed by the OOI's Education and Public Engagement (EPE) Implementing Organization (IO) are currently being configured through the cyber OOI net to display real time OOI glider data with intuitive interactive browser-based tools, reducing the barriers for student participation in sea exploration and discovery. Through U.S. IOOS, forecast ocean data will be harvested from the ephemeral ocean snapshots produced by an ensemble of ocean models along the same glider tracks as Challenger. The parallel observed and forecast datasets, both evolving in real time, will be accessible through the same OOI EV tools, enabling student participation in a crowd-sourced ocean predictive skill experiment. The result will satisfy one of the important goals of the Challenger mission by enabling students to assess of the quality of the ensemble of available global scale ocean models.

Student research team projects that use the new model data comparison capabilities will be conducted during the summer of 2014. Students will compare an ensemble of the global ocean models along the high velocity transport pathways by gliders on basin-scale missions, such as one that traverses the northern side of the South Atlantic gyre along the Brazilian shelfbreak. The lasting impact of the Challenger mission will be a global fleet available to respond to events, an assessment of the ocean models along the fastest ocean transport pathways, and the establishment of a network of gliderports for global response.

Keywords — Ocean Forecasting; Autonomous Underwater Gliders; Challenger Glider Mission.

I. Introduction

Autonomous Underwater Gliders have been utilized by the scientific and defense communities for a multitude of different missions that cover all areas of the globe from the surface of the ocean to 1000 meters below. Recently, long scale endurance missions have started to become a focus. The Challenger Glider Mission is one such mission whose aim is to use gliders to explore five ocean basins covering 128,000 kilometers.

Figure 1: The projected paths of the Challenger Glider Mission.

Two of the gliders that are involved in this Challenger Glider Mission are Silbo and RU29. Silbo has not contributed significantly to the mission since the Dobson et al. [5] article where data from Silbo and RU29 were used to compare against the then current ocean models. As such, an extension on the analysis of the Silbo data is not needed. RU29, however, has stopped in the Ascension Islands and flown all the way to São Paulo, Brazil since the publication of the Dobson et al. [5] article.

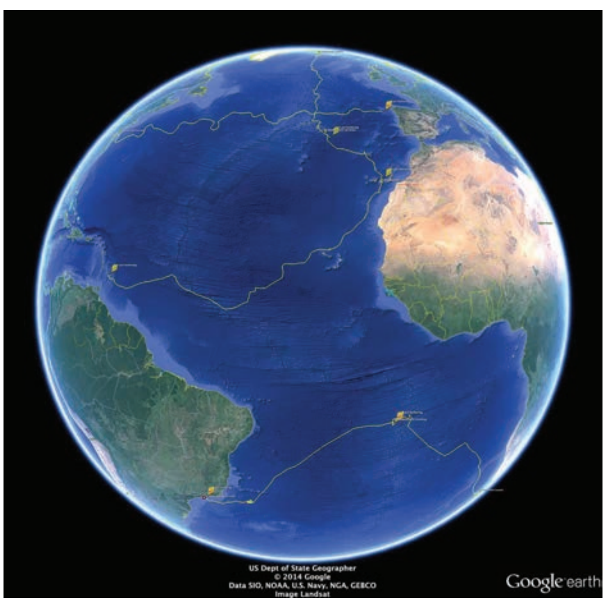

Figure 2: A map of the history of tracks covered by Rutgers Coastal Ocean Observation Lab's Challenger gliders. Basin scale missions, in collaboration with Teledyne Webb Research and Universidad de Las Palmas de Gran Canaria.

The data collected from the flight of RU29 from the Ascension Islands to São Paulo, Brazil can contribute significantly to our understanding of the accuracy of both the American RTOFS ocean model and the European MyOcean ocean model and expand upon the work done last year in the Dobson et al. [5] article. This flight completes the examination of the northern section of the South Atlantic gyre. While the ocean forecast models currently assimilate data from an Argo network of over 3000 drifters, assimilating glider data that crosses frontal features may be beneficial to increasing the forecast accuracy. Glider data can help to increase sampling resolution in areas not covered extensively by Argo drifters.

Figure 3: A photograph of RU29, an autonomous underwater glider that successfully crossed the Atlantic Ocean in 2014.Behind RU29, the Oceanographic Research Vessle Alpha Delphini, from the University of São Paulo

This study will report the results of student investigations comparing temperature, salinity, and depth-averaged currents between RU29 and the model forecasts. Preliminary student observations along RU29's flight indicate that the MyOcean model, while different from RU29 on a wider area, was closer to RU29 at points of discrepancy. The RTOFS model, however, had fewer areas of discrepancy, but the discrepancies that did exist were generally of a greater magnitude.

II. Methods

The two ocean forecasting models used in this paper are the MyOcean model and the RTOFS model. The MyOcean model is the result of collaboration between European countries such as the United Kingdom, France, Germany, and Denmark. The RTOFS model is created by the National Center for Environmental Prediction, a subgroup of the National Oceanic and Atmospheric Administration based in the United States.

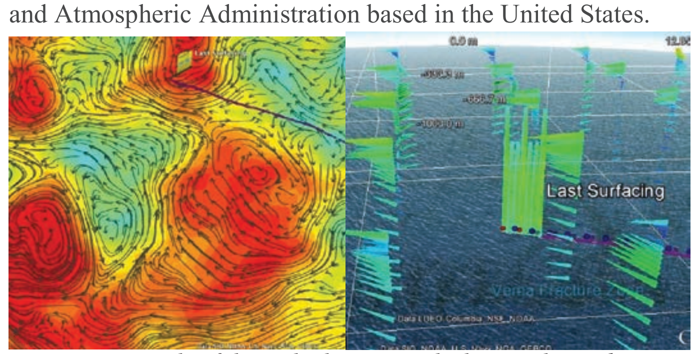

Figure 4: Example of the path planning tools that can be made using data from the ocean forecasting models RTOFS (left) and MyOcean (right) by Universidad de Las Palmas de Grab Canaria.

The sensor used by the G2 category of gliders is a SeaBird pumped Conductivity, Temperature and Depth (CTD) sensor. Temperature and Salinity data is recovered from the glider and thermal inertia from the conductivity sensor is corrected for using the process from Kerfoot et al. [3]. This data is compared to a section of the RTOFS model and the MyOcean model simulations along the path taken by the glider (Figure 5).

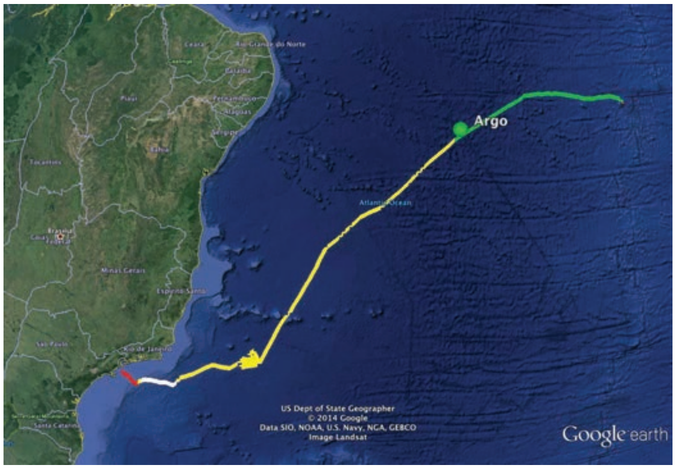

Figure 5: The portion of RU29's track that was used for comparison to the models, focusing on the green, white, and red sections. This track represents an east to west path along the northern side of the South Atlantic Gyre.

The comparisons made in this paper are a result of an analysis of temperature, salinity, and depth-averaged currents made by the models and RU29. MyOcean and RTOFS data was collected from respective Internet sources, while the glider data was collected by RU29 (Figure 3). A series of MATLAB scripts facilitated data processing and figure creation. By comparing the in-situ glider data to data obtained by the Argo Floats (Figures 7 & 9), we were able to confirm the quality of the glider temperature and salinity observations of the conditions of the water column. The most striking observation is of the temperature profiles, where the deep data from RU29, Argo, and RTOFS are similar, but MyOcean deep temperatures are about 1˚C higher.

The temperature and salinity data collected by RU29 was then compared to RTOFS and MyOcean (Figures 6 & 8). The figures were created by observing the difference between glider data and model predicted data. There was a general 1˚C difference between the MyOcean and RU29 temperature data (Figure 6b), whereas the discrepancies between the RTOFS and RU29 data were less widespread but more significant (Figure 6a). The most variation between the two models and RU29 exist within the first 300 meters of the water column, as shown in figures 6 and 8. Hence, the remainder of this paper will focus on analyses of depths above 300 meters.

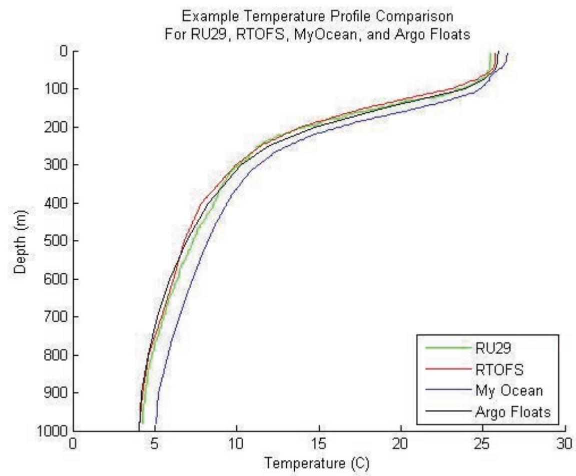

Figure 7: Temperature depth profile comparison between RU29, RTOFS, MyOcean, and Argo Float data at a sample point.

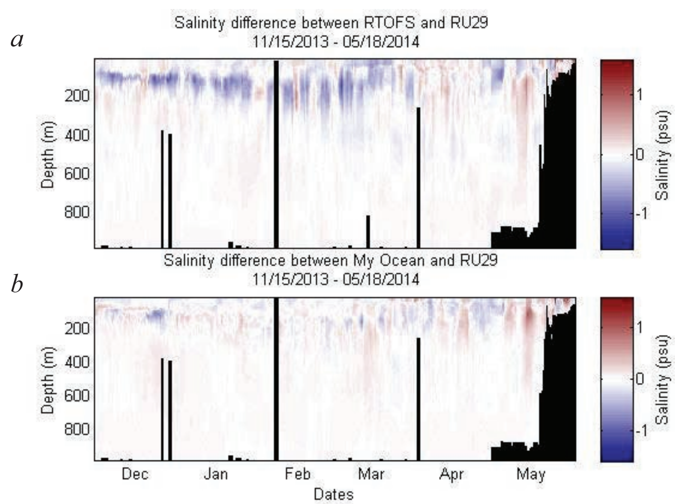

Figure 8: The difference in salinity between the RTOFS model with RU29 (a) and the MyOcean model with RU29 (b).

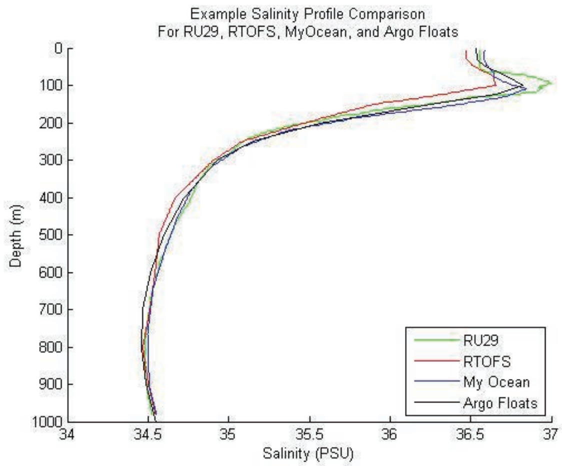

Figure 9: Salinity depth profile comparison between RU29, RTOFS, MyOcean, and Argo Float data at a sample point.

III. RESULTS

RU29's mission from Ascension Island to São Paulo, Brazil lasted from November 15, 2013 to May 18, 2014. It traveled 4,420 km crossing the Atlantic on the northern part of the South Atlantic gyre. An analysis of temperature, salinity and currents was conducted on three areas of interest: a 1,262 km leg off the coast of Ascension Island, a 265km leg off the coast of Brazil, and a 179km leg on the Brazilian continental shelf (Figure 5).

A. Turtle Tracks

The first area of interest occurred from November 15, 2013 to December 30, 2013. This section will be referred to as "Turtle Tracks" and is denoted by the green section of the track in Figure 5. It is worth noting because the migration path of Green Sea Turtles between Ascension Island and Brazil runs along this path.

An analysis of temperature and salinity was conducted. There was not much disparity in temperature between the two models and RU29 (Figure 10). However a difference between RU29 and MyOcean exists at the surface and between 250 and 300 meters (Figures 10b &10c). The salinities of RTOFS and RU29 have larger differences than the salinities of RU29 and MyOcean. Most noticeable is the consistent subsurface salinity peak near 100 m visible in RU29 and MyOcean, but missing from RTOFS. Neither model accurately depicts the depth averaged current vectors measured by RU29 along this area of the track.

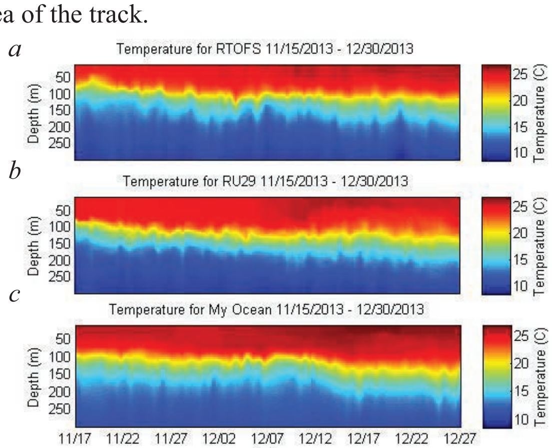

Figure 10: Temperature comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Turtle Tracks.

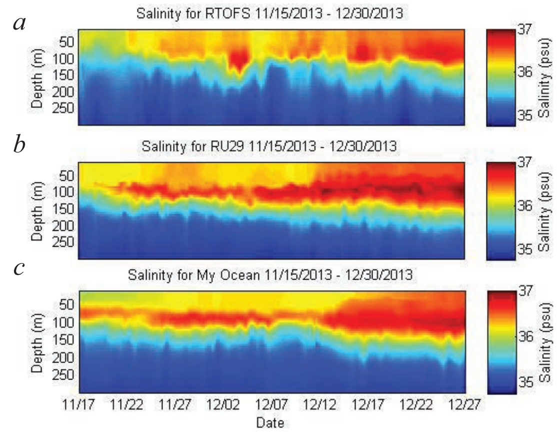

Figure 11: Temperature comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Turtle Tracks.

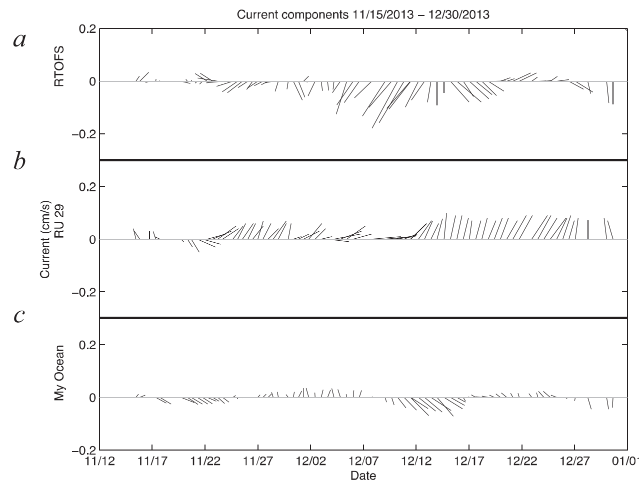

Figure 12: Current Vector comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Turtle Tracks.

B. Deep Eddy

The second area of interest occurred from April 26, 2014 to May 6, 2014. This section will be referred to as the "Deep Eddy" and is denoted by the white section of the track in Figure 5. It is worth noting because of the strong presence of an eddy. This is an area of strong meso-scale activity due to the Brazil Current[6] and the data collected with the glider can provide vertical and horizontal in-situ details that are not possible with other methods

There is evidence of a deep-water clockwise spinning eddy in the current plot of RU29 (Figure 15b), which is also seen in its temperature and salinity plots (Figure 13b & 14b). This eddy appears in the RTOFS current plot as well, with the same clockwise direction (Figure 15a). Although this eddy is present in the same spot as RU29 in both RTOFS' temperature and salinity plots, it manifests less gradually than the eddy shown in RU29's temperature and salinity plots (Figures 13a, 13b, 14a & 14b). MyOcean does not recognize the eddy structure at all (Figures 13c, 14c, & 15c).

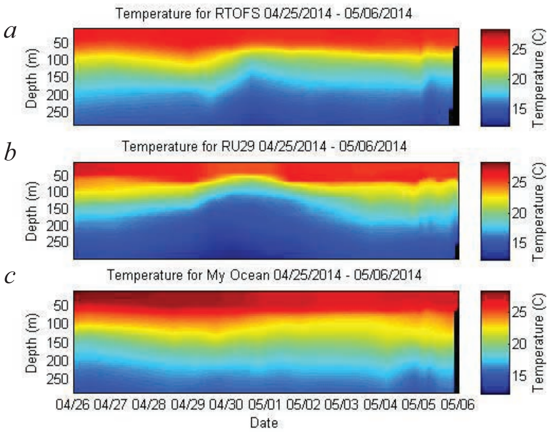

Figure 13: Temperature comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Deep Eddy.

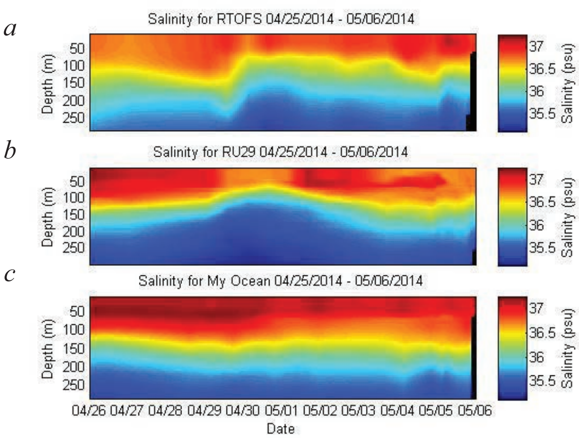

Figure 14: Salinity comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Deep Eddy.

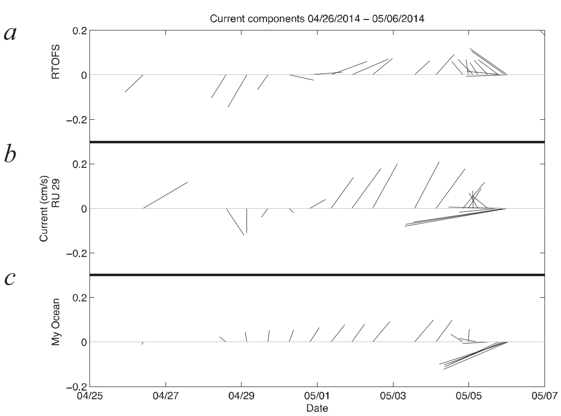

Figure 15: Current Vector comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Deep Eddy.

C. Continental Shelf and Cabo Frio Eddy

The third area of interest occurred from May 7, 2014 to May 18, 2014. This section will be referred to as "Continental Shelf and Cabo Frio Eddy" and is denoted by the red section of the track in Figure 5. It is worth noting because global models often have difficulty resolving features in shallow waters and the Cabo Frio Eddy is a well known eddy.

There is evidence of a shallow-water counter-clockwise spinning eddy in the current plot of RU29 (Figure 18b), which is also seen in its temperature and salinity plots (Figure 16b & 17b). This eddy appears in the MyOcean current plot as well, with the same counter-clockwise direction (Figure 18a). The eddy is present in the same spot as RU29 in the temperature and currents plots but the MyOcean model elongates the eddy (Figure 16b, 16c, 18b, & 18c). The MyOcean salinity plot also shows the eddy elongated, however, the eddy is shifted towards the coast. (Figure 17b &17c). RTOFS does not recognize the eddy structure at all (Figures 13c, 14c, & 15c).

On the continental shelf, possibly because MyOcean elongates the Cabo Frio eddy, the temperature and salinity it reports for the continental shelf are too warm and salty (Figures 16b, 16c, 17b, & 17c). While MyOcean is incorrect, it is not radically different from RU29, especially closest to the continent. RTOFS, however, reports noticeably warmer and saltier water in the very shallow waters (Figures 16a & 17a).

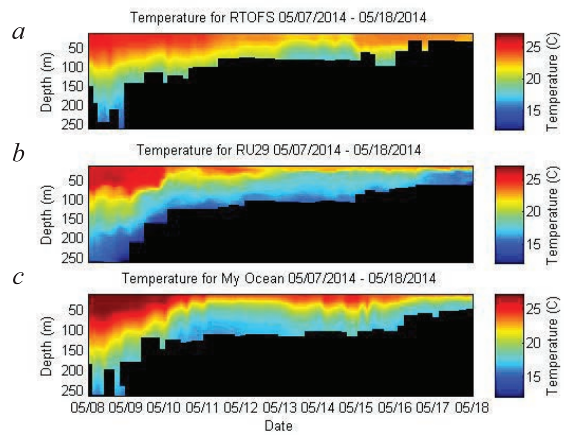

Figure 16: Temperature comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Continental Shelf and Cabo Frio Eddy.

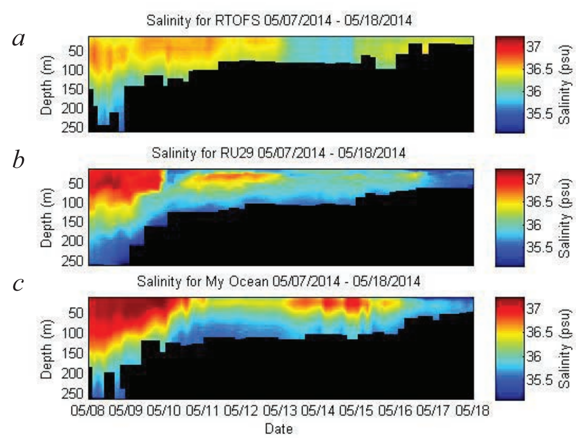

Figure 17: Salinity comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Continental Shelf and Cabo Frio Eddy.

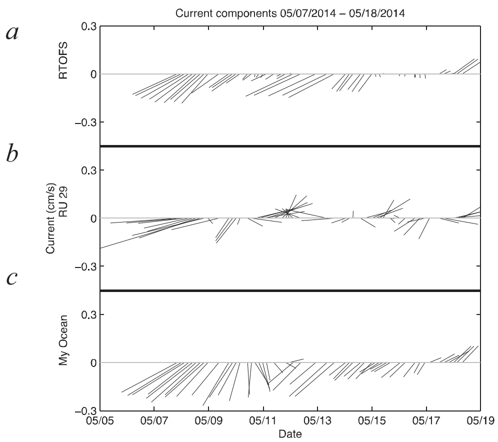

Figure 18: Current Vector comparison between RTOFS (a), RU29 (b), and MyOcean (c) for the Continental Shelf and Cabo Frio Eddy.

IV. Discussion

Two forecasting models, MyOcean and RTOFS have been studied in comparison to the glider RU29. The findings presented have lead to the conclusion that these two models have inconsistencies with in-situ glider data. Neither model can be considered superior as in certain areas, such as the “Deep Eddy”, the MyOcean model was lacking features in the ocean’s structure whereas the RTOFS model did not predict the existence of the Cabo Frio Eddy. Both the RTOFS model and the MyOcean model contain some important features that correspond with the glider data yet both also do not always reflect the structure apparent in the in-situ glider data.

Over the length of the RU29 Ascension Island to Brazil flight, the MyOcean model has a fairly consistent 1˚C to 2˚C difference in temperature from RU29, however there were not many places in either salinity or temperature that the MyOcean model differed notably from RU29. In comparison, the RTOFS model was fairly consistent with the RU29 data at lower depths but had very large discrepancies in magnitude at certain locations.

Ocean forecast models have become an indisputable tool for scientists and students, with the ability to resolve eddy structures and incorporate new data. They are easily accessible to researchers around the world. Such improvements to the models come from data taken from satellite and Argo floats that measure sea-surface temperature, sea surface height, and temperature/salinity profiles. In order to further improve the models, more data must be integrated from other sources. This will help advance forecast modeling in predicting features such as hurricane intensity.

Autonomous Underwater Gliders are able to contribute to the ocean forecast modeling because of their ability to traverse previously under-sampled regions of the ocean. It is crucial to the future of ocean modeling that glider-collected data be incorporated especially where areas of disagreement between the models occur.

V. Acknowledgements

The Challenger Glider Mission is growing global partnership of glider operators, scientists, educators and students coordinated by Rutgers University and endorsed by the Challenger Society. The results presented in this paper were initiated in a Rutgers research course and completed by three undergraduate summer interns (Rachael Sacatelli, Tobias Schofield, and Katherine Todoroff) supported by Teledyne Webb Research and four U.S. Naval Academy Interns (Angela Carandang, Alyson Eng, Ian Lowry, and Harrison Mather). Glider path planning and model/data comparison activities are led by Nilsen Strandskov (Rutgers) and Antonio Ramos (Universidad de Las Palma de Gran Canaria) with cyber infrastructure support provided by John Kerfoot (Rutgers). Glider operators include Chip Haldeman, Dave Aragon, Tina Haskin (Rutgers) and Ben Alsup (TWR). The RU29 deployment in South Africa was enabled by the University of Cape Town, The Nansen-Tutu Center, and the South African Marine Engineering & Robotics Centre at the Council for Scientific and Industrial Research (CSIR). The recovery and redeployment on Ascension Island was facilitated by the British Royal Navy, the U.S. Navy, and Ascension Island Fishing Charters (AIFC). The recovery and redeployment of RU29 in São Paulo, Brazil was enabled by University of São Paulo. RU29 mission support is provided by the U.S. Integrated Ocean Observing System, the U.S. Office of Naval Research – Global, and the G. Unger Vetlessen Foundation. Technology support provided by Teledyne Webb Research, Iridium and CLS America. Argo data was collected and made freely available by the International Argo Program and the national programs that contribute to it. (http://www.argo.ucsd.edu, http://argo.jcommops.org). The Argo Program is part of the Global Ocean Observing System.

Dalhousie University
Halifax, N.S. Canada

Abstract— Gliderpalooza represented a grass-roots coordinated field demonstration of ocean observing technologies spanning the eastern seaboard of North America. The overarching goal was to coordinate disparate ocean research efforts, funded by disparate programs from a variety of agencies to demonstrate continental scale coordination of various ocean observing technologies to sample ecologically relevant scales.

The coordinated data from satellites, HF-Radar surface currents [1], moorings, drifters and models was focused on and around the distributed deployment of Slocum gliders. The seven science and technical goals were to:

1) provide a unique data set the modelers can use for years to come (real-time & hindcast),
2) provide a standardized dataset over ecological scales and information on fish/mammal migrations,
3) provide a 3-D snapshot of the MAB cold pool,
4) provide an extensive distributed instrumented network through the peak period of fall storms, demonstrating a community "surge" capacity,
5) provide one, of many demonstrations, of the potential U.S. national glider network,
6) proof of data flow throughput to the Global Telecommunications System (GTS) via DMAC and,
7) engage undergraduates in ocean observing efforts.

During the summer and fall of 2014, the Gliderpalooza team will once again work together, but with several additions to the group, the geographical scope will cover Texas to Newfoundland. There will be more than 30 glider deployments that will be assimilated by seven numerical ocean models. Acquisition of this massive data set of water column profiles will permit evaluation of the accuracy of the models, especially in the coastal zone. Additionally, new online educational tools developed through the NSF's Ocean Observatory Initiative (OOI) will be used to by students in the undergraduate classroom to analyze, compare and contrast the glider data in real-time during the fall 2014 semester.

Keywords — ocean glider, ocean modeling, data assimilation, physical oceanography, optics, mixing storm, cold pool, fish/mammal migrations, U.S. IOOS, MARACOOS.

I. Introduction

The research performed during Gliderpalooza grew out of the U.S. Integrated Ocean Observing System's (U.S. IOOS) Mid Atlantic Regional Association Coastal Ocean Observation System (MARACOOS) and Ocean Tracking Network's science priorities. Ten universities, one corporation and the US Navy worked together to perform 17 glider deployments along the eastern coast of the U.S. and Canada (Table 1 and Figure 1). Many of the deployment locations were determined by an ocean continuously well sampled by satellites, surface current data provided by the MARACOOS HF-Radar Regional Network [2] and drifters. Much of this data was assimilated into dynamical ocean models which were then used to direct the location of a handful of the deployments in the Mid-Atlantic bight. Upon completion of the project, full resolution data sets from almost all deployed gliders were shared amongst all researchers.

In late February of 2014, the Gliderpalooza team met in Honolulu during the Ocean Sciences meeting to plan research papers focusing on the seven program goals. This paper will summarize the seven science and logistical goals and elaborate on early results from initial data analysis performed during 2014. It will then discuss plans for Gliderpalooza 2 (aka Modelpalooza) which will occur during July-November 2015 but will now span from Texas north to Newfoundland and east to Bermuda.

Fig. 1. Gliderpalooza deployments in summer and fall 2013.

II. GLIDERPALOOZA GOALS & EARLY RESULTS

A. Goal 1: Provide a Unique Dataset for Ocean Modelers

A shelf wide subsurface perspective for the North American east coast was collected through a coordinated range of regional combined with coastal surveys. All gilders provided an extensive survey for the hydrographic and optical data as well as acoustically tracked animal locations. The database spans from the upstream condition of Canadian waters through the South Atlantic Bight. The database is enabling studies to improve data assimilative forecast models.

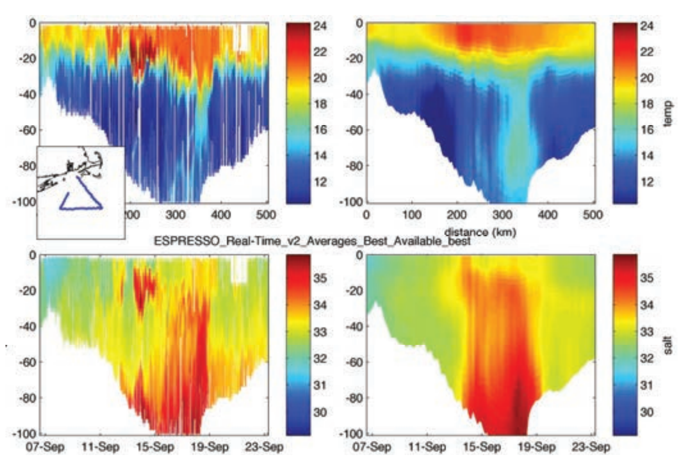

Fig. 2. Observed (left) and ROMS ESPRESSO model (right) temperature (top) and salinity (bottom) following glider BLUE. Inset shows the glider path south of Providence, RI (blue).

Moving forward, the goal is to support the improvement of the ensemble of ocean models through assimilation and validation. Figure 2 highlights a time series of temperature and salinity from a glider and compares it to the identical locations virtually sampled within the ROMS ESPRESSO model [3], [4].

B. Goal 2: Tracking Fish/Mammal Migrations

The glider survey was focused on collecting a broad environmental dataset to provide a map of the hydrography in which to interpret major migration patterns. The Ocean Tracking Network (OTN) is augmenting current capabilities to provide the foundation for a listening network. The collection of gliders provided a subsurface spatial snap shot of a Large Marine Ecosystem (LME) during the fall migration that was mined by scientists in both real-time and in hindcast mode as nine of the gliders were fitted with Vemco trackers. This effort is motivated as the region is home to some of the most migratory fish communities in the eastern United States and Canada. These data from multiple gliders are currently being combined by OTN. Species locations will be analyzed against the subsurface glider data as well as available satellite and CODAR assets and models of subsurface physical/biological parameters to provide a perspective of the northeast United States/Canada ecological domains.

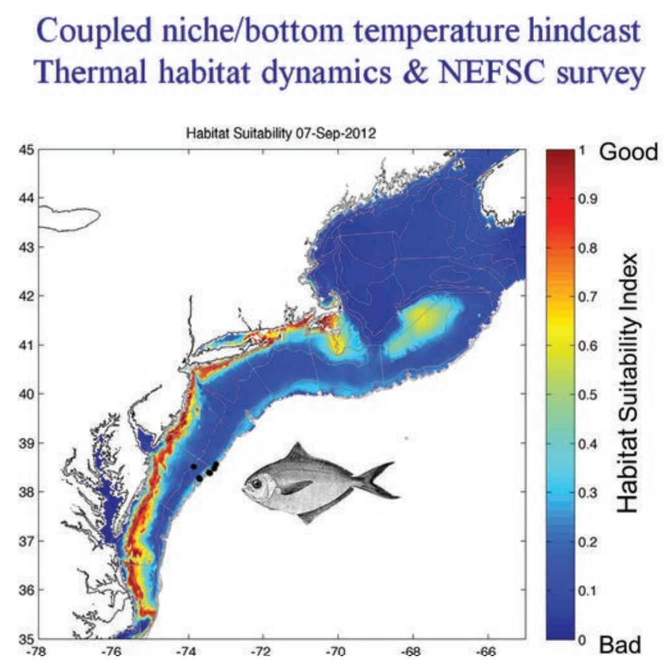

Fig. 3. A habitat sustainability model showing likelyhood of butterfish bycatch with likely areas shown in red. Block dots indicate in situ fishign surveys which tested the accuracy of this early model from 2012. Gliderpalooza data will help to improve these models in the future. Early funding for this work was from the NOAA NEFSC and Fisheries Habitat Program.

Sponsors of this work include NOAA's U.S. IOOS, Ocean Tracking Network Canada, N.J. Department of Environmental Protection, U.S. EPA, U. of Delaware, NASA, ONR, U. of Maine, College of William and Mary, U. of Georgia, Teledyne Webb, US NMFS, NSF Ocean Observatories Initiative and the U.S. Navy. Additional sponsors in 2014 will include Memorial University and Texas A&M U.

The data are also being used to improve fisheries bycatch models. Rutgers and NOAA's Northeast Fisheries Science Center (NEFSC) conducted in situ surveys in 2012 where forecast models were tested that predicted the butterfish bycatch amounts in the mid-Atlantic bight (Figure 2). Subsurface water column profile data, especially geographically distributed bottom temperatures, are key to these forecasting models, and the glider data sets will both aid in improving the models through assimilation and verifying the model's accuracy.

C. Goal 3: Mapping the Mid-Atlantic Cold Pool Water

During summer, a distinctive, bottom-trapped, cold water mass called the Cold Pool Water (CPW) resides as a swath over the mid to outer continental shelf throughout much of the Middle Atlantic Bight (MAB) [3]. This evolving CPW is important because it strongly influences the ecosystem, including several important fisheries. Thus there is a priority to better understand the relevant ocean processes and develop a CPW forecast capability.

Seven gliders crossed the area of Cold Pool during Gliderpalooza. The path of RU23 is show in red in figure 4 overlaid on a ROMS ESPRESSO modeled bottom temperature hindcast off of the New Jersey coast. Cold Pool water sits on the shelf between approximately 35m to 100m. Temperature and salinity glider transects are compared to a 2d version of this this model hindcast in figure 5.

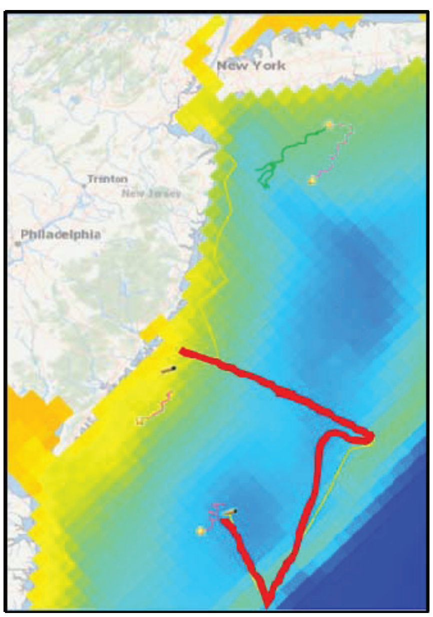

Fig. 4. A habitat sustainability model showing likelyhood of butterfish bycatch with likely areas shown in red. Black dots indicate in situ fishing surveys which tested the accuracy of this early model from 2012. Gliderpalooza data will help to better inform these models in the future through assimilation. Early funding for this work was from NOAA's Nortеast Fisheries Science Center and Fisheries Habitat Programs.

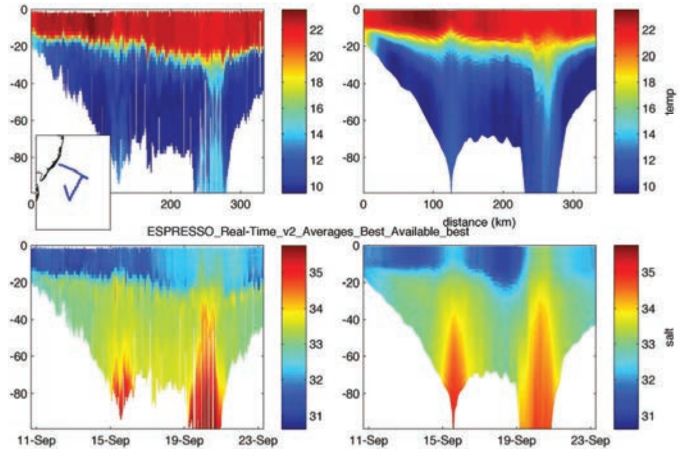

Fig. 5. RU23 glider temperature and salinity on the left are compared to modeled temperature and salinity on the right from ROMS ESPRESSO.

D. Goal 4: Analysis of Fall Mixing Storms

September is the peak month for tropical storm and hurricane landfall along the Eastern coast of North America. The regional array provided a comprehensive sampling of the continental shelves, which are the most undersampled with regards to subsurface temperatures. This subsurface temperature data is increasingly being viewed as valuable in potentially improving the ability to better predict hurricane intensity [6]. The 2013 Gliderpalooza dataset will serve as a baseline as it was a quiet tropical storm season. In 2014-2015, the Cooperative Institute for the North Atlantic Region (CINAR) is providing funding to support deployments of four storm gliders, rapid profile drifters and rapid deployable buoys into both tropical storms and winter Nor'easters. Storm gliders will be equipped with an acoustic Doppler current profiler, a full range of optical instruments, and accelerometers in addition to the standard CTD package. A preliminary in water test of these new storm gliders was performed during Hurricane Arthur in July, 2014 (figure 6).

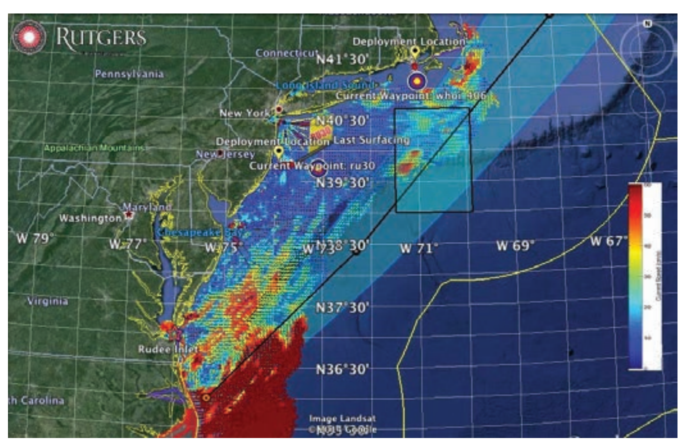

Fig. 6. Hurricane Arthur forecasted storm track from July 4, 2014. Locations of CINAR funded gliders RU30 and WHOI_406 are shown with target icons. HF-RADAR surface currents are shown, highlighting the counterclockwise circulation around the eye of Arthur just north of Cape Hatteras and the forecast track.

E. Goal 5: Demonstration of a National Glider Network

During the summer of 2012 a workshop funded by U.S. IOOS was held at Scripps Institute of Oceanography to discuss plans for a national glider network. As a result, multiple partners from federal agencies, IOOS Regional Associations (RAs) of coastal ocean observing systems, and universities were assembled to develop a National Glider Network Plan for a viable, sustainable, and reliable network that delivers timely monitoring and distribution of coastal subsurface glider data to federal, state, and local governments, as well as the general public. The plan is structured to develop an initial network that includes maintaining existing long term glider sampling lines, acquiring additional glider lines to fill high priority gaps, and improving data management, product development, and data/product delivery. The national plan was released in January 2014 and available at http://www.ioos.noaa.gov/glider/strategy/welcome.html.

Gliderpalooza enabled a first example of a multi-regional coherent effort to deploy, monitor and access glider data in real time through a central site at Rutgers University. The ultimate national goal is to attain funding for long term sustainability of deployments on all U.S. coasts (Figure 7).

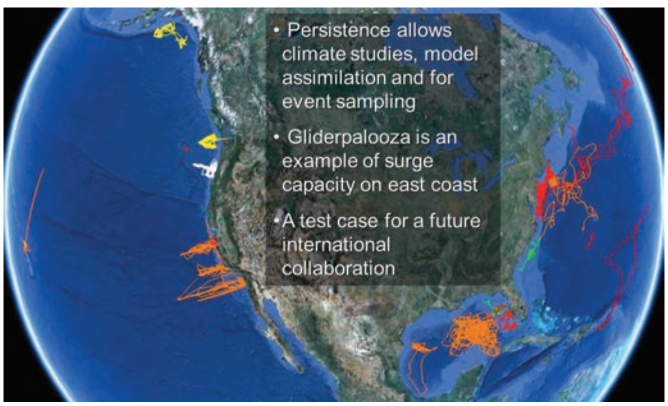

Fig. 7. U.S. glider deployments from 2000 through early 2013.

F. Goal 6: Data Throughput to the GTS

In 2013 IOOS secured funding to begin construction of a Data Management and Communications System (DMAC) specifically for glider data distribution. A successful goal of Gliderpalooza was to have real-time throughput of raw data from the gliders to Dockservers to the DMAC where it was converted to Climate and Forecast (CF) compliant NetCDF files and then sent to the National Data Buoy Center and finally to the Global Telecommunications System. This mission to make glider data available to modelers and forecasters worldwide will continue to expand outside the east coast region to the U.S. and eventually global throughput of glider data to NDBC and GTS.

Fig. 8. Schematic of glider data throughput from acquisition to the GTS.

G. Goal 7: Undergraduate Education

In addition to having undergraduate students assist with glider deployments and recoveries, the Gliderpalooza data were made available to undergraduate classrooms in real-time during the fall semester of 2013. During fall 2014, both real-time and archived glider data are going to be used by numerous Community and 4-Year college professors in the undergraduate classroom through cooperation with the NSF's Ocean Observatory Initiative's Education and Public Engagement team's (OOI EPE) newly developed online educational tools (Figure 9). This software can be used by undergraduate educators to build and share online lessons using ocean data from both the OOI and outside resources, including global glider deployments.

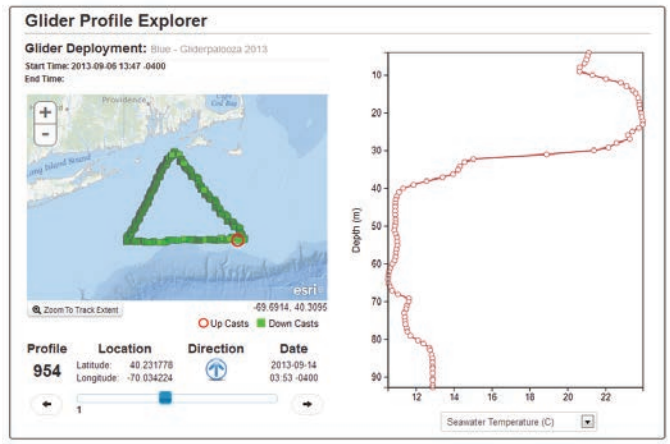

Fig. 9. Newly developed glider profile explorer tool that allows users to search and display glider profiles through the OOI EPE's website at: http://education.oceanobservatories.org/.

III. Next Steps: Gliderpalooza 2 – Modelpalooza!

The success of Gliderpalooza 2013 built on a collaborative community which was a great start, and one the team wishes to build on for the coming year. Gliderpalooza 2 will begin during the summer of 2014 but this time with a focus of using the real-time data for ocean model assimilation and validation in several models and, in turn, using model output to help drive sampling locations throughout the east coast, not just the mid-Atlantic bight. At least seven ocean models are going to be used for this effort (table 2). A new glider tool that will support comparison of the glider profiles to any of these ocean models is shown in figure 10.

The list of groups involved with glider deployments and models is expected to expand to include Memorial University of Newfoundland, Dalhousie University (Ocean Tracking Network), University of Maine, Woods Hole Oceanographic Institute, University of Massachusetts Dartmouth, Stevens Institute of Technology, Rutgers University, University of Delaware, University of Maryland, College of William and Mary, North Carolina State University, University of Georgia, Texas A&M University, the US Navy and the Bermuda Institute of Ocean Sciences.

TABLE II. MODELS TO BE USED FOR ASSIMILATION AND VALIDATION TESTING DURING GLIDERPALOOZA 2: MODELPALOOZA.

	Models	Affiliation
1	Regional Ocean Modeling System 1 (ROMS)	North Carolina State University
2	ROMS Experimental System for Predicting Shelf and Slope Optics (ROMS HOPS)	Rutgers University
3	Harvard Ocean Prediction System (HOPS)	University of Massachusetts Dartmouth
4	New York Harbor Ocean Prediction System (NYHOPS)	Stevens Institute of Technology
5	Real Time Ocean Forecast System (RTOFS)	NOAA National Centers for Environmental Prediction
6	MyOcean	European Union
7	Mercator Ocean	Europe (France)

In addition to the science and technical goals outlined in this paper, additional goals for Gliderpalooza 2 include; 1) Improved data flow of all gliders to the World Meteorological Organization's GTS, 2) Visualization of all data in the NOAA U.S. IOOS National Underwater Glider Network Map portal, 3) Data assimilation by four ocean models and validation testing of at least seven ocean models (hence the name Modelpalooza), 4) Using the ocean models to assist in planning glider sampling activities, 5) Building an active community blog, 5) Improving coordination between distributed teams, 6) Strengthening science working groups thereby accelerating the publishing of potential products/manuscripts/articles for the ocean science community and general public, and 7) Improving the existing web portal tools that link the community.

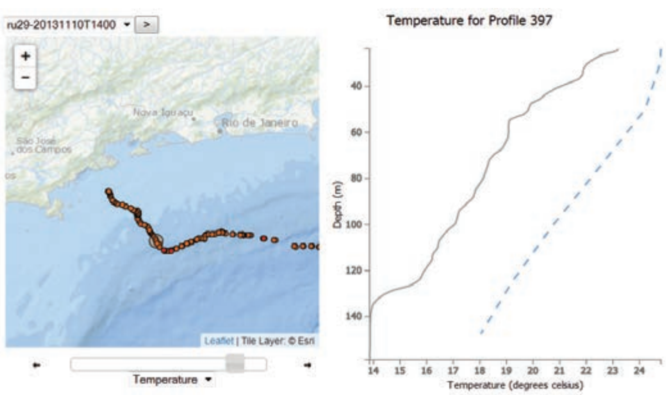

Fig. 10. Newly developed NSF OOI visualization tool that will enable researchers to compare glider profiles to model output. This example highlights a single profile from glider RU29 located just south of Rio de Janerio on the outer edge of the continental shelf (145 meters). The temperature data is compared to RTOFS and highlights that RTOFS is significantly warmer (~3C) throughout much of the water column. Development of this tool leveraged both NOAA US IOOS funds and NSF OOI funds.

ACKNOWLEDGMENTS

There were dozens of co-authors to this work from the numerous groups involved with the Gliderpalooza effort. They include J. Kerfoot, C. Haldeman, D. Aragon, A. Comeau, R. Davis, J. Pye, N. Beauchamp, K. Morton, S. Iverson, N. Fisher, M. Neary, N. Pettigrew, L. St. Laurent, J. Reilly, K. Decoteau, C. Jones, C. DeCollibus, C. Jacubiak, J. Kohut, T. Miles, T. Haskins, J. Wilkin, N. Strandskov, M. Breece, M. Oliver, D. Haulsee, G. Kuska, C. Thoroughgood, W. Boicourt, D. Gong, R. He, W. Woods, C. Edwards and the U.S. Navy Glider Team headed by C. Szczechowski

Funding for this work came from the National Oceanographic and Atmospheric Administration's U.S. Integrated Ocean Observing System (much of which came through the Mid Atlantic Regional Association Coastal Ocean Observation System Regional Association), Ocean Tracking Network, New Jersey Department of Environmental Protection, U.S. Environmental Protection Agency, U.S. Department of Environmental Protection, University of Delaware, National Aeronautics and Space Administration, U.S. Office of Naval Research, University of Maine, College of William and Mary, University of Georgia, Teledyne Webb Research Corporation, NOAA National Marine Fisheries Service, the National Science Foundation's Ocean Observatories Initiative and the U.S. Navy.

In addition to the funding agencies and partners listed here, the authors would like to thank Doug Webb for his futuristic vision, and, leading us one step at a time toward 'changing the world'.

"Have fun, work hard, change the world" – Doug Webb

Amundsen Sea

ABSTRACT

The Amundsen Sea is one of the most productive polynyas in the Antarctic per unit area and is undergoing rapid changes including a reduction in sea ice duration, thinning ice sheets, retreat of glaciers and the potential collapse of the Thwaites Glacier in Pine Island Bay. A growing body of research has indicated that these changes are altering the water mass properties and associated biogeochemistry within the polynya. Unfortunately difficulties in accessing the remote location have greatly limited the amount of in situ data that has been collected. In this study data from a Teledyne-Webb Slocum glider was used to supplement ship-based sampling along the Dotson Ice Shelf (DIS). This autonomous underwater vehicle revealed a detailed view of a meltwater laden outflow from below the western flank of the DIS. Circumpolar Deep Water intruding onto the shelf drives glacial melt and the supply of macronutrients that, along with ample light, supports the large phytoplankton blooms in the Amundsen Sea Polynya. Less well understood is the source of micronutrients, such as iron, necessary to support this bloom to the central polynya where chlorophyll concentrations are highest. This outflow region showed decreasing optical backscatter with proximity to the bed indicating that particulate matter was sourced from the overlying glacier rather than resuspended sediment. This result suggests that particulate iron, and potentially phytoplankton primary productivity, is intrinsically linked to the magnitude and duration of sub-glacial melt from Circumpolar Deep Water intrusions onto the shelf.

1. Introduction

The collapse of the West Antarctic ice sheet appears to be irreversible (Joughin et al., 2014a; Mouginot et al., 2014; Rignot et al., 2014) due to changing winds, ocean warming, and changes in ocean circulation (Jenkins et al., 2010; Pritchard et al., 2012; Schmidtko et al., 2014). The largest changes are expressed in the Amundsen Sea, in the Southeast Pacific sector of the Antarctic. Climate changes in the Amundsen Sea, and its associated glaciers, include reductions in sea ice duration by 60 ± 9 days (Stammerjohn et al., 2012), thinning ice sheets (Rignot et al., 2014), and retreating glaciers (Rignot and Jacobs, 2002; Rignot et al., 2008, 2014). Recent studies (Joughin et al., 2014b; Sutterley et al., 2014) have indicated that the Thwaites Glacier in Pine Island Bay is losing mass at a rate of 83 ± 5 Gt yr^{-1} and has begun to undergo early-stage collapse, with the potential for causing over 1 mm yr^{-1} of global sea level rise. These changes are altering the water mass properties and associated biogeochemistry in the polynya. Unfortunately, difficulties in accessing the remote location have greatly limited the amount of *in situ* data that has been collected, which limits our understanding of the physical mechanisms that regulate the biological processes in this area (Lee et al., 2012).

The Amundsen Sea Polynya (ASP) has one of the highest satellite derived mean phytoplankton concentrations in the Antarctic with seasonally averaged chlorophyll concentrations (2.18 ± 3.01 mg m^{-3}) larger than the more frequently studied Ross Sea Polynya (1.51 ± 1.52 mg m^{-3}) (Arrigo and van Dijken, 2003). With high levels of unused macronutrients year-round, the availability of iron (Fe) or light, or both, is thought to limit primary productivity in the coastal Antarctic (Sunda and Huntsman, 1997; Boyd, 2002; Arrigo et al., 2012). Strong relationships exist between phytoplankton and the depth of the upper mixed layer suggesting the importance of light (Schofield et al., in press) while deck board incubations also confirm the importance of Fe (Alderkamp et al., 2015). Previous studies have observed high levels of dissolved (Alderkamp et al., 2012; Arrigo et al., 2012; Gerringa et al., 2012) and particulate (Planquette et al., 2013) Fe in proximity to the Pine Island Ice Shelf (PIIS) and the Crosson, Dotson, and Getz ice shelves

to the west. Likely sources of this Fe include basal melt from beneath ice shelves (Gerringa et al., 2012; Yager et al., 2012), and direct observations have been made of dissolved and particulate Fe in the meltwater-laden outflow from beneath the Dotson Ice Shelf (DIS) (Alderkamp et al., 2015).

The main driver of basal melt is believed to be the warm Circumpolar Deep Water (CDW) (up to 4 °C above the freezing point) intruding onto the Amundsen Sea continental shelf and below ice shelves (Jenkins et al., 2010; Jacobs et al., 2011; Dutrieux et al., 2014). Processes controlling the flow of warm CDW on the shelf are only broadly identified and there is a lack of sufficiently long (decadal or more) time series to enable linking of the oceanographic processes to climate variability. These processes include the establishment of an eastward undercurrent (Chavanne et al., 2010; Walker et al., 2013); bottom Ekman transport (Wåhlin et al., 2012); eddies (Thompson et al., 2014) and wind (Thoma et al., 2008). The cross shelf-break inflow to the DIS occurs through the same outer trough that channels CDW toward the Getz Ice Shelf, also known as the Dotson Trough. Closer to the ice shelves the trough branches out into three deep basins, leading into the sub-ice cavities below the Dotson and Getz ice shelves (Fig. 1). Observations of the circulation in these troughs (Walker et al., 2007; Wåhlin et al., 2010) show that CDW inflows are located on their eastern flanks and mooring data indicate the circulation patterns are persistent and steady (Arneborg et al., 2012; Assmann et al., 2013; Wåhlin et al., 2013). The outflows on their western flanks are colder and fresher due to the addition of meltwater (Ha et al., 2014; Wåhlin et al., 2015). As these water masses reach the glaciers and ice shelves the warm CDW melts ice and forms a modified CDW (mCDW) and meltwater mixture (Jenkins, 1999; Jenkins and Jacobs, 2008; Jenkins et al., 2010; Wåhlin et al., 2010; Jacobs et al., 2011; Randall-Goodwin et al., 2015). Few observations of the ocean circulation and water properties at ice shelf fronts exist. The paucity of data in this region is largely due to the remote location of the Amundsen Sea as well as limited resources to investigate the ~1200 km of coastline. A summary of three US-led cruises to the ice shelf fronts in the Amundsen Sea Embankment (ASE) can be found in Jacobs et al. (2013). A large number of these transects show a core of CDW leaning on the eastern flank of the entrance to the ice shelf cavity, i.e. associated with geostrophic flow into the cavity, and cooler, fresher, and more buoyant, water is commonly found on the western side higher up in the water column, associated with a geostrophic flow out of the cavity. Focused field campaigns (Jacobs et al., 1996, 2011) have observed this phenomenon along the Pine Island Glacier in 1994 and 2009.

The first observation of an outflow of meltwater-laden mCDW in the central Amundsen shelf area was done in 4 moorings placed in the Dotson Trough (Ha et al., 2014), where a steady outflow on the eastern flank of Dotson Trough was observed throughout 2011. Similar hydrographic properties at a nearby location were also recorded during 2012–2013 (Wåhlin et al., 2015). Due to challenging ice conditions cross-trough CTD transects extending sufficiently far west to cover the entire outflow do not exist, The estimates of volume flux derived from the single-point moorings are hence uncertain. Based on the most complete CTD transect, an outflow corresponding to about 1/3 of the inflow was obtained (Ha et al., 2014). It is not known which path the remainder of the outflow takes. Explanations that have been proposed include flow in a narrow coastal current; below a possible tunnel underneath the Getz Ice Shelf; or into the surface mixed layer (Ha et al., 2014). More recent work shows a similar circulation pattern, with outflow along the far western edge of the DIS with high meltwater concentrations (Randall-Goodwin et al., 2015). In this work we present observations from the front of the DIS collected by ship and a Teledyne-Webb Slocum glider. The glider permitted high vertical and horizontal resolution sampling in a relatively short time frame (days). The physical and bio-optical datasets collected provide a detailed snapshot of the location and water properties of the DIS outflow with optical backscatter profiles indicating ice melt as the primary source of particulate matter from the subglacial cavity to the near-surface ASP.

2. Methods

Data was collected in the Amundsen Sea during January of 2014 as part of the Korea Polar Research Institute (KOPRI) ANA04B cruise onboard the IBRV *Araon*. This cruise was designed with the goal of understanding regional circulation and how that circulation may impact the biogeochemistry of the ASP. A total of 35 hydrographic stations were sampled and two Teledyne-Webb Slocum gliders (one shallow class (< 100 m) and one deep class (< 1000 m)) were deployed and recovered during ANA04B. As this paper is focused on the transport of mCDW, only the glider capable of profiling to 1000 m was able to provide relevant data and was used in this paper.

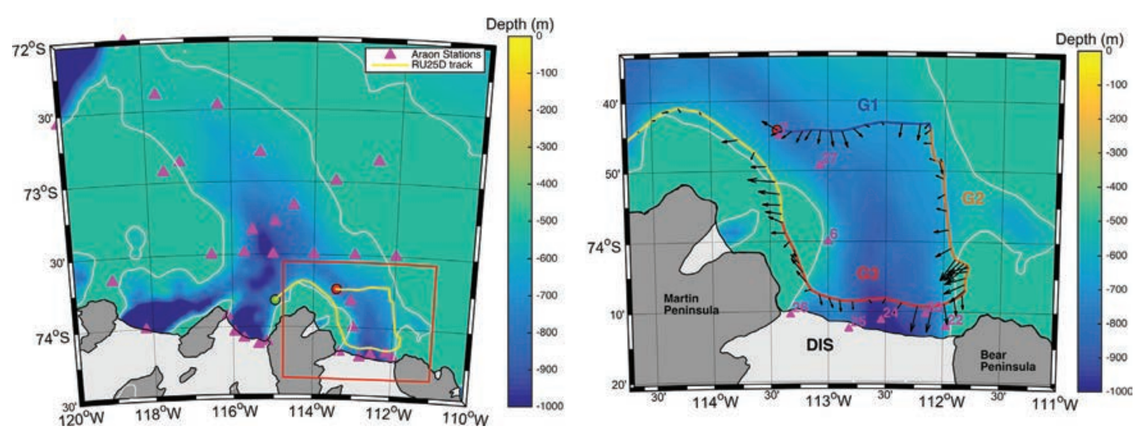

Fig. 1. (Left panel) Map of the KOPRI cruise ANA04B study area in the Amundsen Sea with hydrographic stations sampled by the IBRV Araon (magenta triangles) and the track of the glider RU25D (yellow line) with the deployment location (red circle) and the recovery location (green circle). The red box bounds the displayed area in the right panel. (Right panel) zoomed in view of the glider and ship sampling area directly in front of the Dotson Ice Shelf with the glider track separated into three distinct tracks including across trough (blue G1), along the eastern flank (orange G2), and along the Dotson Ice Shelf Face (red G3). Ship sampling locations are numbered and continue to be represented by magenta triangles. There are additional ship-based stations that were collected off the continental shelf not included in this map. Black vectors represent the depth- and time- averaged glider velocities.

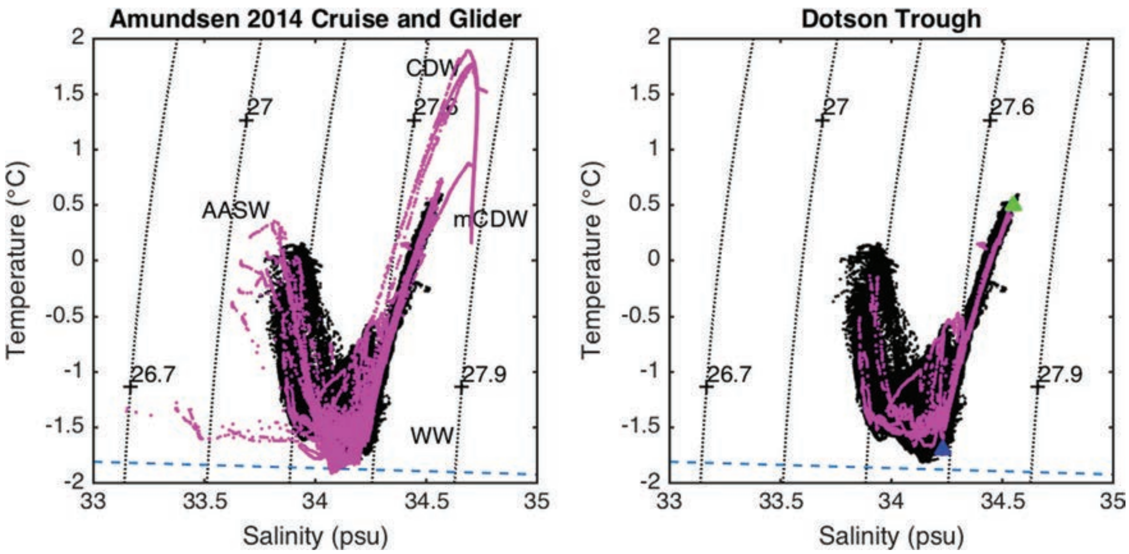

Fig. 2. (Left panel) A temperature and salinity diagram of all data collected by the IBRV Araon (magenta) and glider RU25D (black), with labels of the major water masses. (Right panel) A subset of the data collected directly in front of the Dotson Ice Shelf, corresponding to locations shown in the right panel of Fig. 1. Green and blue triangles represent the mCDW and WW end-members used for calculating meltwater fractions.

2.1. Ship sampling

Ship-based measurements were made from a rosette that included Niskin bottles for discrete water sampling, a Seabird SBE-911plus with dual conductivity temperature and depth (CTD) sensors, and velocity structure from a 300-kHz Teledyne-RDI lowered acoustic Doppler current profiler (LADCP). During upcast of the CTD, discrete water samples were collected and used to calibrate the temperature and conductivity probes following standard practices. The LADCP data was processed using Lamont Doherty Earth Observatory (LDEO) Matlab®-based software version IX (Thurnherr, 2010). Tidal signals were removed from the LADCP-measured velocity profiles using a 10-component barotropic tide model, CATS2008b (Padman et al., 2002).

2.2. Glider sampling

Teledyne-Webb Slocum gliders are buoyancy driven mobile sensor platforms with interchangeable and customizable science bays (Webb et al., 2001; Davis et al., 2003; Schofield et al., 2007). These 1.5 m torpedo shaped autonomous underwater vehicles profile the water column in a sawtooth pattern by shifting small amounts of ballast to dive and climb at $\sim$15–20 cm s^{-1}. Wings, vehicle shape, and the set nominal pitch angle of $\sim$26° result in horizontal speeds of $\sim$20–30 cm s^{-1}, or $\sim$20 km per day depending on ambient current conditions. Vehicle navigation is done using "dead-reckoning" to a set waypoint. When the glider surfaces an air-bladder in the aft section inflates, raising the tail section out of the water. An iridium satellite phone antenna within the tail section transmits data to shore and receives new mission characteristics depending on the sampling strategies designed by the operator. Oceanographic data is collected at two-second intervals resulting in high vertical resolutions. Gliders have been used in numerous difficult to sample environments including on continental shelves (Castelao et al., 2010; Adams et al., 2013; Pelland et al., 2013), long duration cross-basin missions (Glenn et al., 2011), within storms (Glenn et al., 2008; Miles et al., 2013; Mrvaljevic et al., 2013), and have had a significant presence in the Western Antarctic (Kahl et al., 2010; Schofield et al., 2013; Kohut et al., 2015).

The glider used in this study was a Deep glider (RU25D) rated to 1000 meters, near the maximum depth of the approach to the Dotson Trough. The glider was deployed on January 4th, 2014 at 113.4°W (Fig. 1) and 73.74°S and performed three distinct sections, with the first over 40 km west to east across the Dotson Trough at 74°S, the second was 46 km southward toward the DIS on the eastern flank of the Dotson Trough. The third transect was 54 km across the face of the DIS from east to west and was approximately 5 km from the ice edge and continued westward around the Martin Peninsula and toward the Getz Ice Shelf until recovery on January 13th. Throughout this deployment RU25D collected a total of 206 profiles and traveled 234 km in 9 days.

RU25D was equipped with a suite of oceanographic sensors including an un-pumped Seabird glider payload CTD (GPCTD), an Aanderaa Oxygen Optode (Model 3835), and a Wetlabs Environmental Characterization Optics puck (ECO-triplet). Glider temperature and conductivity measurements were compared with shipboard CTD casts on deployment and recovery to ensure data quality, as well as with a calibrated laboratory CTD prior to deployment. All measurements were binned into 2-m bins per segment (a segment is a collection of profiles between surfacing and acquisition by GPS) and assigned a mid-point latitude and longitude.

2.2.1. Oxygen measurements

The Aanderaa Oxygen Optode measures raw phase shifts across a calibrated foil. This instrument, in combination with temperature measurements from the CTD, provides the concentration and saturation percent of dissolved oxygen (DO). The manufacturer calibration and a two-point test (0% and 100% saturation) were performed in the laboratory prior to deployment (Kohut et al., 2014). During post-processing DO data was time shifted backward to account for a 25 s response rate of the foil.

2.2.2. Optical measurements

The Wetlabs ECO-triplet collected chlorophyll-a fluorescence, colored dissolved organic matter (CDOM), and the volume scattering function (VSF) of optical backscatter at a wavelength of 700 nm in the 117° back direction. The VSF measurements are then

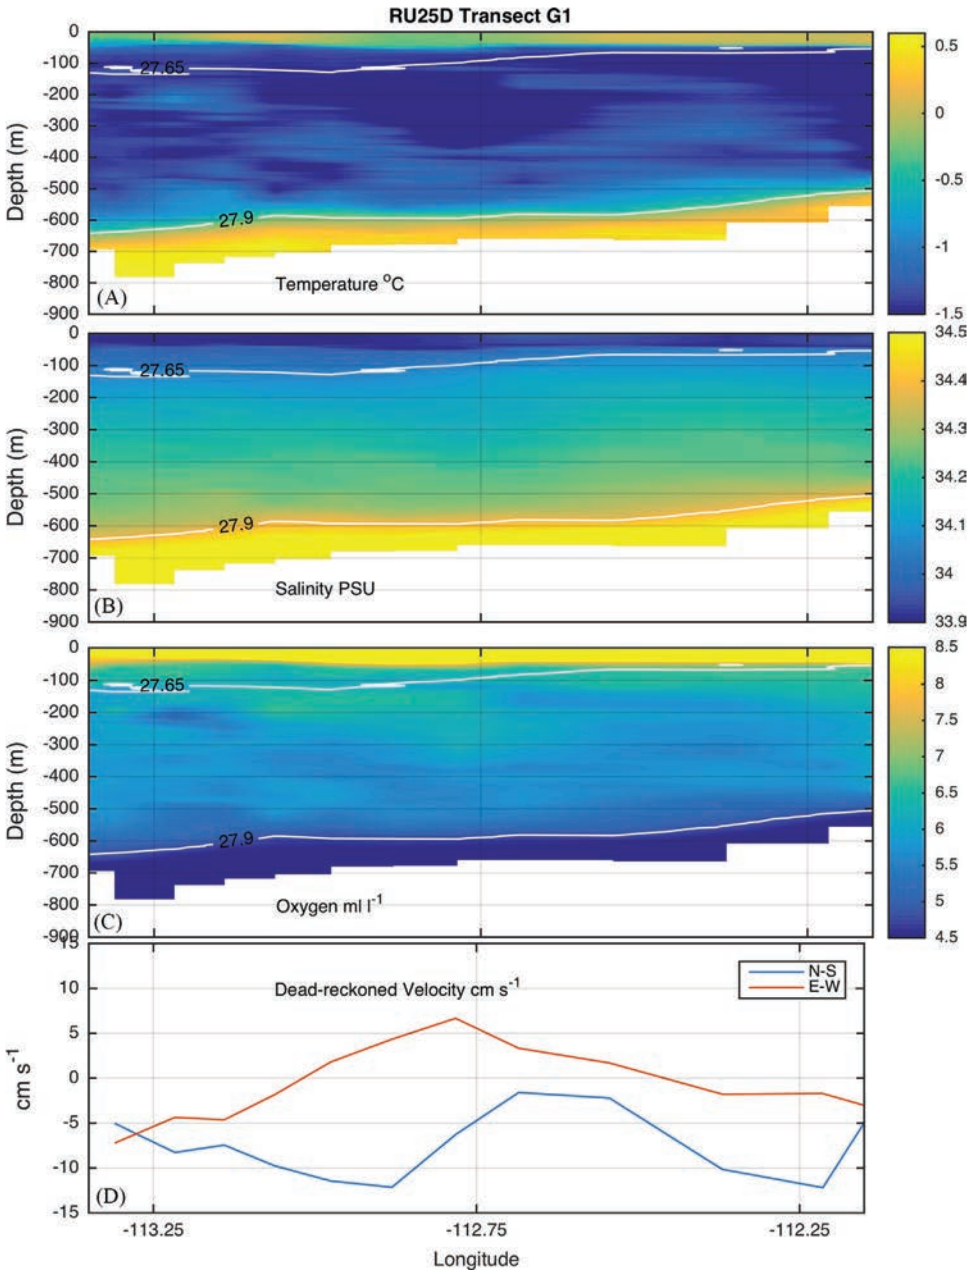

Fig. 3. Cross-sections of (A) temperature, (B) salinity, (C) oxygen, and depth averaged dead-reckoned glider currents along glider transect G1 with longitude along the *x*-axis. White contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

converted to backscatter coefficients following Boss and Pegau, (2001) with resultant units of m^{-1}. Optical backscatter responds linearly to suspended particle concentration, but is sensitive to particle size, shape, color, and composition (Boss and Pegau, 2001). Thus we used these values as a proxy for the relative changes in suspended particle concentration rather than absolute concentration.

2.2.3. Glider velocity calculations

Water velocities were calculated from the glider data using a dead-reckoning technique (Davis et al., 2003). Glider vertical speeds are derived from the pressure sensor and used in combination with a measured pitch angle to estimate the glider horizontal motion. The initial glider waypoint pre-dive and time integrated estimated horizontal speeds were used to estimate the gliders surfacing position. The difference between the expected and actual surfacing location divided by the total dive time results in a total depth and time-averaged velocity that we assign to the mid-point of the each pre- and post-dive latitude and longitude. RU25D did not surface frequently enough to resolve tidal currents, but as evidenced by the CATS2008b barotropic tidal model (Padman et al., 2002) the dominant M2 and S2 tidal currents were relatively small (<2 cm s^{-1}) for the duration of the deployment. Potential sources of error in dead-reckoned glider depth and time-averaged velocities have been discussed in detail previously (Todd et al., 2011) and include uncertainties in angle-of-attack, vertical water velocities, and accumulated errors from integrated measured heading, pitch, and glider vertical velocities. For RU25D heading dependent compass corrections were applied based on pre-deployment calibrations removing a major source of error. Uncertainties from other sources listed above have been found to be typically on the order of 1 cm s^{-1}.

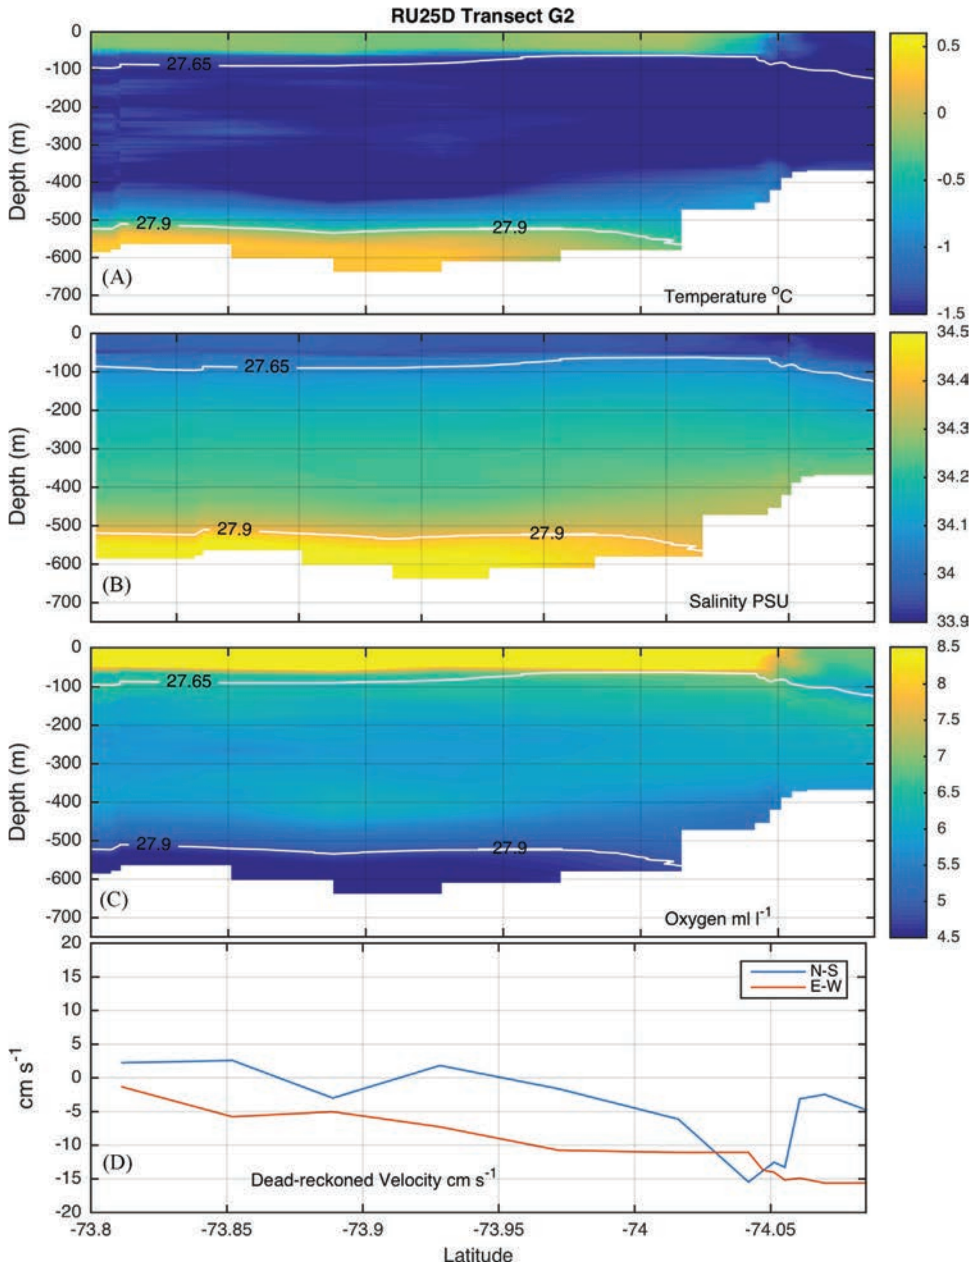

Fig. 4. Cross-sections of (A) temperature, (B) salinity, (C) oxygen, and depth averaged dead-reckoned glider currents along glider transect G2 with latitude along the *x*-axis. White contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

2.3. Meltwater concentrations

Meltwater fraction calculations are performed following Jenkins (1999) and Jenkins and Jacobs (2008). This method assumes that the ice-seawater system is closed and that in its simplest form, with only two uniform end-members including a single water mass and ice, the meltwater concentration of a single tracer can be represented as:

$$\frac{Q_i}{Q}=\frac{\chi_w-\chi}{\chi_w-\chi_i} \tag{1}$$

where Q_i is the mass of ice, Q is the total mass represented by $Q=Q_i+Q_w$, Q_w is the mass of seawater, χ is the measured tracer property, and χ_i and χ_w are the tracer properties of the ice and seawater, respectively. Mixtures of meltwater and seawater will have two conservative properties that plot as a straight line on a bivariate graph and the concentration of meltwater can be determined from where measurements fall on that mixing line. Temperature and salinity are two typical tracers used in this method (Gade, 1979). For our case, and many other realistic cases, there is a third water mass involved, namely Winter Water (WW) that mixes with the CDW-meltwater mixture and further complicates the analysis. In order to address this, a composite tracer approach (McDougall, 1990; Jenkins and Jacobs, 2008) has been developed, where $\psi^{2,1}$ is the composite of two tracers represented by

$$\psi^{2,1}=\left(\chi^2-\chi^2_{CDW}\right)-\left(\chi^1-\chi^1_{CDW}\right)\left(\frac{\chi^2_{WW}-\chi^2_{CDW}}{\chi^1_{WW}-\chi^1_{CDW}}\right), \tag{2}$$

which is the difference between the measured value of an additional tracer, such as oxygen, and the idealized two component mixture mentioned above. The resultant meltwater fraction is then the ratio of the mixture composite tracer $\psi^{2,1}_{mix}$, to the meltwater $\psi^{2,1}_{melt}$. The method is described in more detail in Jenkins (1999) and Jenkins and Jacobs (2008).

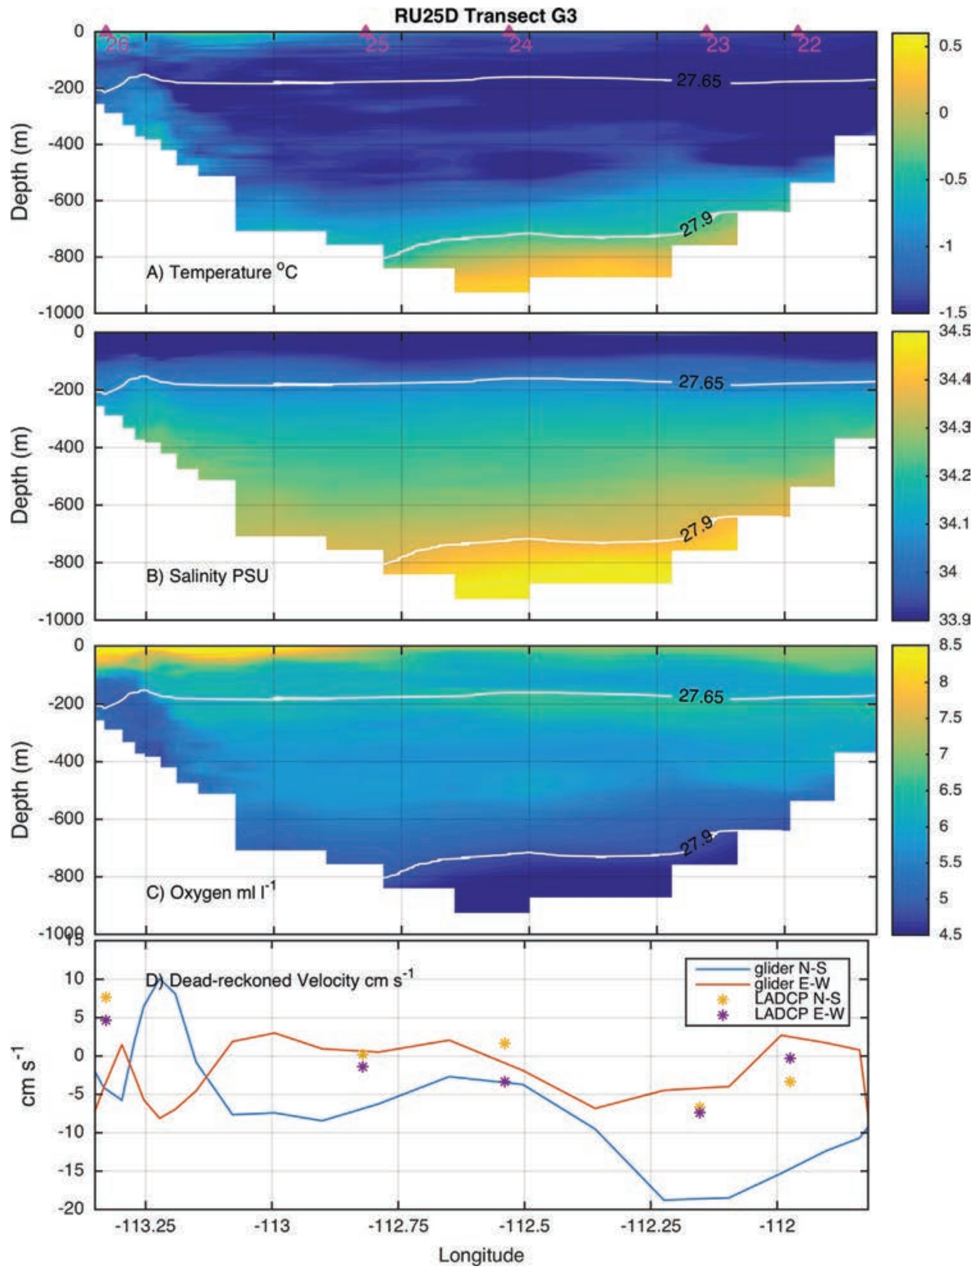

Fig. 5. Cross-sections of (A) temperature, (B) salinity, (C) oxygen, and (D) depth averaged dead-reckoned glider currents (lines) and depth averaged LADCP currents (stars) along glider transect G3 with longitude along the *x*-axis. Ship sampling locations are plotted along the top of Fig. 5A (magenta triangles) with numbers corresponding to the right panel of Fig. 1. White contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

The tracers used here are salinity, potential temperature, and dissolved oxygen. Outside of the surface layers where atmospheric properties influence these tracers there are distinct end members for WW, CDW, and glacial ice in the Amundsen Sea (Jenkins and Jacobs, 2008). Based on the ambient water masses observed on the Amundsen Sea continental shelf in 2014 we use an mCDW end-member derived from the maximum temperature and salinity measured by the glider in the Dotson Trough and its associated oxygen concentration with $T\sim0.5$ °C, $S\sim34.55$ PSU, and $O_2\sim4.2$ ml l^{-1}; WW derived from the minimum temperature on the shelf with properties ~-1.7 °C, $S\sim34.23$ PSU, and $O_2\sim6.15$ ml l^{-1} (Fig. 2b); and theoretical ice properties $T\sim-90.75$ °C, $S\sim0$ PSU, and $O_2\sim28.46$ ml l^{-1}. These ice values are derived from past studies in the Amundsen Sea (Hellmer et al., 1998; Jenkins, 1999; Jenkins and Jacobs, 2008), with temperature values representative of losses in the phase change from ice to liquid water. Oxygen values within the ice are drawn from oxygen concentrations within air pockets in the ice, which are forced entirely into solution when ice melts at the pressures beneath the ice sheet. Meltfractions are reported as the mean of the three independent meltfraction T–S, O_2–S, and O_2–T pairs. Standard deviations were calculated across all three pairs for each measured bin and values greater than one quarter of the theoretical upper bound of expected meltwater fractions were flagged and not included in the analysis. This occurred primarily in the upper mixed-layer where the calculations are unreliable due to the influence of air–sea exchanges on water properties.

In addition to calculating meltfractions using the above method, we also use the Gade line (Gade, 1979), a line of constant mixing between the ice and ocean water, to visualize meltwater in

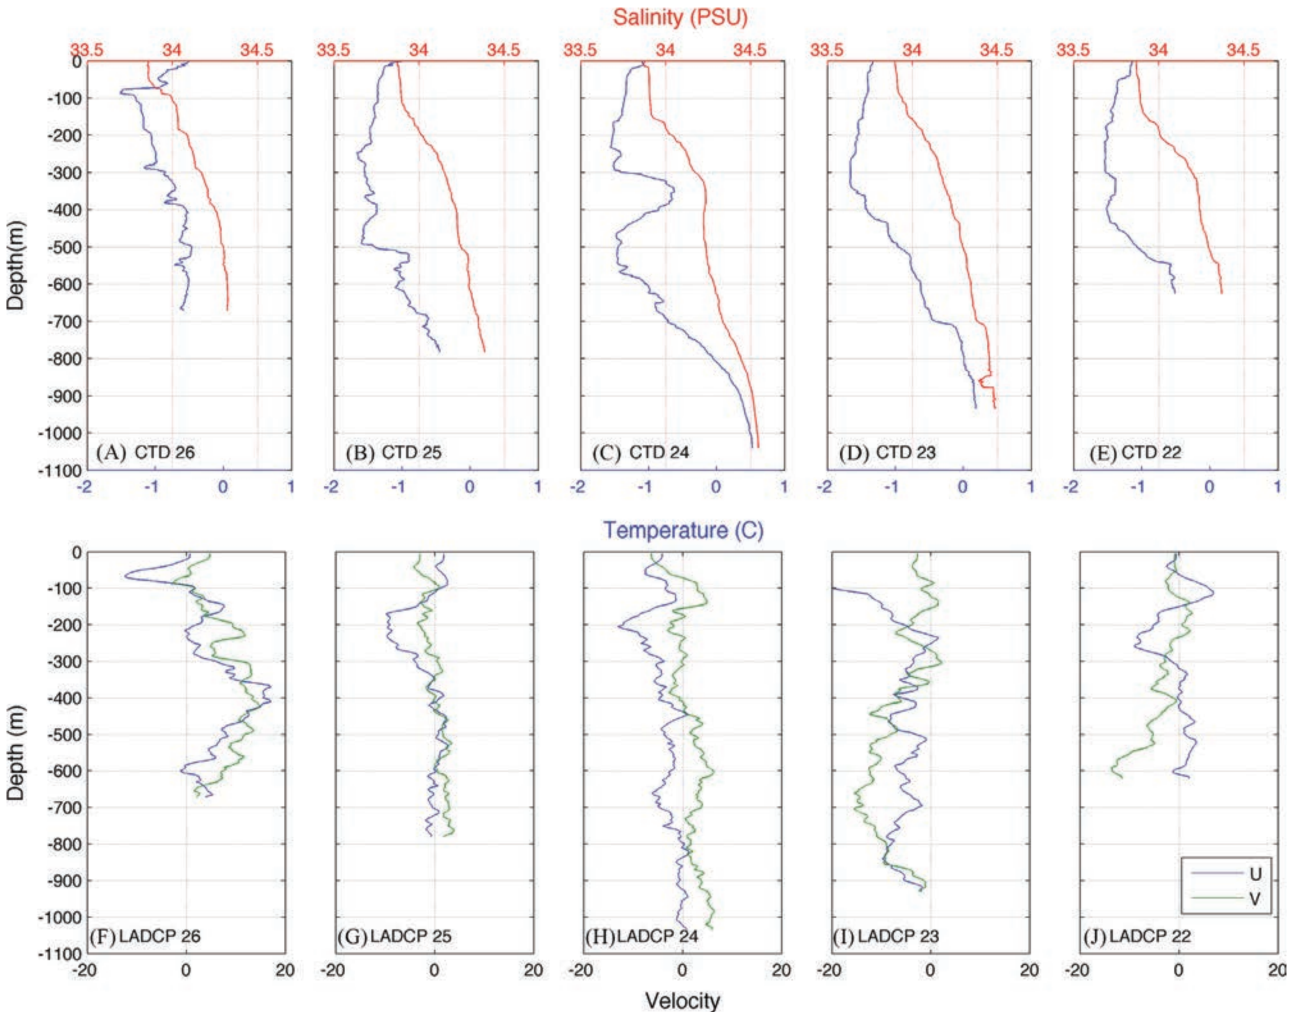

Fig. 6. Profiles of (A)–(E) IBRV *Araon* temperature (blue) and salinity (red) and (F)–(J) LADCP east-west (blue U) and north-south (green V) velocity at the locations indicated in Figs. 5A and 1B.

T–S space. The Gade line is represented by the equation:

$$T_p(S_p) = T_{ocean} + \frac{L_F}{C_p}\left(1 - \frac{S_{ocean}}{S_p}\right) \tag{3}$$

where T_{ocean} and S_{ocean} are the ocean end-members prior to melting, in this case mCDW end-members listed above. L_F is the latent heat of fusion for ice (334 kJ kg^{-1}); and C_P is the specific heat of water (3.97 kJ kg^{-1}) at salinity of 34.7 PSU, temperature of 1 °C, and pressure of 400 dbar.

3. Results

In January 2014 the Amundsen Sea continental shelf had three major water masses present (Fig. 2); i.e. Antarctic Surface Water (AASW) ($T > 0$ °C, $S < 34$ PSU), Winter Water (WW) ($T \sim -1.8$ °C, $S \sim 34.2$ PSU), and mCDW ($T \sim 0.5$ °C, $S \sim 34.55$ PSU). Pure CDW ($T > 1.5$ °C, $S > 34.5$ PSU) was observed in ship-borne CTD profiles off the shelf, and was not present in the Dotson Trough.

RU25 traveled across the Dotson Trough from east to west (transect G1) on January 4th 2014 (Fig. 1B). Along this transect warm (0.5 °C), salty (34.5 PSU) mCDW was observed leaning on the eastern flank of the trough (Fig. 3) consistent with along-isobath southward flow observed in previous studies (e.g. Wåhlin et al., 2010; Ha et al., 2014). Oxygen concentrations in the warm layer were below 5 ml l^{-1}, with minimum values of 4.2 ml l^{-1} near 800 m. dead-reckoned depth and time-averaged velocities are shown in Fig. 3D, with primarily southward velocities exceeding 5 cm s^{-1} for the majority of the transect, with minimum values near 0 cm s^{-1} at 112.75 °W. The velocity minimum in the center of the transect coincides with a region where the glider track runs parallel to curving bathymetry between 112.8 and 112.4 °W (Fig. 1B), so the current likely continued along-isobath although the direction changed.

RU25D was turned southward on January 6th, 2014 and traveled along the 600 m isobath toward the DIS (transect G2), along the ridge separating the Dotson from the Crosson basin. Temperature, salinity, and oxygen (Fig. 4) in the near bottom mCDW layer was uniformly distributed near bottom from north to south between between 73.8 and 74°S indicating limited interaction and mixing with overlying WW on the eastern side of the Dotson Trough. There was a persistent westward velocity increasing with proximity to DIS up to 10 cm s^{-1}, consistent with a coastal current that flowed along the DIS (Figs. 1B and 4D). RU25D was briefly piloted nearshore into shallower waters of ~400 m depth, just offshore of the Bear Peninsula. The velocity there showed a stronger westward current component, and the hydrography a significantly cooler (< -1.5 °C), fresher (< 33.9 PSU), and less oxygen rich (< 7 ml l^{-1}) surface water. No mCDW was present near the bottom in this region (Fig. 4), indicating that the mCDW remained at depth and continued along-isobath deeper than 400 meters.

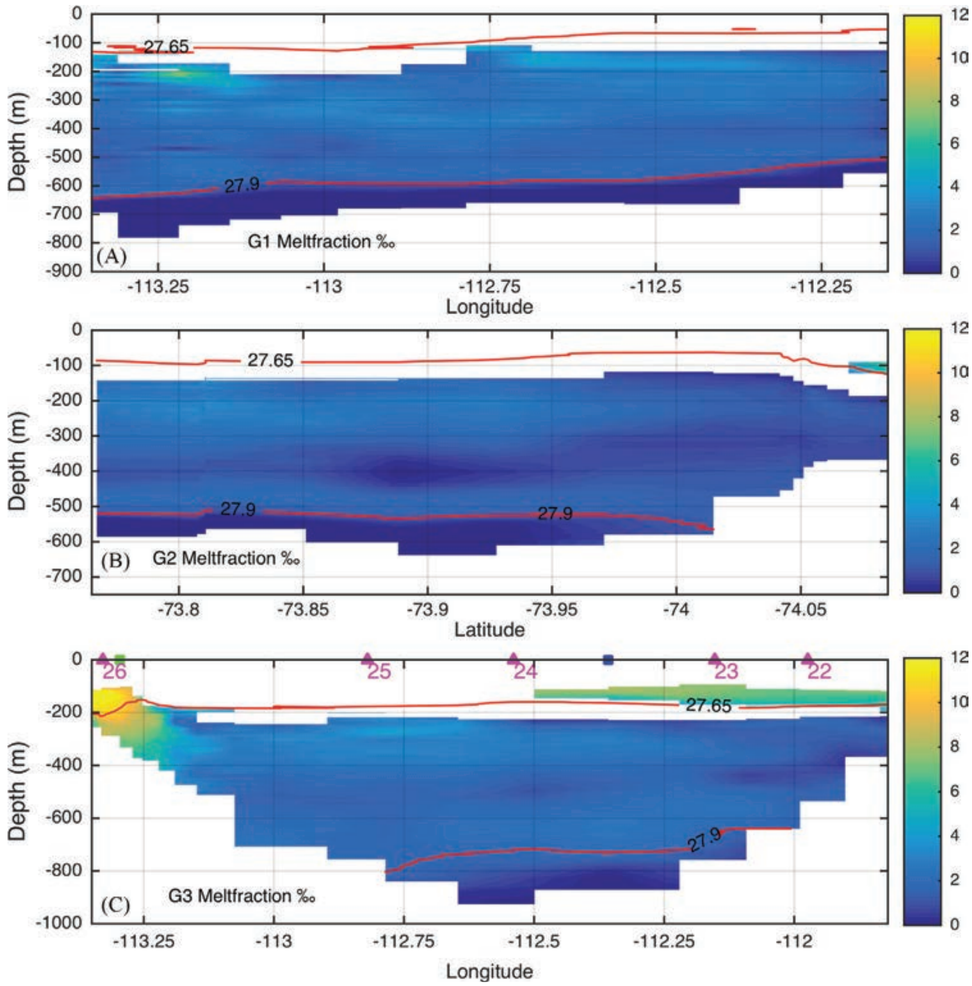

Fig. 7. Meltwater fraction cross-sections corresponding to 7A) transect G1, 7B) transect G2, and 7C) transect G3. Ship sampling locations are plotted along the top of 7C (magenta triangles) with numbers corresponding to the Fig. 1B and profiles in Fig. 6. Surface values where the three tracer pair meltwater fractions exceeded two standard deviations were removed as they are likely not valid due to atmospheric input. Red contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

3.1. *Dotson Ice Shelf inflow*

On January 8th, 2014 RU25D performed a cross-trough transect near the ice shelf front, G3 (Figs. 1B and 5), toward the west from the edge of the Bear Peninsula to within 8 km of the Martin Peninsula. The glider remained within 6 km of the DIS until ice conditions to the west forced RU25D to be piloted toward the northwest. Additionally, five CTD and LADCP stations (22 through 26) were performed by the IBRV *Araon* along the DIS within a few kilometers south of the glider track (Figs. 1B and 6). In similarity with the cross-trough glider section further north, the mCDW layer is spread on the eastern flank of the trough (Fig. 5). The shipboard profiles (Fig. 6) at stations 22 through 25 show similar characteristics as glider profiles with the warmest (> 0.5 °C) and saltiest waters at station 24 (> 34.55 PSU). However many of the fine-scale features are naturally lacking in the CTD transect, in particular the pronounced cold and fresh core seen at the bottom to the east of station 26. Oxygen concentrations in the central trough were less than 4.5 ml l^{-1} consistent with upstream values of mCDW along transects of G1 and G2. The 27.9 kg m^{-3} contour in all three transects (Figs. 3A, 4A, and 5A) shows that the near bottom layer is consistent throughout the trough and suggests that there was limited mixing of the core mCDW near the bottom with overlying WW prior to entering into the ice shelf cavity. A strong (up tp 20 cm/s) southward flow toward the ice shelf cavity can be seen over the eastern part of the transect (Fig. 5D) where weaker currents (near 5 cm s^{-1}) were present in the central portion of the trough. Ship-borne LADCP profiles at stations 22 and 23 show de-tided southward velocities below 200 m depth to the bottom with maximum values over 15 cm s^{-1} at 600 m in station 22 and at 700 m depth in station 23 (Fig. 6). At station 24 near the bottom within the mCDW layer velocities were near ~5 cm s^{-1} northward. Depth averaged LADCP velocities on the eastern flank of the Dotson Trough showed weaker (~7 cm s^{-1}) southward flow than glider measurements near the same location (Fig. 5D). If shipboard data is considered on its own, this would suggest that the waters flowing toward and beneath the DIS were limited to the slightly weaker mCDW signature at stations 22 and 23, though based on glider dead-reckoned currents and hydrographic observations there is still significant southward flow between stations 23 and 24 where mCDW presence remains high.

3.2. *Dotson Ice Shelf outflow*

On the western flank of the trough, west of 113.2°W there is a distinct water mass with elevated temperature and salinity and reduced oxygen relative to other water masses between 100 and 500 meters depth. Temperatures within this water mass ranged from −0.5 to −1.3 °C. Salinities were between 34 and 34.25 PSU. The signal is most clearly seen in the oxygen data; with oxygen

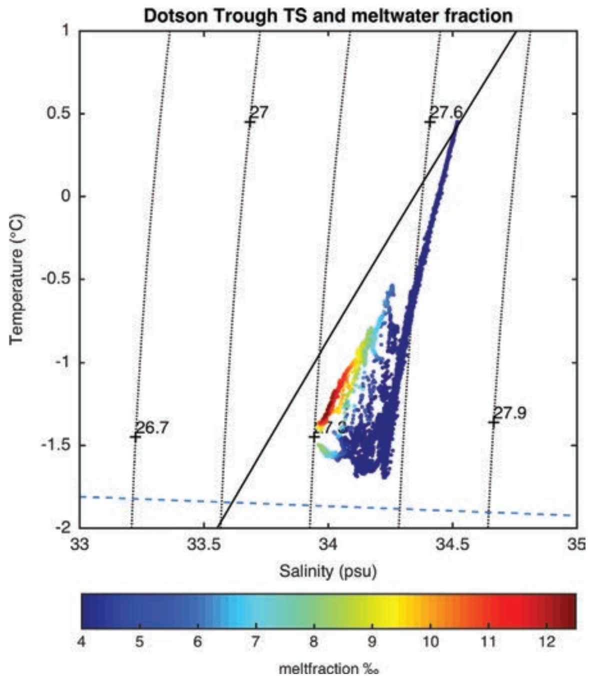

Fig. 8. Temperature and salinity diagram with meltwater fraction plotted in colors. The blue dashed line indicates the freezing point of seawater and the black solid line is the Gade Line (Gade, 1979) with end members of −0.5 °C and 34.55 PSU and for ice −90.75 °C and 0 PSU (Hellmer et al., 1998).

values between 5 and 5.5 ml l^{-1} standing in stark contrast to the oxygenated AASW and WW. Dead-reckoned glider velocities show northward flow of up to 10 cm s^{-1} coinciding with this water mass, indicating that this is a northward flowing jet focused on the steep bathymetry of the western flank of the DIS trough. While the CTD data at station 26 did not capture the main outflow clearly, the LADCP data does show northward velocities between 100 and 700 m, with peak vales of near 20 cm s^{-1} at 400 m, just below the core depth of the outflow region in the glider data. Depth-averaged LADCP velocities were northward at ~8 cm s^{-1} and compared well with glider velocities (Fig. 5D), though they were shifted westward as the glider sampled a more northerly location where bathymetry curved toward the east (Fig. 1B).

3.3. Meltwater fraction

Meltwater fractions for transects G1, G2, and G3 are all shown in Fig. 7, with the highest values of over 12 parts per thousand found on the western portion of G3. The lowest meltwater fractions are evident in the near bottom regions of G1, G2, and the inflow region of G3 between 112.75 and 112.20°W. The low values of G1, G2, and the inflow region of G3 indicate little mixing with the overlying WW along the trough. When plotted as a scatter plot in *T–S* space, along with the Gade Line (Gade, 1979), it can be seen that the meltwater falls bellow and parallel to the Gade Line with end members presented above (Fig. 8). This indicates that for the current time period WW is either further mixed with mCDW prior to inducing melt or mixed with outflowing meltwater before being sampled by the glider.

3.4. Optical properties

As mentioned above, optical backscatter serves as a proxy for suspended particle concentration in the water column. Values in the uppermost 50 m within the AASW layer on transects G1, G2, and G3 are elevated with values of consistently over 0.01 m^{-1} (Fig. 9). These surface values are highest further away from the glacial face along transect G1 and are most likely related to the high biomass associated with a large chlorophyll bloom away from the shelf. Chlorophyll values recorded by the glider were in excess of 25 mg m^{-3} along transect G1 and G2 and were much lower with proximity to the DIS in transect G3 (Fig. 10b). Winter water in all three transects has the lowest optical backscatter values, while near bottom values in the mCDW are approximately an order of magnitude greater than WW. Optical backscatter generally increases toward the bed indicating a possible sedimentary source of particles with near bottom maxima of ~0.001 m^{-1} for sections G1, G2, and the portion of G3 east of 112.8°W that is associated with the Dotson Trough inflow.

Meltfractions greater than 1 parts per thousand and optical backscatter have a linear relationship (Fig. 11A) with R^2 of 0.657, which suggests that suspended particulate matter is sourced from glacial melt water in the outflow region. Fig. 12 shows the lower 100 m of two optical and meltfraction profiles from the inflow and outflow regions. The western outflow region of G3 has near-bottom values of optical backscatter of about ~0.001 m^{-1}, nearly equal to the near-bottom values in the inflow but in contrast to the inflow region optical backscatter increases with distance from the bed, indicating an overlying particle source. There are two distinct regions where meltfractions increase and optical backscatter does not represented in blue and green in Fig. 11A. Both of these regions have neutral densities of less than 27.65 kg m^{-3} (Fig. 7). The first peak has an optical backscatter of ~0.0006 m^{-1} and meltwater fractions between 4 and 8 parts per thousand, while the second peak has an optical backscatter of ~0.00125 m^{-1} and meltfraction between 8 and 13 parts per thousand.

4. Discussion

Observations of the pathways of warm mCDW and glacial meltwater beneath ice shelf cavities are limited. Yet, the evolving circulation is critical to understanding how climate shifts will affect physical and biogeochemical processes in the highly productive polynya waters close to these cavities (Arrigo et al., 2012; Lee et al., 2012; Yager et al., 2012). Previous field campaigns have used a handful of individual ship-based profiles to identify inflow and outflow regions along Pine Island Glacier (Jenkins et al., 2010; Jacobs et al., 2011; Dutrieux et al., 2014), the DIS (Randall-Goodwin, 2012; Yager et al., 2012), and other systems (Jenkins and Jacobs, 2008). Traditional CTD transects would collect at best only a few profiles in outflow regions, and often miss them all together. For example, in the 2014 ANA04B cruise just one profile (station 26) was located on the western flank of the DIS, and it did not capture the core or the vertical and horizontal spatial extent of the main outflow.

As described by Ha et al. (2014), past studies have found the outflow on the western flank of the Dotson Trough to account for approximately 1/3 of the inflow. Using the width and height of the 27.9 kg m^{-3} neutral density contour from the bed and glider depth-averaged velocities we obtain an inflow estimate of ~0.39 Sv. This is slightly larger but on the same order of magnitudes as inflow estimates by Ha et al. (2014).

RU25 collected 15 profiles within the outflow region. At the time this outflow extended approximately 7 km from the 500 m isobaths to inshore of the 200 m isobaths. Using the glider sampled bathymetry, the 27.6 kg m^{-3} neutral density contour, the 7 km width of the outflow, and the depth and time-averaged velocities within the outflow we estimate a northward transport of ~0.06 Sv (1.9 × 10^{12} m^3 yr^{-1}). With an average metlwater fraction

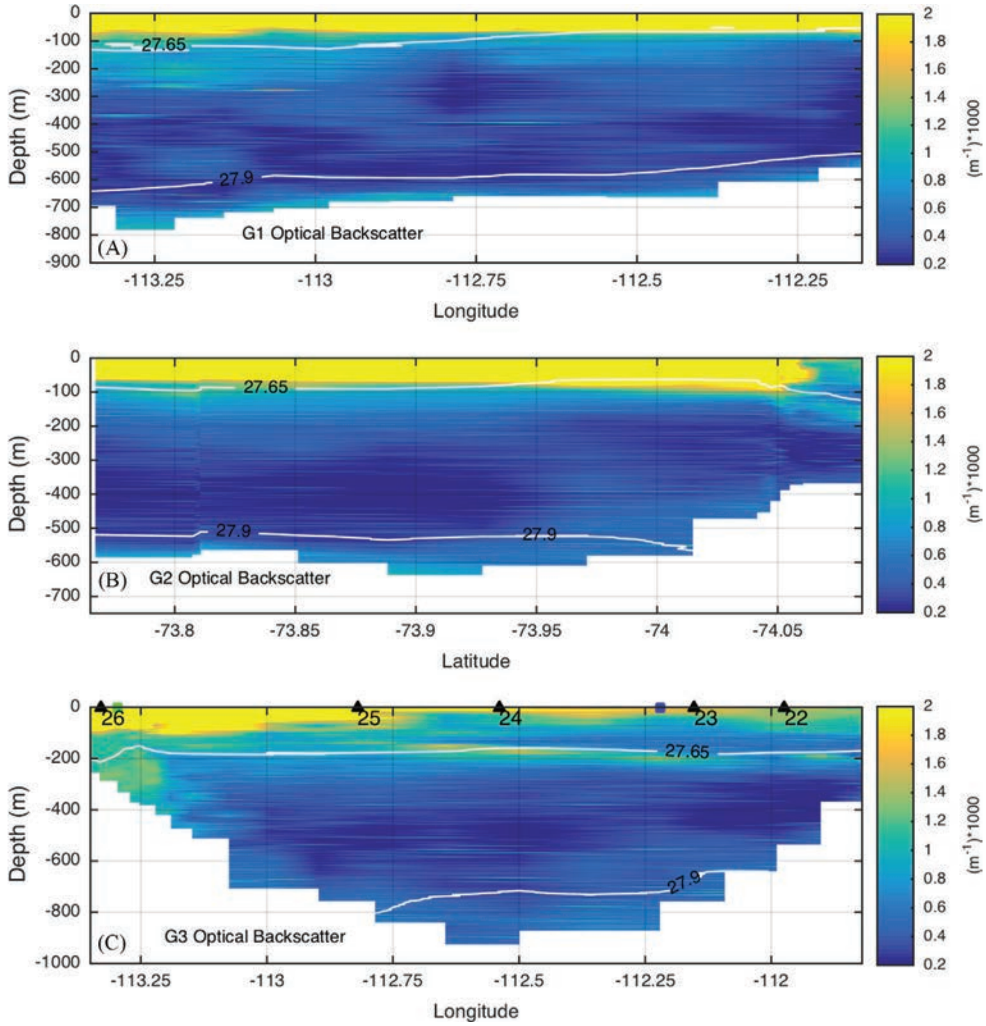

Fig. 9. Optical backscatter cross-sections corresponding to 9A) transect G1, 9B) transect G2, and 9C) transect G3. Ship sampling locations are plotted along the top of 9C (black triangles) with numbers corresponding to the right panel of Fig. 1 and profiles in Fig. 6. Blue and Green squares correspond to the glider profiles plotted in Fig. 12, with the Blue representing the inflow region and green representing the outflow region. White contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

of ~1% this equates to 1.9×10^{12} m^3 yr^{-1} of meltwater in the DIS outflow, or ~19 Gt yr^{-1}. This is less than instantaneous estimate of 81 Gt yr^{-1} from the 2011 ASPIRE cruise (Randall-Goodwin et al., 2015) and the 5-year average of 42 Gt yr^{-1} from Rignot et al. (2013), but likely reflects high seasonal and interannual variability in the region. While this value is uncertain due to the usage of glider depth and time-averaged velocities, a similar result using ship based methods would require extensive and focused LADCP profiling in this region, which is costly and not feasible due to the remote nature of the region. Furthermore, future modeling efforts will need to have resolutions that can capture the narrow width of the outflow in order to accurately represent the DIS outflow.

Among other environmental factors such as light availability, macronutrient supply, and upper mixed layer depth Fe has been identified as a necessary micronutrient to support large phytoplankton blooms in the ASP (Arrigo and van Dijken, 2003; Arrigo et al., 2008; Smith and Comiso, 2008). Recent studies have identified high levels of Fe in meltwater near the DIS (Alderkamp et al., 2015) and significant concentrations have been observed as far as 150 km from the Pine Island Glacier (Gerringa et al., 2012). Fe has been hypothesized to originate from a number of sources including basal melt of the sediment laden ice shelf or sub-glacial sediment resuspension from the bed.

While no direct observations of Fe are possible from the gliders, optical backscatter can serve as a proxy of suspended particulate matter. Not all particulate matter may contribute to Fe concentrations, but particulate Fe has been observed near the DIS and found to be important for the ASP. The glider based optical backscatter measurements increase logarithmically toward the bottom for the eastern (inflow) region. This is known as a Rousian sediment distribution and is typical of resuspended sediment on continental shelves (Grant and Madsen, 1986; Glenn and Grant, 1987; McLean, 1991; Madsen et al., 1993). In semi-log space, as in Fig. 12, Rousian profiles increase linearly toward the bed. The distribution is a result of the balance between the turbulence generated from the current shear within the bottom boundary layer that acts to keep sediment in suspension and gravitational forces, which cause sediment particles to fall out of suspension. A reduction in shear away from the bed leads to reduced turbulence and a smaller sediment concentration. Unlike the inflow region, the outflow region optical backscatter profile is non-Rousian (Fig. 12b). The fact that the optical backscatter increases with distance above the bottom in the glacial meltwater outflow indicates an external source of particles to the water column.

There are two regions where meltwater concentration increases but optical properties remain constant (Fig. 12) suggesting that some portion of the DIS is not sediment laden and contributes minimally

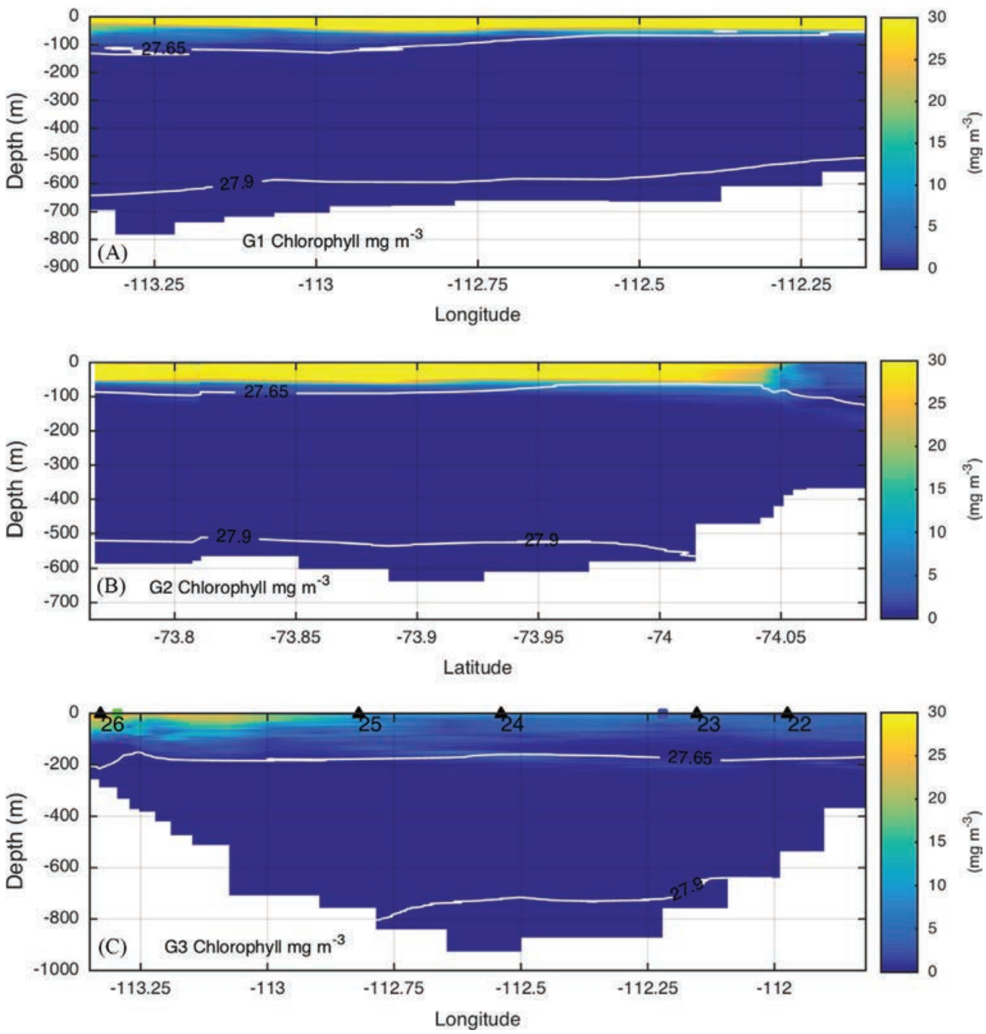

Fig. 10. Chlorophyll concentration cross-sections corresponding to 10A) transect G1, 10B) transect G2, and 10C) transect G3. Ship sampling locations are plotted along the top of 9C (black triangles) with numbers corresponding to the right panel of Fig. 1 and profiles in Fig. 6. Blue and Green squares correspond to the glider profiles plotted in Fig. 12, with the Blue representing the inflow region and green representing the outflow region. White contours are neutral densities of 27.65 and 27.9 (kg m^{-3}).

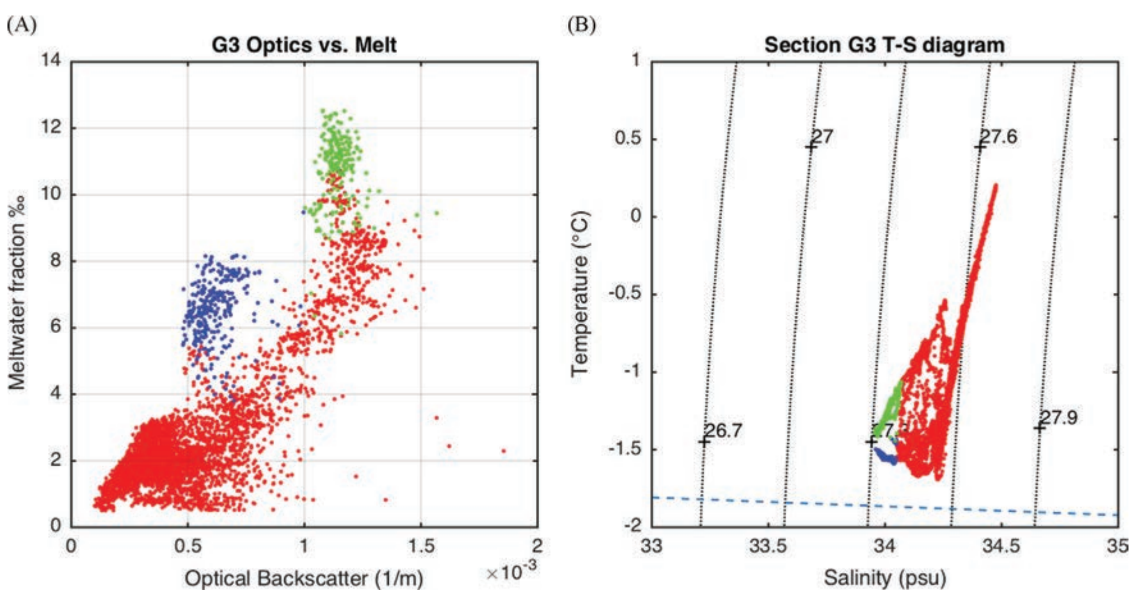

Fig. 11. (A) plot of meltwater fraction (*y*-axis) vs. optical backscatter (*x*-axis) and (B) *T–S* diagram of the data from panel A. Blue and green points represent regions where meltwater fractions increase independent of optical backscatter.

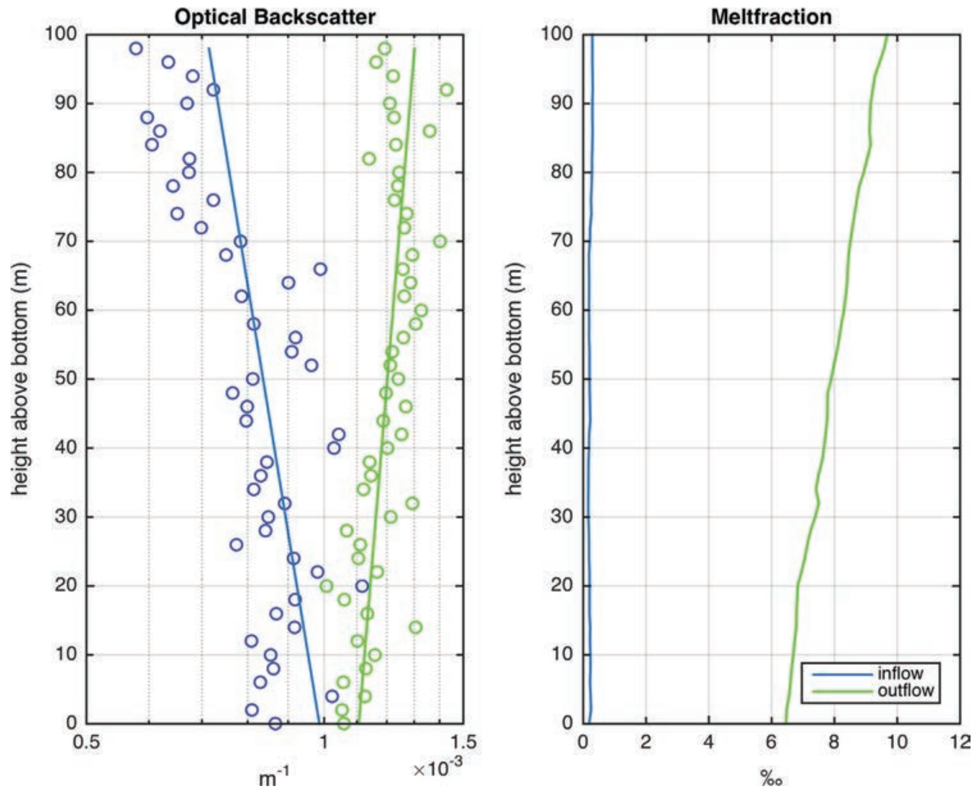

Fig. 12. (Left panel) Profiles of optical backscatter on a semi-logarithmic x scale and (right panel) meltwater fraction with the *y*-axis for both corresponding to height above bottom. Blue lines represent the inflow and green represent the outflow at locations denoted by the Blue and Green squares in Fig. 9C.

to the suspended particle concentration. In *T–S* space (Fig. 11B) the first peak (blue) with low optical backscatter is closely related to WW, indicating a region where WW reached the ice-shelf face near 150 meters depth (above the 27.65 kg m^{-3} contour in Fig. 7) on the eastern flank of the trough. Observations from the 2011 ASPIRE (Yager et al., 2012) cruise show the ice shelf draft on the eastern flank was at approximately 200 meters (Randall-Goodwin, 2012) depth, supporting this finding. The second peak (green) coincides with the region running parallel to the Gade line (Fig. 8) indicating that the same water mass that induced suspended particle laden melt also interacted with ice that made a limited particle contribution. One potential explanation for this is that buoyant meltwater rises up along the ice shelf base and induces further melt in the shallower part of the cavity close to the ice shelf edge where the ice may have lower sediment concentrations.

Aside from the two regions mentioned above, the nearly linear relationship between optical backscatter and meltwater fraction (Figs. 11 and 12b) points to glacial meltwater as the primary source of particles and the existence of a muddy ice shelf base inland of the grounding zone. This has implications for the flow speed of the grounded ice and also indicates that glaciers can serve as an important source of Fe to the water in this region. Detailed marine geological surveys and dating of the sediments (Smith et al., 2014) indicate that the ice sheet base has been sediment-laden for the last 20,000 years as it retreated across the ASE. Elevated optical and meltwater fraction signatures were also observed offshore near 113.25°W and 73.72°S in transect G1 at 200 m (Figs. 7 and 8). This is nearly 35 km north of the outflow and indicates that the particle heavy outflow waters continue northward toward the central ASP, and are not limited to the nearshore coastal zone consistent with glider observations of the phytoplankton blooms in the 2010–2011 field year (Schofield et al., in press). This is also consistent with the observations of meltwater-rich outflows near the outer shelf (Wåhlin et al., in press; Ha et al., 2014); i.e. observations that at least a third of the outflow makes it back to the outer shelf.

Past studies have indicated that the phytoplankton bloom in the ASP also has strong interannual variability (Arrigo and van Dijken, 2003). The intrusion of CDW into the Dotson Trough, while persistent (Arneborg et al., 2012) has significant interannual variability in the thickness and temperature (Assmann et al., 2013). The limited multi-year observations (Wåhlin et al., in press; Wåhlin et al., 2013; Ha et al., 2014) show a strong annual and interannual variability of CDW intrusion along the deep troughs, which presumably reflects on the circulation beneath the Dotson Ice Shelf, and subsequently to the supply of Fe to the ASP. This modulation of the Fe-supply could potentially account for variability in size and duration of the ASP summer and spring blooms.

5. Conclusions

In this study we used a Teledyne-Webb Slocum glider to obtain high spatial and temporal resolution oceanographic data along the front of DIS in the ASP. With the glider RU25D, a narrow ($\sim$7 km) outflow of glacial meltwater was identified on the western flank of the DIS, a feature nearly missed in the ship based profiles due to too large spacing between stations. The outflow was northward flowing, had high meltwater fractions, and elevated optical backscatter. The shape of the optical backscatter profiles and their high correlation with meltwater fraction indicate that particles in the outflow were primarily sourced from basal melt of the DIS, not resuspended sediments. This suggests that the DIS originates in a sediment-rich ice sheet base inland of the grounding zone, that particulate Fe previously found in the region is likely of glacial origin, and that its interannual variability could potentially be linked to the size and duration of CDW intrusions onto the shelf. In order to confirm this result future studies should target the DIS outflow, examination of the Kohler glacier base, and use a combination of ship-based profiles, moorings, and autonomous underwater vehicles to track the properties and fate of this outflow as it moves northward toward the central polynya. By leveraging glider systems to take over hydrographic survey responsibilities research vessels could be better focused on process-based studies in regions of interest and perform mooring recovery and deployment activities while increasing data density in these difficult to access, yet climate critical, regions of interest.

Acknowledgments

The authors acknowledge the Korea Polar Research Institute for its support and funding from Grant programs (PP14020 and PP15020), Teledyne-Webb graduate fellowship for graduate student funding, the Rutgers University Center for Ocean Observing Leadership for glider piloting and support, and the dedication and support of the crew and scientists of the IBRV Araon. Inha University research Grant (INHA-51416) supported Ho Kyung Ha. We would also like to thank Pierre Dutrieux for scientific codes and commentary on many of the draft figures. Additionally, we thank the two anonymous reviewers for the helpful and thoughtful comments that greatly improved this paper.

***Abstract*— The Mid Atlantic Bight continental shelf has one of the largest summer temperature gradients in the world, with near bottom temperatures below 8C and peak surface temperatures over 28C. This is largely due to the summer Cold Pool, remnant winter water that is generated on the northern MAB and transported southward along the continental shelf in spring and early summer. During tropical cyclones that impact the MAB continental shelf, such as Hurricane Irene in 2011, shear driven mixing of Cold Pool water across the thermocline has the potential to cool the oceans surface and reduce storm intensity. In this study we compare coastal ocean advection and mixing processes during Hurricane Sandy and Hurricane Arthur, an offshore tracking tropical cyclone in the summer of 2014, to demonstrate the range of potential storm impacts on the coastal ocean of the MAB. To perform this analysis we use data from advanced Slocum autonomous underwater glider deployments in each storm as well as the Regional Ocean Modeling System (ROMS).**

***Keywords*— Coastal storms, ocean observing systems, autonomous underwater vehicles, coastal ocean modeling.**

I. Introduction

The Mid Atlantic Bight continental shelf has one of the largest summer temperature gradients in the world, with near bottom temperatures below 8C and peak surface temperatures over 28C. This is largely due to the summer Cold Pool [1], remnant winter water that is generated on the northern MAB and transported southward along the continental shelf in spring and early summer. During tropical cyclones that impact the MAB continental shelf, such as Hurricane Irene in 2011, shear driven mixing of Cold Pool water across the thermocline has the potential to cool the oceans surface and reduce storm intensity [2]. While this process was observed in detail from a networked coastal ocean observatory in Hurricane Irene, a coupled ocean-atmosphere model study has shown the ocean to have a limited impact on Hurricane Sandy in 2012 [3].

In this study we compare coastal ocean advection and mixing processes during Hurricane Sandy and Hurricane Arthur, an offshore tracking tropical cyclone in the summer of 2014. Hurricane sandy was a late-season tropical cyclone that crossed the New Jersey shelf in late October, when stratification had already partially broken down for the season. Hurricane Arthur was one of the earliest tropical cyclones to make landfall in North Carolina in early July prior to crossing the southern portion of the Mid-Atlantic Bight, when stratification was at its highest. With vastly different trajectories and shelf stratification conditions they demonstrate the range of potential storm impacts on the coastal ocean of the MAB. To perform this analysis we use data from advanced Slocum autonomous underwater gliders deployed ahead ofeach storm as well as the Regional Ocean Modeling System (ROMS).

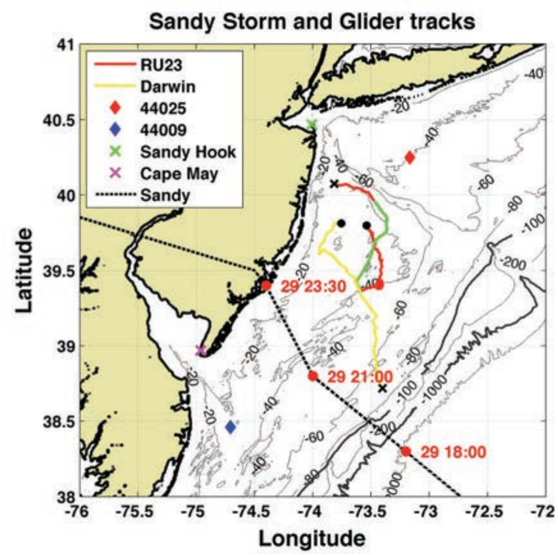

Figure 1 Map of the NJ Shelf with the dashed line representing Hurricane Sandy's onshore track (times in GMT). Glider RU23 (red) and it's storm sampling period represented in Figure 2 (green). A second glider, Darwin (yellow), is also plotted.

II. Methods

Teledyne-Webb Research Slocum gliders are buoyancy driven autonomous underwater vehicles that are mobile profiling sensor platforms, with interchangeable science bays [Schofield et al., 2007; Schofield et al., 2010]. Gliders have a proven history of sampling in extreme weather conditions, [4]–[7]. A Slocum G1 glider, RU23 was deployed

978-0-933957-43-5 ©2015 MTS

ahead of Hurricane Sandy in October 2012, while a specially designed G2 Storm glider RU30 was deployed ahead of Hurricane Arthur in July of 2014. RU23 and RU30 were equipped with Seabird Electronics (SBE) un-pumped and pumped conductivity temperature and depth (CTD) sensors, respectively. Both gliders were equipped with two Wetlabs Eco-triplets that measured chlorophyll fluorescence, colored dissolved organic matter (CDOM), and four channels of optical backscatter.

To measure water-column currents Nortek Aquadopp current profilers with custom glider heads were externally mounted in an upward looking position and logged data internally. The Aquadopps were configured to collect data in beam coordinates in one meter bins with a beam length of ten meters every two seconds. On downcasts with a glider pitch angle of 26.5 degrees the Aquadopps had a pitch angle of 0 degrees. We emply a shear-least squares method originally detailed for lowered current profilers [8] and adapted for use on autonomous platforms [9]. We calculate water column shear at one meter intervals on downcasts only and use a combination of pitch angle, heading and depth, known as dead-reckoning [10] to calculate the mean water-column velocity.

ROMS is a three-dimensional sigma coordinate numerical ocean model [11]–[13] that is commonly used for coastal and regional model applications. The Experimental System for Predicting Shelf and Slope Optics (ESPreSSO) setup [14]–[18] used here covers from Cape Hatteras to Cape Cod, and near shore to beyond the shelf-break. The system has an approximately 5 km horizontal resolution, 36 vertical levels and a 6-minute time step with model data output hourly. Boundary conditions are derived from the HYCOM-NCODA (http://hycom.org/) and tides derived from the ADCIRC tidal model (http://adcirc.org/). For the Sandy case the model is initialized from the original assimilative ESPreSSO 4-dimensional variational data assimilations (IS4DVAR) output on October 25th and run forward. Atmospheric forcing is from the Rutgers University Weather Research and Forecast model setup described in detail in [7]. The ESPreSSO model has been used extensively on the MAB for a range of applications including for sediment transport studies during Hurricane Sandy on the MAB[7].

III. Results

A. Hurricane Sandy

Hurricane Sandy developed as a late-season tropical wave off the coast of Africa on October 11th 2012. On October 24th the cyclone made landfall as a category 1 hurricane in Jamaica and continued to make landfall in Cuba as a category 3 on October 25th. The cyclone left the Caribbean the storm turned toward the northeast again as a category one hurricane. During this period, as the storm passed to the east of North Carolina, the radius of maximum winds covered approximately 180 kilometers. Early on October 29th Sandy took a sharp left turn toward the NY/NJ coastline. After a brief re-intensification period as the storm crossed the continental shelf it interacted with cooler waters and a cold air mass over the eastern United States, ultimately

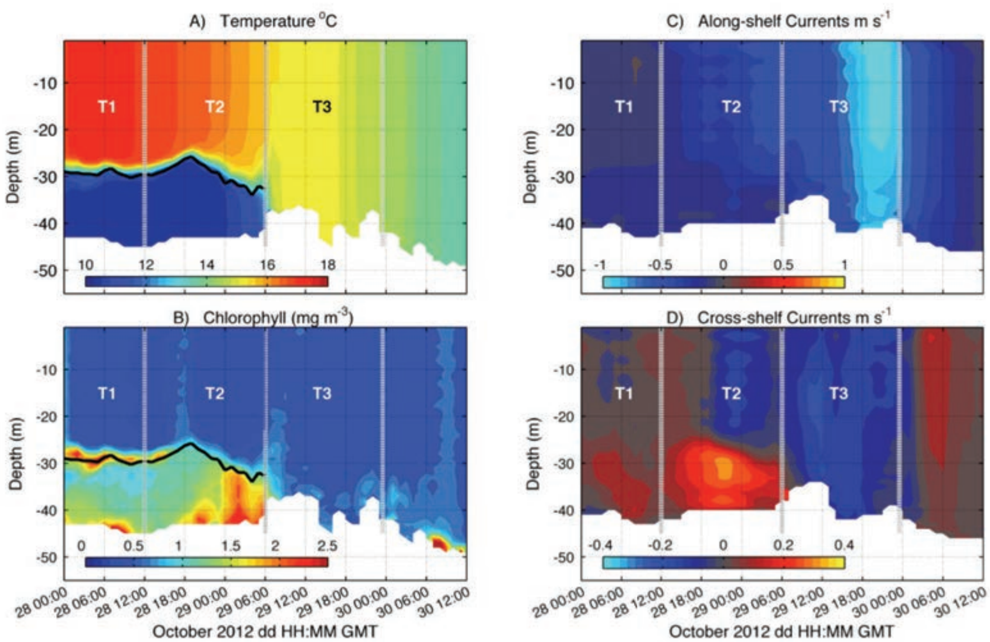

Figure 2 RU23 glider data during the storm forcing period on October 28th at 00:00 GMT to the 30th at 12:00 GMT (represented by the black line in Figure 1). A) Temperature and B) Chlorophyl (mg/m3) with a black contour representing the thermocline. C) Along-shelf and D) cross-shelf de-tided currents calculated from the Nortek Aquadopp current profiler. Positive is toward the southwest and offshore in the along- and cross- shelf directions respectively. Note the different colorbar between the along and cross- shelf currents.

transitioning to extra-tropical at 2100 GMT on October 29th just prior to landfall at 2330 GMT near Brigantine, New Jersey. This storm drove extensive storm surge along the NY/NJ coastlines and resulted in over $68 Billion in damages[19].

Glider RU23 was deployed 15 km southeast of Sandy Hook, NJ on October 25th, (Figure 1) as forecasts indicated Sandy would approach the MAB. The glider was piloted due east to the 40 meter isobath in order to sample the coastal ocean at a safe distance from the coastline. Cross-sections of RU23 temperature and currents (Figure 2) show three distinct time periods based on the evolution of the thermocline, which we refer to as T1, T2 and T3.The initial stratified period T1 was between 00:00 and 12:00 GMT on October 28th and showed warm surface temperatures of over 17°C consistent with pre-storm conditions sampled by Darwin and a sharp thermocline at 25 meters depth. Below the thermocline temperatures were 10°C and uniform to the bottom. During T1 de-tided along-shelf surface currents were weak and southwestward with flow below 0.1 m s^{-1}, while the lower layer showed bottom intensified flow over 0.2 m s^{-1}. There was slight onshore flow near the surface and offshore flow near the bottom of ~ 0.1 m s^{-1}. During T2 between 12:00 GMT on the 28th and 06:00 GMT on the 29th (Figure 2) the thermocline initially rose and then deepened dramatically, reaching the bottom in twelve hours. Along-shore currents increased to over 0.6 m s^{-1} in the surface layer and remained near 0.2 m s^{-1} in the bottom similar to the initial stratified phase. In the cross-shelf direction currents were onshore in the surface as along-shore surface winds, which had now persisted for over an inertial period (~18 hours), spun up the surface

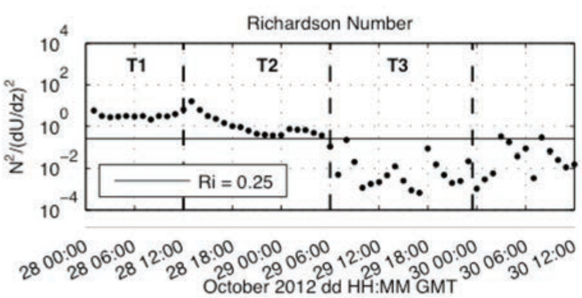

Figure 4 Bulk Richardson number calculated from equation 1 along the glider track. The horizontal black line represents Ri of 0.25.

Ekman layer. Cross-shelf flow in the lower layer was offshore and over 0.5 m s^{-1} at 20:00 GMT on the 28th. Surface temperatures dropped gradually, despite a sharp increase in bottom temperatures of 4°C in two hours as the thermocline deepened. In T3, between the 29th at 06:00 GMT and landfall on the 29th 23:30 GMT the watercolumn transitioned from a two- to one- layer system (Figure 2). Cross-shelf circulation shut down and currents rotated to be along-shelf and uniform throughout the watercolumn, with peak values over 1 m s^{-1} as the eye of Sandy crossed the shelf. Full watercolumn temperatures continued to gradually decrease until they dropped below 13C after eye passage

Two-layer cross-shelf flow during the deepening phase between 12:00 GMT on the 28th and 06:00 GMT on the 29th was consistent with the seaward side of a downwelling front, while single-layer flow was consistent with the shoreward side of a downwelling front similar to results discussed in [Lentz, 2001] and [Austin and Lentz, 2002]. Along-shelf displacement of the glider was over 50 km, but piloting to maintain cross-shelf position and two-layer flow limited cross-shelf displacement during T2 and T3, thus the glider likely sampled the shoreward and seaward sides of the downwelling front, in T2 and T3 respectively, as it was advected past the glider in the offshore direction. Bulk Richardson numbers from:

$$Ri = N2/(\partial u\ \partial z) \qquad (1)$$

where N^2 is the hourly averaged water-column buoyancy frequency across the thermocline, and $(\partial u\ \partial z)^2$ is the hourly averaged maximum shear across the thermocline calculated from the Aquadopp. Studies have shown [20], [21] that the water column is stable (unstable) when Richardson number is above (below) a critical number (Rc) of 0.25. Richardson numbers (Figure 3) were greater than 0.25 until the 29th at 06:00 after the thermocline had already deepened

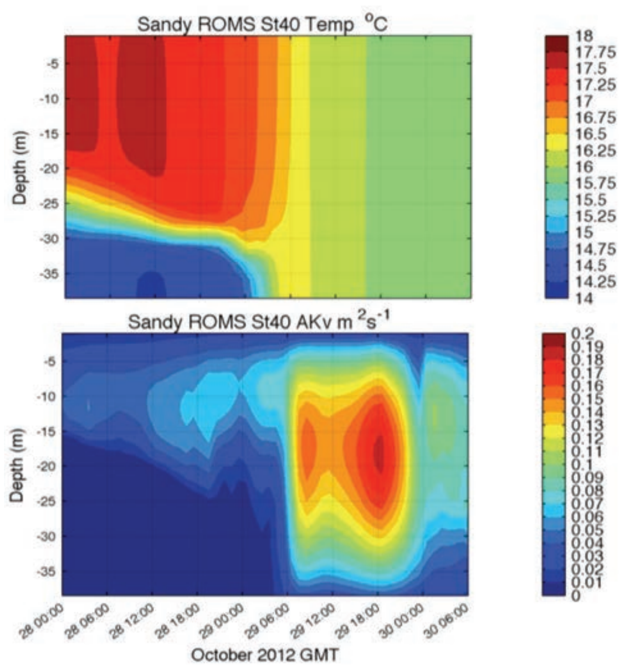

Figure 3 Cross sections of temperature (upper) and eddy diffusivity at the 40 meter isobaths in the ROMS model near the glider position.

approximately 5 meters.

A cross section of the storm time period from ROMS near the glider location on the 40 meter isobaths (Figure 4) shows similar stratification with a few differences. Bottom waters were approximately ~3°C warmer prior to the storm and the thermocline was deeper and slightly more diffuse. Similar deepening of the thermocline occurred ahead between

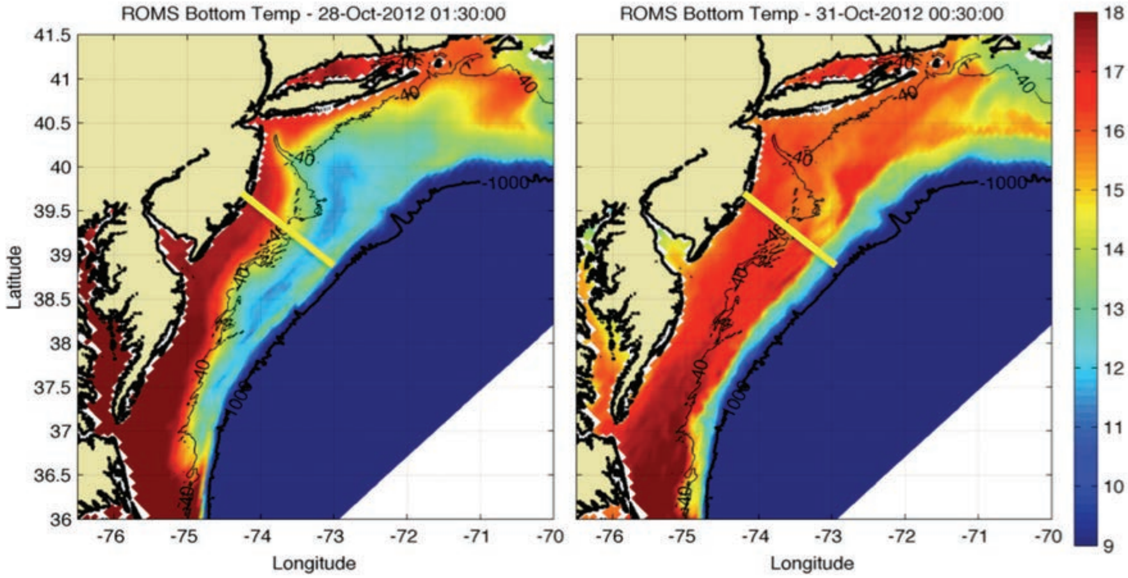

Figure 5 Bottom temperatures from the ESPreSSO ROMS model before (left panel) and after (right panel) eye passage.

the 28th at 00:00 GMT and the 29th at 06:00 GMT, followed by a transition from two-layers to one-layer (Figure 4). Eddy diffusivities were relatively low in prior to the 29th at 06:00 GMT with limited increases in the surface layer indicating limited mixing across the thermocline. Eddy diffusivities increase dramatically after the transition from a one- to two-layer system supporting the argument that advection was responsible for the transition rather than mixing (Figure 4). From a shelf-wide perspective bottom temperatures inshore of the 40 meter isobaths were near 18°C indicating a well-mixed nearshore region. Bottom temperatures offshore of the 40 meter isobaths pre-storm are near ~13°C across (Figure 5) the majority of the shelf. After the storm the warm bottom temperatures found inshore extend nearly to the shelf-break, with a total offshore advection of ~30 km.

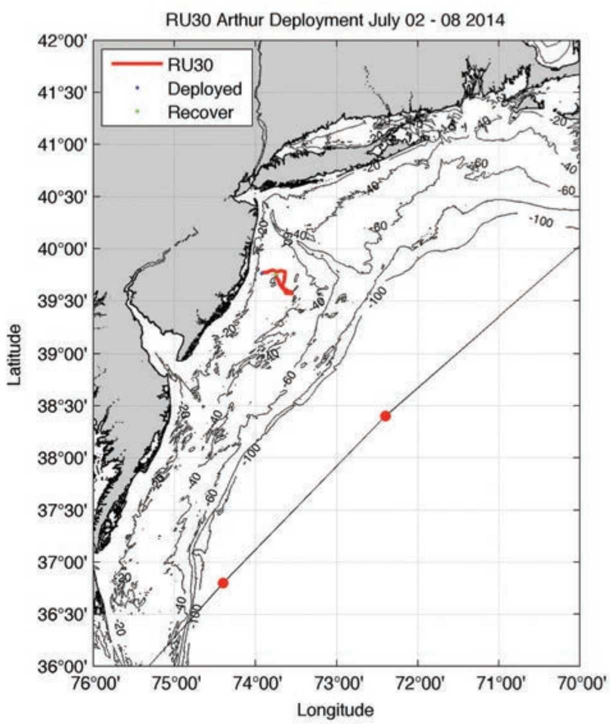

Figure 6 Map of the MAB with Hurricane Arthurs track (black with red dots), the glider track (red line).

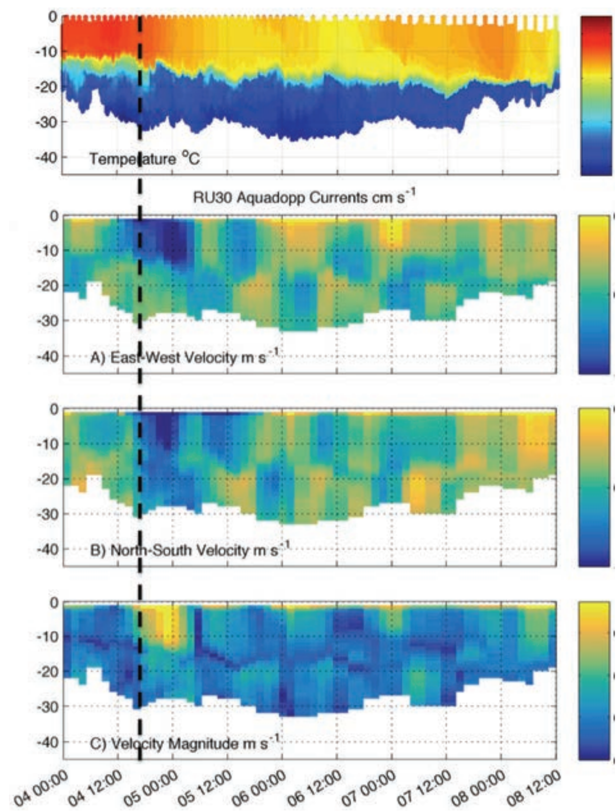

Figure 7 Cross-sections of glider RU30 temperature and velocity components and magnitude. Vertical black line denotes time of storm passage.

B. Hurricane Arthur

Hurricane Arthur developed east of Florida on July 1st when a depression that had crossed from the Gulf of Mexico into the South Atlantic bight interacted with a region of mid-level anticyclone over the Western Atlantic. This interaction caused Arthur to accelerate northward rapidly throughout July 2nd and 3rd. The hurricane strengthened as it passed east of Savannah Georgia and eventually reached peak intensity off the coast of Cape Fear, North Carolina. After crossing the Outer Banks, Arthur accelerated northeastward over the western Atlantic east of the Mid-Atlantic until it weakened into a tropical storm on July 5th east of Provincetown, Massachusetts.

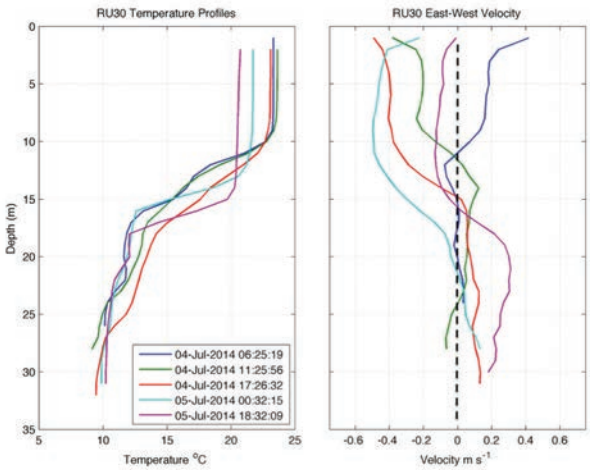

Figure 8 RU30 segment averaged profiles of temperature (left panel) and east-west velocity (right panel).

RU30 was deployed as part of a NOAA Cooperative Institute for the North Atlantic region (CINAR) Tempests project on July 3rd 2014 out of Tuckerton, NJ (Figure 6). The glider was piloted due east toward the 40 meter isobath similar to RU23 in Sandy. As Arthur was a fast moving storm the glider was only in the field for approximately 18 to 24 hours before experiencing outer edge winds from the storm. Initially on July 4th at 00:00 GMT the watercolumn (Figure 7) was highly stratified typical of summer conditions on the MAB. Surface temperatures were near 23 to 24^{o}C, bottom temperatures were near 10^{o}C and there was a shallow thermocline at 10 meters depth. Segment averaged profiles (mean profiles between each glider surfacing) between July 4th at 06:25 GMT and July 5th at 18:32 show limited cooling of only about 0.5^{o}C over the first 12 hours in the surface layer. Despite the limited surface cooling the thermocline deepened and grew less sharp by the end of July 4th at 17:26 GMT. After this first 12-hour period surface temperatures dropped over 3^{o}C and the thermocline lowered to 15 meters depth (Figure 8). Profiles of the east and west current velocities during this same period show maximum vertical shear starting on July 4th at 17:26 GMT with westward surface velocities and low near-bottom velocities.

After the eye passed the surface currents continue to rotate for a number of days after. Wavelet spectral analysis of the surface currents (Figure 9) shows the surface currents oscillating with a period of near 18 hours, near the local inertial period, that slowly lengthens with time. This suggests that any additional cooling is likely due to inertial surface currents driving intermittent shear driven mixing across the thermocline. Further analysis of glider data and ROMS modeling are underway in order to confirm this result.

IV. Discussion & Conclusion

RU23 and RU30 were deployed off the MAB continental shelves in response to Hurricanes Sandy and Arthur respectively. The storms had vastly different tracks, speeds, and struck at the far extremes of the Atlantic Hurricane season with different stratification regimes. Thus they represent two very different coastal ocean responses to summer storms on the MAB. Sandy struck during the late season fall transition period between summer and winter, thus temperatures were lower and the thermocline deeper than typically occurs on the shelf. The onshore track and large size of the storm drove large volumes of water above the thermocline onshore leading to a downwelling circulation that ultimately advected the bottom Cold Pool offshore nearly 30 kilometers. The limited mixing observed by the glider and model output support this finding. Previous studies have identified this type of circulation for persistent downwelling

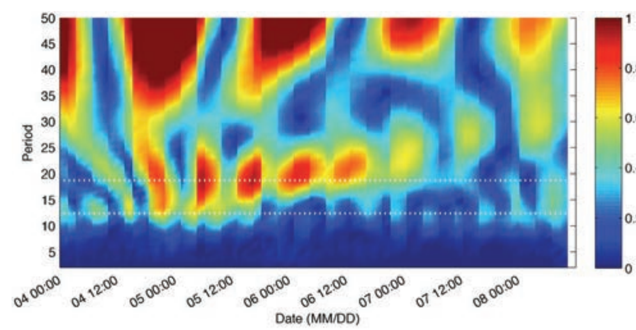

Figure 9 Wavelet spectrum of glider RU30 surface currents.

favorable winds, with deeper thermoclines resulting in more advection than shallower thermoclines [22], [23].

Hurricane Arthur, with its fast moving offshore track, and enhanced stratification did not setup advective downelling circulation on the MAB shelf. Rather the storm had limited direct mixing prior to eye-passage and enhanced mixing behind the eye during the post-storm inertial response. The shallower thermocline was more conducive to direct wind-forced mixing. Further analysis of these two storms, as well as Hurricane Irene are ongoing and provide a broad view of the three-dimensional processes that occur on the stratified MAB continental shelf during summer tropical cyclones.

The dynamic ocean response to these two storms indicates that fully coupled three-dimensional ocean and atmosphere models may be necessary to resolve changes to the surface ocean and further investigate the impact of the coastal ocean on atmospheric forecasts of hurricane intensity in the MAB. Further observational assets such as gliders and moorings should be included in data assimilation for these models to improve the accuracy the modeled ocean ahead of and during storm events. Future observational work will include downward looking current profilers to more accurately measure bottom stress, and accelerometers to resolve wave motions at glider locations.

V. Acknowledgements

Glider data used in this study is available through the MARACOOS assets page http://maracoos.org/data and http://marine.rutgers.edu/cool/auvs/index.php?did=369 with more detailed datasets available upon request to tnmiles@marine.rutgers.edu. Regional Ocean Modeling System and WRF model results are also available upon request to tnmiles@marine.rutgers.edu. Buoy data and WaveWatch III datasets are publicly available through http://www.ndbc.noaa.gov/ and http://polar.ncep.noaa.gov, respectively. We are grateful for the funding support provided by NOAA Grant NA11NOS0120038 as part of MARACOOS, the regional partner of U.S. IOOS and NOAA Grant NA13OAR4830233 as part of CINAR, the regional partner of the CIPO. We would also like to thank Teledyne-Webb Research for providing graduate student funding, NortekUSA for providing equipment through a student equipment grant.

Abstract

The Amundsen Sea Polynya is characterized by large phytoplankton blooms, which makes this region disproportionately important relative to its size for the biogeochemistry of the Southern Ocean. *In situ* data on phytoplankton are limited, which is problematic given recent reports of sustained change in the Amundsen Sea. During two field expeditions to the Amundsen Sea during austral summer 2010–2011 and 2014, we collected physical and bio-optical data from ships and autonomous underwater gliders. Gliders documented large phytoplankton blooms associated with Antarctic Surface Waters with low salinity surface water and shallow upper mixed layers (< 50 m). High biomass was not always associated with a specific water mass, suggesting the importance of upper mixed depth and light in influencing phytoplankton biomass. Spectral optical backscatter and ship pigment data suggested that the composition of phytoplankton was spatially heterogeneous, with the large blooms dominated by *Phaeocystis* and non-bloom waters dominated by diatoms. Phytoplankton growth rates estimated from field data ($\leq$ 0.10 day^{-1}) were at the lower end of the range measured during ship-based incubations, reflecting both *in situ* nutrient and light limitations. In the bloom waters, phytoplankton biomass was high throughout the 50-m thick upper mixed layer. Those biomass levels, along with the presence of colored dissolved organic matter and detritus, resulted in a euphotic zone that was often < 10 m deep. The net result was that the majority of phytoplankton were light-limited, suggesting that mixing rates within the upper mixed layer were critical to determining the overall productivity; however, regional productivity will ultimately be controlled by water column stability and the depth of the upper mixed layer, which may be enhanced with continued ice melt in the Amundsen Sea Polynya.

Introduction

The Southern Ocean is disproportionately important to the global biogeochemical system, accounting for up to half of the annual oceanic uptake of anthropogenic carbon dioxide (CO_2) from the atmosphere (Arrigo et al., 2008; Gruber et al., 2009). Models suggest that the vertical mixing there supplies enough nutrients to fertilize three-quarters of the biological production in the global ocean north of 30°S (Sarmiento et al., 2004). Given the large-scale documented changes being observed in many sectors of the Southern Ocean gaining a better understanding of the biogeochemical dynamics is critical (Ducklow et al., 2007; Schofield et al., 2010).

One region showing dramatic change is the Amundsen Sea, which is influenced by some of the largest and most rapid glacier melt and ice sheet thinning in the Southern Ocean (Rignot, 2008). The Amundsen

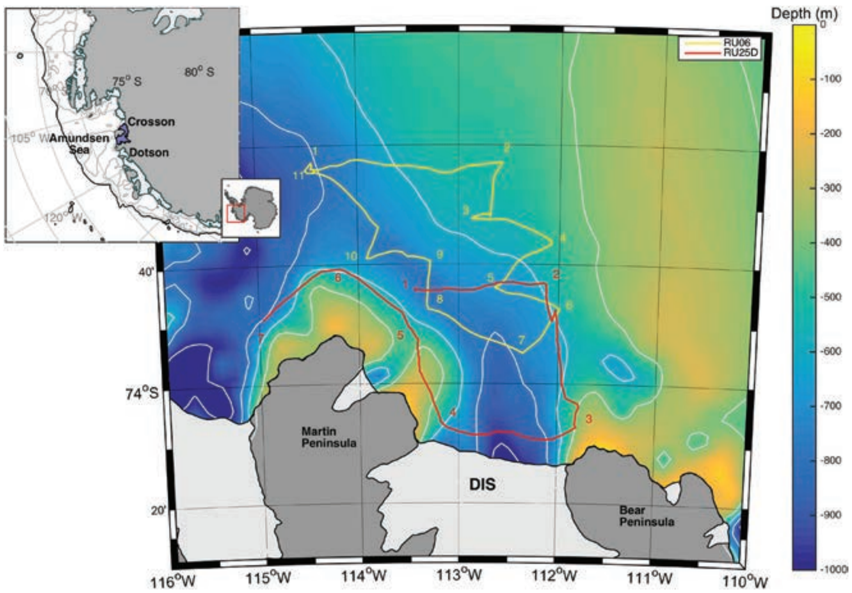

Figure 1

Map of the study area for the ASPIRE and KOPRI cruises.

The Amundsen Sea located near the Dotson and Crosson Ice shelves shown in blue on the inset map (adapted from Rignot et al., 2013). Colored lines indicate the glider missions: yellow for the glider mission during ASPIRE, red for the glider mission during the KOPRI cruise. Numbers on the lines are used to delineate different segments of a glider transect. Depths are indicated by the blue color scale and contour lines, the Antarctic continent is dark gray, and the ice shelves are light gray.

doi: 10.12952/journal.elementa.000073.f001

Sea (Figure 1) harbors two particularly productive polynyas, the Amundsen Sea Polynya (ASP) with an area of ~ 27,000 km^2 and the Pine Island Polynya at ~ 18,000 km^2 (Arrigo et al., 2012). The ASP is a perennially occurring latent heat polynya (Arrigo et al., 2012), though there are indications of a significant sensible component (Stammerjohn et al., 2015). A small portion appears to remain ice-free in winter, but in November it begins to expand, reaching a mean maximum opening in February, after which it rapidly closes in March. In the ASP, the length of the sea ice season has declined by 60 ± 9 days since 1979, a change largely due to the ASP opening earlier in the year by 52 ± 9 days (Arrigo et al., 2012). The shorter sea ice season facilitates increased solar ocean warming, leading to greater sea ice declines. The loss is hypothesized to reflect a poleward intensification of the prevailing storm tracks in the Amundsen-Bellingshausen Sea region (Marshall, 2007; Stammerjohn et al., 2012).

Changes in the Amundsen Sea have significant biological and chemical implications (Yager et al., 2012). The ASP is one of the most productive polynyas (per unit area) in the Antarctic (Arrigo and van Dijken, 2003). Satellite-derived seasonally averaged chlorophyll *a* levels (2.2 ± 3.0 mg m^{-3}) are 40% greater than the Ross Sea Polynya (RSP; 1.5 ± 1.5 mg m^{-3}). Primary productivity in Southern Ocean polynyas tends to be dominated by prymnesiophytes (*Phaeocystis antarctica*) or diatoms (Arrigo et al., 2008). The relative contributions of prymnesiophytes and diatoms reflect a complex interplay of physical circulation/mixing conditions, the light environment, and concentrations of macro- and micro-nutrients. A better understanding of the physical forcing of these communities is important because community composition has biogeochemical implications and this regional system is changing (Arrigo et al., 1999; Alderkamp et al., 2012; Fragoso and Smith, 2012). For example, *P. antarctica* takes up twice as much CO_2 per mole of phosphate removed as diatoms (Arrigo et al., 1999), it is not a preferred prey of microzooplankton (Caron et al., 2000), and its presence has been linked to dimethyl sulfide cycling between the ocean and atmosphere (Liss et al., 1994). The processes driving local productivity and community composition are affected by local weather, which results in high interannual variability in the phytoplankton concentrations (Smith et al., 2006). In the ASP, the interannual variability is higher (138%) than in the RSP (101%) (Arrigo and van Dijken, 2003), emphasizing the critical need to better understand the links between the physical environment of the Amundsen Sea region and the corresponding response in the phytoplankton communities.

Autonomous technologies, which have matured greatly over the last decade, provide means for sampling temporal and spatial domains that are difficult to resolve using traditional ship-based sampling (Davis et al., 2003; Schofield et al., 2007). Underwater Slocum gliders are effective at measuring a wide range of physical (temperature, salinity, currents; Schofield et al., 2007), chemical (oxygen) and bio-optical properties (spectral optical backscatter, chlorophyll fluorescence, colored dissolved organic fluorescence; Schofield et al., 2007; Glenn et al., 2008). Slocum gliders have proven to be effective at characterizing high-resolution horizontal scales, from tens of meters to thousands of kilometers with vertical resolutions < 1 m, and are important tools for studying physical/particle interactions in marine systems (Glenn et al., 2008; Rudnick and Cole, 2011; Miles et al., 2012; Xu et al., 2012; Schofield et al., 2013a).

Physical and bio-optical data were collected using both ship and gliders during two separate field expeditions to the Amundsen Sea. The combined data from both expeditions were used to assess commonalities in the phytoplankton distributions in the polynya. Both expeditions document that high phytoplankton biomass is associated with stratified, shallow, upper mixed layer depths, suggesting the critical role of light in promoting phytoplankton blooms.

Materials and methods

Data were collected during two expeditions to the Amundsen Sea in the South Pacific sector of the Southern Ocean in 2010 and 2013 (Figure 1). The majority of the data was collected during the 2010 field season of the Amundsen Sea Polynya International Research Expedition (ASPIRE; Yager et al., 2012). ASPIRE was conducted as part of the International Polar Year onboard the RVIB *Nathaniel B. Palmer* (NBP) chartered by the US National Science Foundation through its Antarctic Program. The primary objective of the ASPIRE program was to investigate the climate-sensitive processes driving the productivity and carbon sequestration of the ASP. The second data set was collected in January of 2014 as part of the ANA04B cruise of the Korean Polar Research Institute (KOPRI) onboard the IBRV Araon. This effort was conducted in the same area as ASPIRE, with a goal to understand regional circulation and corresponding impacts on Amundsen Sea biogeochemistry.

For both expeditions, discrete sampling was conducted with a CTD rosette outfitted with Niskin bottles allowing for water collection. In this paper we focus on the discrete data from the ASPIRE expedition. During ASPIRE, water was sampled with 12-L bottles from discrete depths in the upper 300 m of the water column at 19 stations (Sherrell et al., 2015). Continuous vertical profiles of temperature, salinity, irradiance, fluorescence, and beam attenuation were obtained from the water column using a SeaBird 911+ CTD, a Chelsea fluorometer, photosynthetically active radiation (PAR) sensor (Biospherical Instruments), and a 25-cm WetLabs transmissometer, mounted on a conventional rosette, deployed using a kevlar cable and winch. Discrete water samples were analyzed for chlorophyll *a* and phytoplankton accessory pigments. Chlorophyll *a* samples were filtered onto 25 mm Whatman GF/F filters, extracted overnight in 5 ml of 90% acetone, and analyzed on a Turner Model 10AU fluorometer before and after acidification (Holm-Hansen et al., 1965). High pressure liquid chromatography (HPLC) analyses were conducted on discrete samples to provide estimates of the chlorophylls and carotenoids. For the HPLC samples, 0.1–2 L were filtered onto 25 mm Whatman GF/F filters, flash-frozen in liquid nitrogen, and stored at –80°C until analysis on a Schimadzu system according to Wright et al. (1991). Chlorophyll *a* measurements on the discrete samples at the time of glider deployments (see below) were considered the "correct values" and used to adjust fluorometric estimates of chlorophyll *a*. Given the relatively short deployment times (just under two weeks) we assume that bio-fouling was negligible.

During both of these expeditions, Webb Slocum gliders (Schofield et al., 2007) were deployed to provide high-resolution surveys of the physical and bio-optical properties near the ice edge (Figure 1). Slocum gliders are autonomous buoyancy-driven vehicles. These 1.5 m long platforms maneuver up and down within the water column through the ocean at a forward speed of 20–30 cm s^{-1} in a sawtooth-shaped gliding trajectory by means of a buoyancy change, where wings translate the sinking motion, due to gravity, into the forward direction. A tail fin rudder provides the steering. The forward navigation system of the vehicle is based on an onboard GPS receiver coupled with an attitude sensor, depth sensor and altimeter. This configuration allows for "dead-reckoning" navigation to a designated waypoint based on the desired target location. Additionally the altimeter and depth sensor allow scientists to program the sampling in the water column. Global iridium phones embedded within the glider tails are periodically raised out of the water when the vehicle sits at the surface at predetermined intervals. Once at the surface, the glider retrieves its position, transmits data to shore, and checks for any programmed changes to the mission. For the gliders, sensor data are logged every 2 seconds on downcast and upcast as it travels with vertical speeds of 20 cm s^{-1}, resulting in high data density relative to traditional shipboard sampling. The gliders used in this study were G2 gliders equipped with a suite of oceanographic sensors. This suite included three science sensors: a Seabird unpumped conductivity temperature and depth (CTD) sensor, a Wetlabs triplet sensor, and an Aanderaa oxygen Optode. While a pumped CTD is preferred to minimize any thermal lag associated with the conductivity cell, none was available for these efforts; however, there was no evidence of salinity spiking, suggesting no bias in the derived salinity values resulting from thermal inertia. Prior to and after deployment, the glider CTD was compared to independent CTDs in a tank test, and the results indicated that the glider CTD did not exhibit any drift.

The pre- and post-dive latitude and longitude of the glider, along with glider pitch, heading, and vertical velocity, were combined to calculate dead-reckoned currents (Davis et al., 2003). The horizontal velocity of the glider was estimated using simple geometry by combining the systems-measured pitch angle and the vertical velocity calculated from the change in pressure with time, while the glider compass was used to determine heading. The instantaneous horizontal velocities were integrated in time for the duration of the glider dive time to obtain an estimated glider position independent of ambient currents. The difference between the estimated surfacing position and actual position divided by the duration of the dive results in a time- and depth-integrated, dead-reckoned water column velocity. The largest source of error in this method of current calculation is the calibration of the glider compass. Both RU06 and RU25D compasses were calibrated

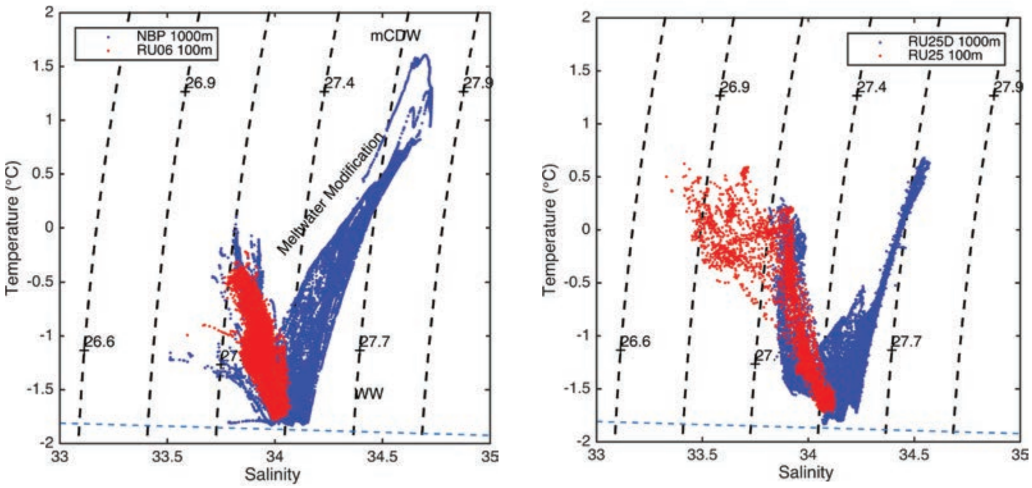

Figure 2

Temperature and salinity properties measured during the ASPIRE and KOPRI cruises.

Shown in (A) are the temperature and salinity properties measured during ASPIRE in austral summer of 2010–2011 using both the CTD from the ship (NBP) over the full 1000-m water column (blue) and the glider (RU06) which profiled only the upper 100 m (red). Glider data from the KOPRI cruise in austral summer of 2013–2014 are shown in (B) where blue indicates glider data for the full water column (RU25D) and red indicates glider data from the upper 100 m (RU25). Side by side casts of the ship CTDs and the gliders showed that both measured the same features in the water column, as shown for ASPIRE data in (A). Glider measurements for temperature were lower than the CTD by 0.05° C. Glider measurements for salinity were lower than the CTD by 0.01. We took the ship CTD data as correct and adjusted the glider measurements by those offsets.

doi: 10.12952/journal.elementa.000073.f002

following manufacturer specifications and checked using an 8-point heading test prior to deployment. This dead-reckoned current estimation method has been used extensively in a range of conditions (Glenn et al., 2008; Merckelbach et al., 2008; Miles et al., 2012, 2015a) and has been shown to perform well compared to moored acoustic Doppler current profilers (Davis et al., 2003).

In order to assess the influence of tidal velocities on glider currents for each deployment, we extracted all ten tidal constituents from the Circum-Antarctic Tidal Simulation Model (CATS2008b) (Padman et al., 2002) in the vicinity of the deployments (74° S and 112.5° W). CATS2008b represents the barotropic tidal velocities and has been used in previous studies in the Amundsen Sea Polynya (Wåhlin et al., 2010, 2012; Assmann et al., 2013; Ha et al., 2014).

ASPIRE took place between 25 November 2010 and 18 January 2011. Two glider deployments were conducted while in the ASP; the first mission (Dec 15–28) covered 300 km in 13 days. The glider was recovered and redeployed for a second shorter deployment (Jan 01–05) covering 75 km in 3.5 days. The glider for this mission (RU06) was outfitted with a 200-m buoyancy pump and a non-pumped SBE41cp Seabird Conductivity-Temperature sensor, though it only profiled in the upper 100 m of the water column. There was good agreement between the glider and ship rosette temperature and salinity data (Figure 2). The glider was also equipped with two WET Labs Environmental Characterization Optics (ECO) pucks. The ECO pucks measured chlorophyll *a* fluorescence, colored dissolved organic matter (CDOM) fluorescence and optical backscatter at 470, 532, and 660 nm. The CDOM fluorometer was outfitted with an excitation wavelength of 370 nm and emission wavelength of 460 nm, with the sensor having a sensitivity of 0.09 ppb. The ECO Pucks were factory-calibrated prior to deployments. The backscatter measurements were measured at 117 degrees, the angle determined as a minimum convergence point for variations in the volume-scattering function induced by suspended materials and water itself. We converted from the volume-scattering function to estimated backscatter coefficients following Boss and Pegau (2001). As a result, the signal measured was less determined by the type and size of the materials in the water and more directly correlated to the concentration of the materials.

For the KOPRI expedition (27 December 2013 – 18 January 2014), the RU25D glider was outfitted with a 1000-m pump, a non-pumped SBE41cp Seabird Conductivity-Temperature sensor, a single WET Labs puck configured to make measurements of optical backscatter at 470 and 532 nm, along with chlorophyll *a* and CDOM fluorescence and an Aandeara oxygen optode. This deep-water glider conducted a 234-km mission over 9 days (04–14 January 2014).

Ship-based ocean currents during ASPIRE were measured with a 'narrow beam' 150-kHz and 'Ocean Surveyor' 38-kHz hull mounted Acoustic Doppler Current Profilers (ADCP) from Teledyne RD Instruments, Inc. The ADCP data were calibrated and post-cruise corrected by the University of Hawaii. The Teledyne instrument provides accurate data to a depth of 400 m, while the Ocean Surveyor data cover a larger depth range but with coarser vertical resolution.

Ocean color imagery was obtained from the National Aeronautics and Space Administration (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) onboard the polar orbiting Aqua satellite. The products used here are the standard level-3 mapped 8-day composites for chlorophyll *a* (obtained from http://oceancolor.gsfc.nasa.gov/). Typically for these waters, satellite-derived chlorophyll concentrations tend to be under-estimated (Johnson et al., 2013); therefore, these maps should be considered lower limit estimates.

The mean satellite-derived chlorophyll fields, as well as the integrated water column chlorophyll data measured by the gliders, were used as inputs to the Hydrolight 4.3 radiative transfer model (Mobley, 1994) to estimate optical properties within the water. For the Hydrolight simulations, we used default settings and assumed a constant backscatter to total scatter ratio of 0.005. We assumed there was no inelastic scattering and kept wind speeds at zero. The surface flux of light was calculated using a semi-empirical sky model (Mobley, 1994) at local noon on a cloudless day. We assumed that the water column was infinitely deep. These Hydrolight simulations assumed no vertical structure in the phytoplankton biomass. For these simulations we treated these waters as Case I waters (Mobley et al., 1994).

Results

Water masses and flows along the ice sheet in the Amundsen Polynya

Ship and glider surveys encountered three major water masses in this region: Antarctic Surface Water (AASW), Winter Water (WW), and modified Circumpolar Deep Water (mCDW). AASW was observed by ships and gliders during both ASPIRE and KOPRI cruises (Figure 2). It ranged in thickness from ~ 5 to 80 m and was characterized by low salinity (< 34.1), presumably freshened by sea ice melt, and by a temperature range of −1.8 to > 0°C (Figures 3, 4). The glider encountered, at lower latitudes, low salinity surface water (salinity values reduced by ≥ 0.3) (Figure 3, 4). Cold (< −1.7°C) WW, with a well-defined salinity value (34.14) reflecting sea ice growth during the previous winter, was typically found extending either from the surface or from the AASW layer down to 300–400 m depth (Figure 4). The warmer (0.6 to 1.2°C) and saltier (34.5 to 34.7) mCDW was observed by RU25D, with warmest temperatures encountered below 600 m (Figure 4A, 5A). Regions with low surface salinity generally had homogeneous mixed layers with a stratified region at base over the WW. We defined the upper stratified layer by the depth of the highest water column buoyancy frequency (N^2). The upper mixed layer ranged from 20 to 80 m in depth (Figures 3D, 4D, 5D). Highest chlorophyll was associated with water columns when the N^2 was shallower than 50 m. During ASPIRE the shallow upper mixed layers and highest chlorophyll were associated with regions of lower surface salinity. During the KOPRI effort the shallow upper mixed layers and highest chlorophyll were associated with regions of warm surface waters (0.0–0.5° C). Possible reasons for these differences might reflect the general position of the glider missions, as the KOPRI glider surveyed directly adjacent the outflow at the ice edge while the ASPIRE glider surveyed further offshore in the polynya potentially allowing for radiant heating as the water flowed offshore (Figure 1).

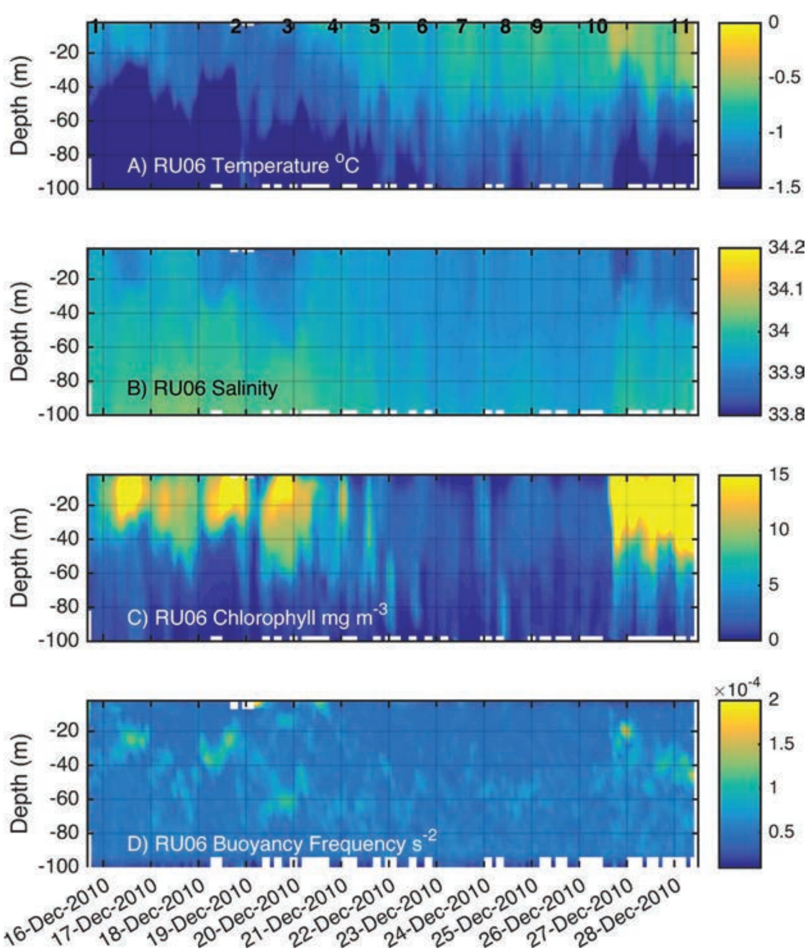

Figure 3

The water column data collected by the Webb Slocum glider during the ASPIRE cruise.

Temperature, salinity, chlorophyll fluorescence and buoyancy frequency are shown for the upper (100-m) water column, as measured by glider RU06. Temperature ranged from 0.0 to −1.5° C (A); salinity showed a range of 0.3 (B); chlorophyll fluorescence showed a range of 30 mg m^{-3} (C); and buoyancy frequency (s^{-2}) ranged in magnitude two-fold. The numbers along the top (A) are the markers of glider mission segments identified on the yellow line in Figure 1.

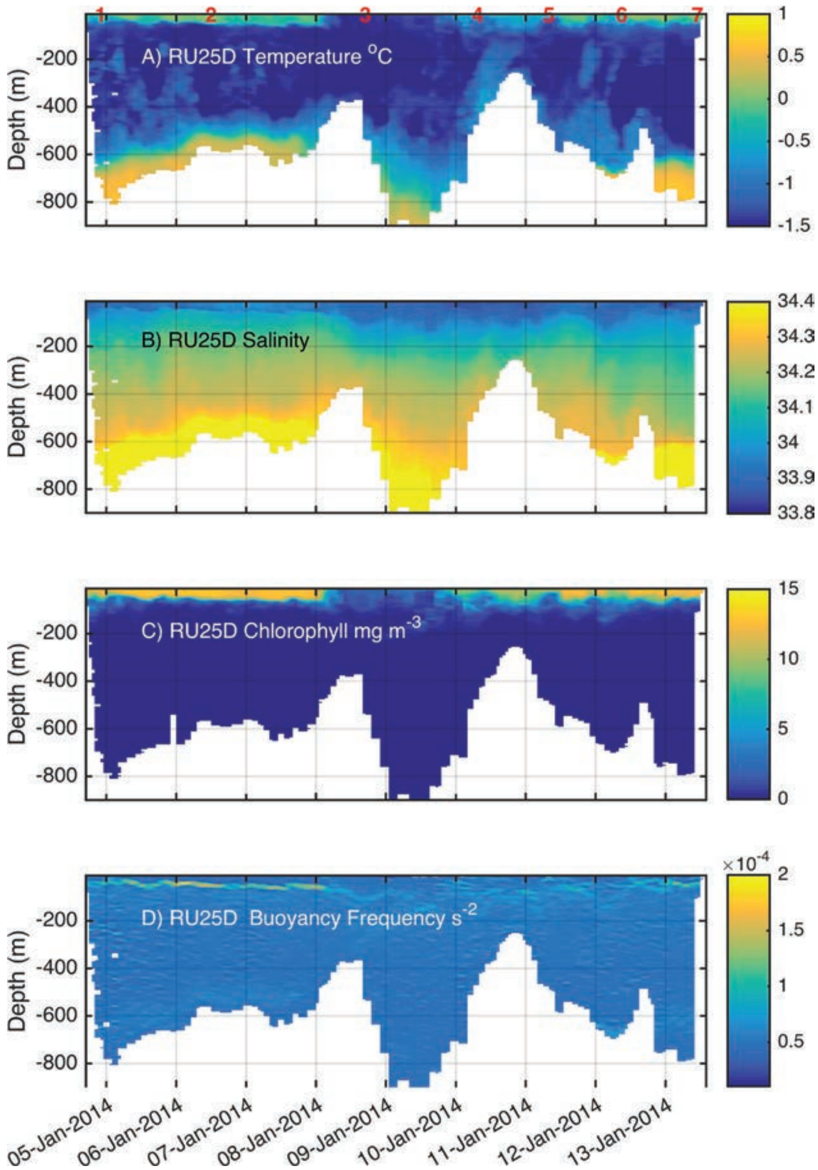

Figure 4

The full water column data collected by the deep-water glider during the KOPRI expedition.

Temperature, salinity, chlorophyll fluorescence and buoyancy frequency are shown throughout the water column, as measured by deep-water Webb glider RU25D. Temperature ranged from 1.0 to −1.5° C (A); salinity showed a range of 0.6 (B); chlorophyll fluorescence showed a range of 30 mg m^{-3} (C); and the buoyancy frequency (s^{-2}) calculated from the glider data ranged in magnitude greater than two-fold (D). The numbers along the top (A) are the markers of glider mission segments identified on the red line in Figure 1.

doi: 10.12952/journal.elementa.000073.f004

During ASPIRE, the ship and glider observed similar flow patterns. The depth-averaged currents from RU06 indicated the upper 100 m was characterized by low mean northward flow of 0.056 m s^{-1} and a mean east–west flow of –0.048 m s^{-1} (Figure 6, top panel) originating from the Dotson Ice Shelf. The shipboard along-shelf ADCP transect confirmed northward flow in the upper 100 m (Figure 7) with current speeds ranging from 0.15 to 0.05 m s^{-1}, similar in magnitude to the depth-averaged currents measured by the glider. The deeper current velocities measured by the ship showed depth dependence and spatial variability (Figure 7). At the eastern edge of the along-shelf transect, subsurface water (> 200 m) flowed south towards the ice sheet. On the western edge, bottom waters associated with a shallowing bathymetry showed subsurface waters (> 200 m) with a northward flow (> 0.25 m s^{-1}) associated with a topographic high. During most of the ASPIRE glider deployment, wind levels were consistent in direction and velocity; except during a few hours at the start of deployment, winds were consistently less than 10 m s^{-1}. Therefore, significant regional shifts in the upper ocean circulation were not likely driven by significant changes in weather forcing.

During the KOPRI cruise, RU25D encountered mean offshore flow relative to the Dotson Ice Shelf in the northwestern regions of the study area (Figure 8). Potential outflow of the deeper mCDW was observed on the western flank of the canyon during the KOPRI cruise. This outflow was seen as a filament of higher temperature water on the canyon edge (Figure 4, between segment 4 and 5 denoted at the top of panel A), located below 200-m water depth, and, like the ASPIRE ADCP sections, was associated with a shallowing of the seafloor. Generally, tidal currents were small relative to glider dead-reckoned velocities and thus were

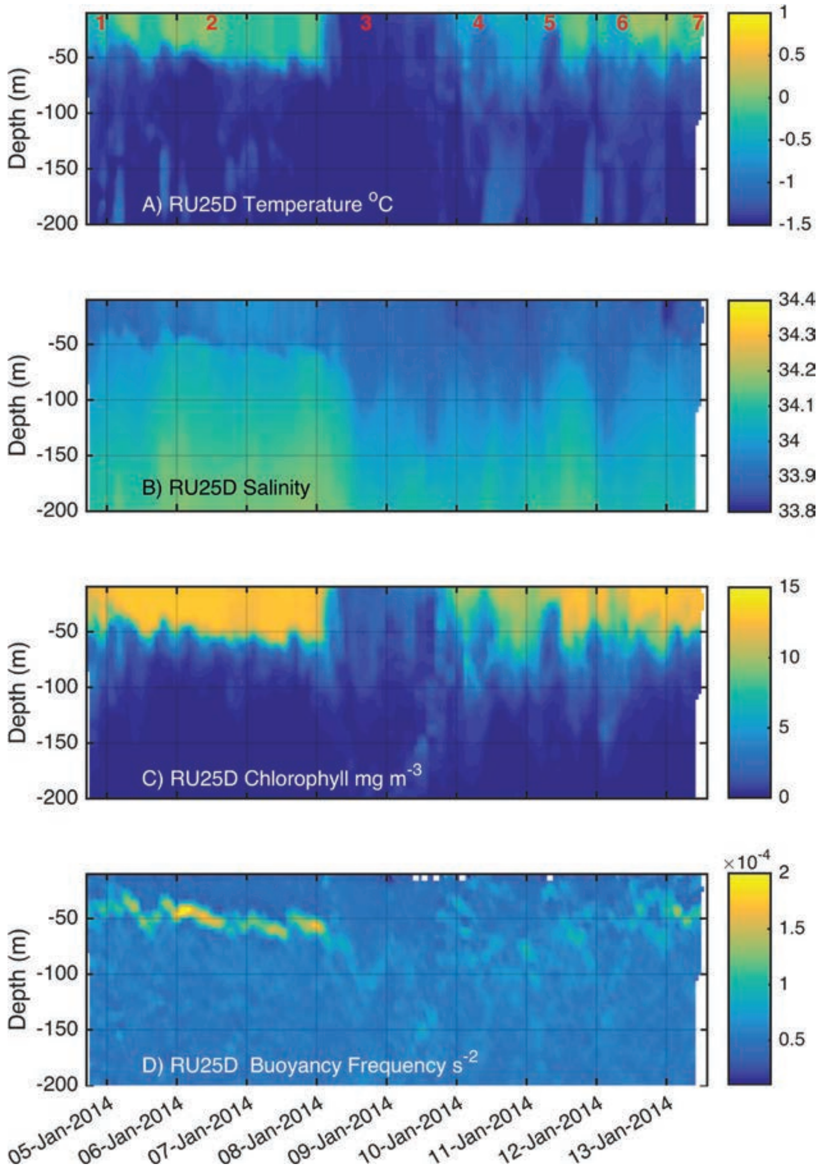

Figure 5

The upper 200-m water column data collected by the deep-water glider during the KOPRI expedition.

Temperature, salinity, chlorophyll fluorescence and buoyancy frequency are shown for the upper 200 m of the water column, as measured by deep-water Webb glider RU25D. Temperature ranged from of 0.0 to –1.5° C (A); salinity showed a range of 0.3 (B); chlorophyll fluorescence showed a range of 30 mg m^{-3} (C); and the buoyancy frequency (s^{-2}) calculated from the glider data ranged in magnitude just under two-fold (D). The numbers along the top (A) are the markers of glider mission segments identified on the red line in Figure 1.

doi: 10.12952/journal.elementa.000073.f005

not considered to greatly impact interpretation of mean flow patterns as derived from the glider and ship transects (Figures 6 and 8).

Bio-optical properties of the Amundsen Sea Polynya

Both the ASPIRE and KOPRI cruises coincided with the development of the phytoplankton spring/summer bloom (Figure 9). The timing of the peak phytoplankton concentrations in January was consistent with past studies (Arrigo et al., 2012). In both years, blooms were concentrated over deep water with lower phytoplankton biomass observed near the ice edge and on the shallower banks to the north (Figure 9). Satellite imagery indicated low biomass adjacent to the ice shelf consistent with ship and glider data; therefore, the land adjacency effects in the satellite imagery likely did not account for low values nearshore.

During ASPIRE, the RU06 mission was conducted when satellite-derived chlorophyll *a* concentrations (8-day average) ranged from < 1 to 10 mg m^{-2} (Figure 9). Highest phytoplankton biomass was found at the northern edge of the seafloor canyon, with lower levels on the northern polynya sea ice edge and bordering the Dotson and Getz ice shelves. By the end of the deployment, MODIS imagery showed that chlorophyll biomass had increased by ten-fold in the region (Figure 9). Glider chlorophyll estimates ranged from 1 to 15 mg chlorophyll *a* m^{-3}, which was similar to satellite estimates. During the KOPRI expedition, the blooms were spatially extensive with higher biomass observed throughout the same northern sector of the polynya

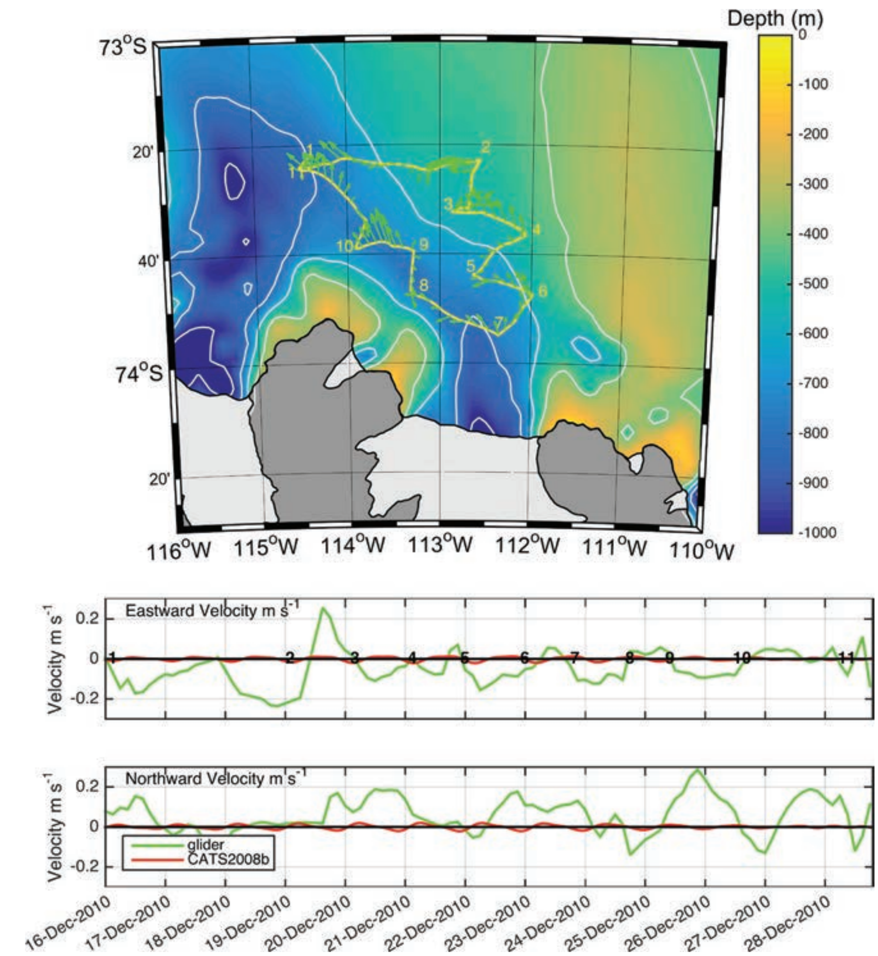

Figure 6

The depth-averaged current velocity and directional components estimated from the ASPIRE glider experiment.

The current velocity representing the average for the upper 100 m of the water column in austral summer 2010–2011 is shown for the study region, with the eastward and northward velocity components derived from the glider (green line) and modeled for the tides (red line). Numbers on the map and in the eastward velocity panel indicate segments of the glider mission presented in Figure 1.

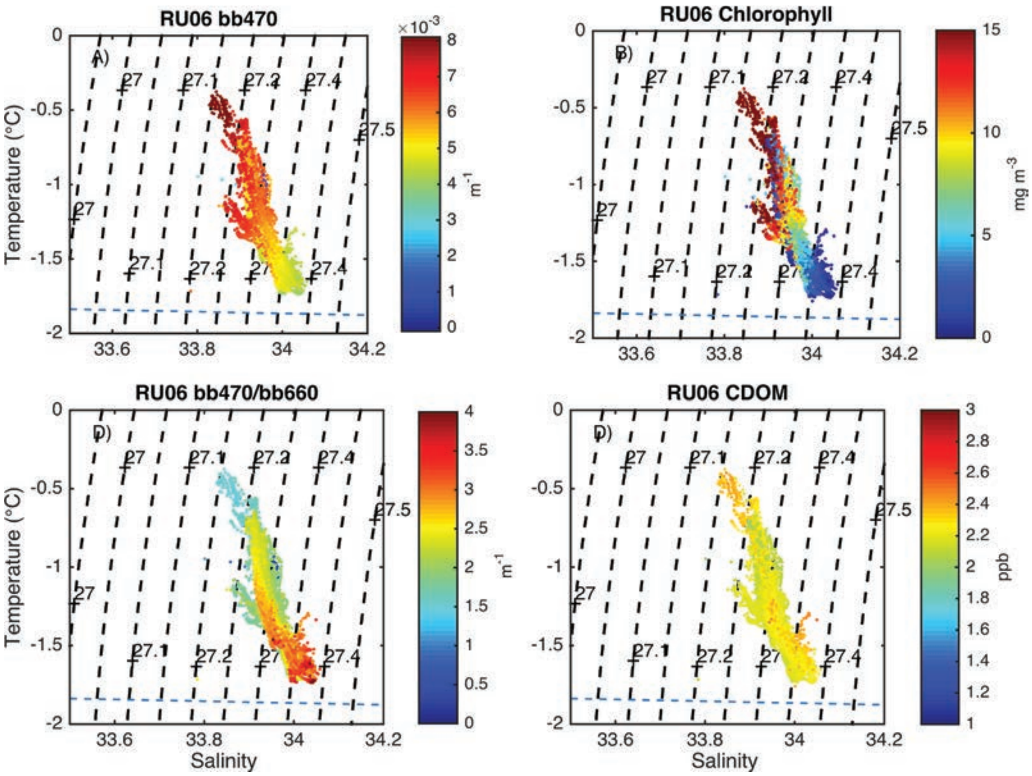

Figure 10

Bio-optical properties in temperature-salinity space measured by a 100-m glider experiment during the ASPIRE cruise.

Water column properties measured by Webb glider RU06 over a 100-m deployment are presented as a function of temperature and salinity: (A) optical backscatter at 470 nm (bb470 nm); (B) chlorophyll estimates (mg m^{-3}) from fluorescence; (C) the ratio of 470 to 880 nm optical backscatter (bb470/bb660); and (D) the fluorescence of colored dissolved organic matter (CDOM).

doi: 10.12952/journal.elementa.000073.f010

with the peak concentrations occurring in the first week of January (Figure 9B). The bloom appeared to have begun prior to the deployment of the glider with biomass remaining high by mid-January (Figure 9).

Glider surveys during ASPIRE indicated phytoplankton and particle concentrations were highest in warm (–1 to –0.5° C) lower salinity (< 34) AASW (Figures 10). In contrast, CDOM fluorescence indicated relatively uniform distributions across the temperature and salinity range encountered by the glider; therefore, the CDOM fluorescence did not have much power in discriminating water masses in this region. This finding was consistent with results from the Aaron expedition, when water masses were less well discriminated by CDOM compared to optical backscatter or oxygen data (Figure 11). Consistent with ASPIRE, during the Aaron cruise the highest values of optical backscatter were observed in the warm low saline waters (Figure 11). Fluorescence-based estimates of chlorophyll were > 10-fold higher in warmer and lower saline surface waters. Chlorophyll fluorescence measurements indicated concentrations > 15 mg m^{-3}. Chlorophyll fluorescence at ASPIRE glider recovery (same location after 13 d; Figure 12) showed a 5-fold increase relative to when the glider was deployed. This increase was consistent with the increasing chlorophyll concentrations observed in the satellite imagery (Figure 9). While chlorophyll increased dramatically, water temperature increased by < 0.5° C with a corresponding decrease of salinity by 0.1, suggesting a water mass with similar hydrographic features as when deployed. During the deployment there were steady, low wind speeds (10 m s^{-1}) which, combined with the depth-averaged flow measured by the glider, suggests flow from the low biomass waters near the ice sheet to the high biomass waters within the polynya. Given the minor shifts in water properties and transport, if we assume biomass accumulation represents the net growth rate of the phytoplankton, this observed increase translates to a net growth rate of ~ 0.10 d^{-1}. During the ASPIRE cruise deckboard incubations of natural phytoplankton populations over a range of modified light levels and micronutrient conditions exhibited growth rates that ranged from 0.07 to 0.28 d^{-1} (Alderkamp et al., 2015). Lowest growth rates were observed for low light (1% light incubation levels) and low iron (Fe) conditions consistent with the ambient conditions of the AASW (Alderkamp et al., 2015).

High phytoplankton biomass in the AASW resulted in extremely turbid surface waters. The depth of the 1% light level ranged from 5 to 40 m during ASPIRE, as measured with the CTD rosette and modeled based on chlorophyll inputs into the Hydrolight model. The high biomass layers ranged in thickness from 20 to 50 m, consistent with the depth of the upper mixed layer. The fluorescence estimates of chlorophyll showed little variability in the upper mixed layer. Thus, given the high biomass and depth of the upper mixed layer, the majority of the phytoplankton biomass resided well below the 1% light level at any given time. Photosynthesis-irradiance curves indicated the light saturation intensity for photosynthesis (E_k) ranged from 37 to 67 □mol photons m^{-2} s^{-1} (Alderkamp et al., 2015), which was consistent with low-light-acclimated phytoplankton populations when compared to average water column measurements of E_k in other pelagic

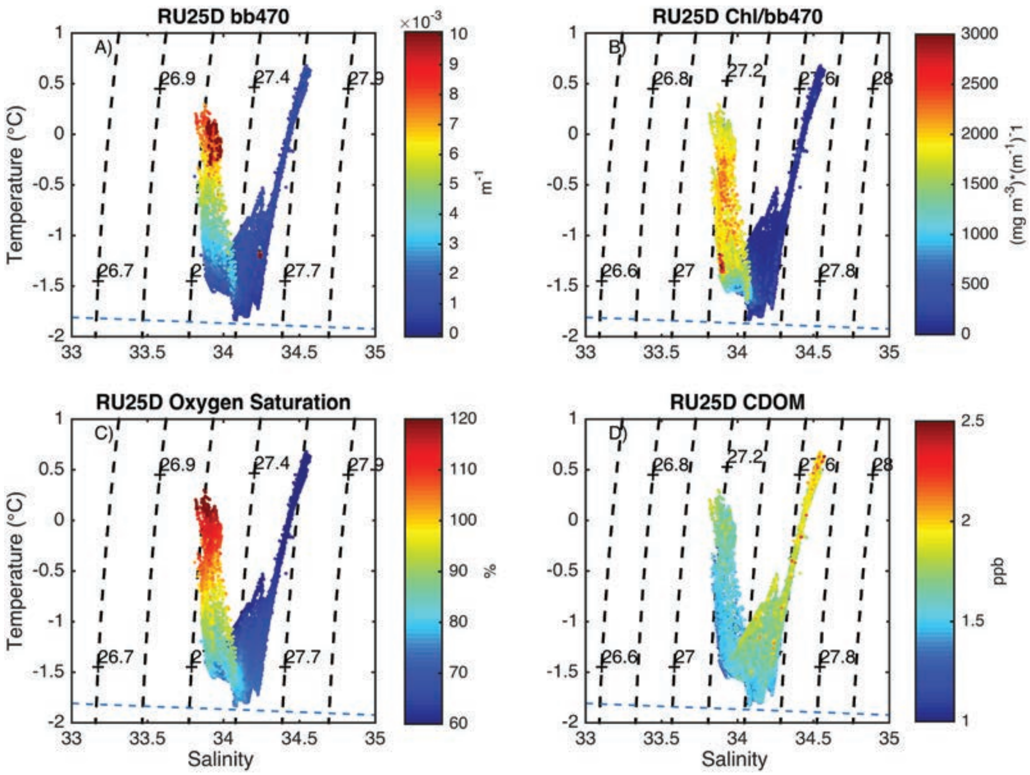

Figure 11

Bio-optical properties in temperature-salinity space measured by a 1000-m glider experiment during the KOPRI expedition.

Water column properties measured by Webb glider RU25D over a 1000-m deployment are presented as a function of temperature and salinity: (A) optical backscatter at 470 nm (bb470); (B) the ratio of chlorophyll from fluorescence to backscatter at 470 nm (mg m^{-3}/bb470); (C) the oxygen concentration (% saturation); and (D) the fluorescence of colored dissolved organic matter (CDOM).

doi: 10.12952/journal.elementa.000073.f011

and coastal locations in the Southern Ocean (Moline et al., 1998). While low salinity AASW was associated with regions of high phytoplankton biomass, it was not a guarantee of high phytoplankton biomass. During the KOPRI expedition high biomass was observed only when low salinity surface waters were confined to < 50 m. Near and along the ice edge, phytoplankton biomass was low within the upper 150 m despite the observed lower salinity (Figures 3, 5). Here, low water column stability confirmed the critical requirement of light in contributing to the phytoplankton blooms. There was a significant relationship with the depth of the upper mixed layer as defined by the maximum N^2 and the mean chlorophyll in the upper water column during both the ASPIRE and KOPRI expeditions (Figure 13; RU06 R^2 = 0.43 and p-value

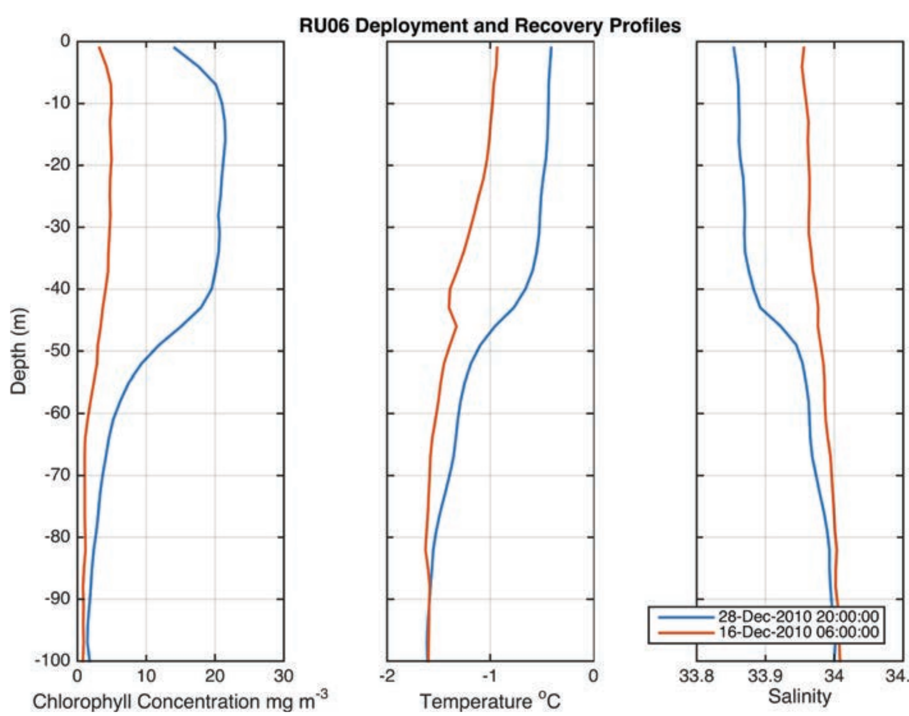

Figure 12

Depth profiles of chlorophyll fluorescence, temperature, and salinity at time of glider deployment and recovery.

The chlorophyll fluorescence (mg m^{-3}), temperature (°C), and salinity are shown as a function of depth for the deployment (green line) and recovery (blue line) of Webb Slocum glider RU06. The deployment and recovery locations were at the same geographic location (73 23 12°.15'S and 114 26° 04.91W).

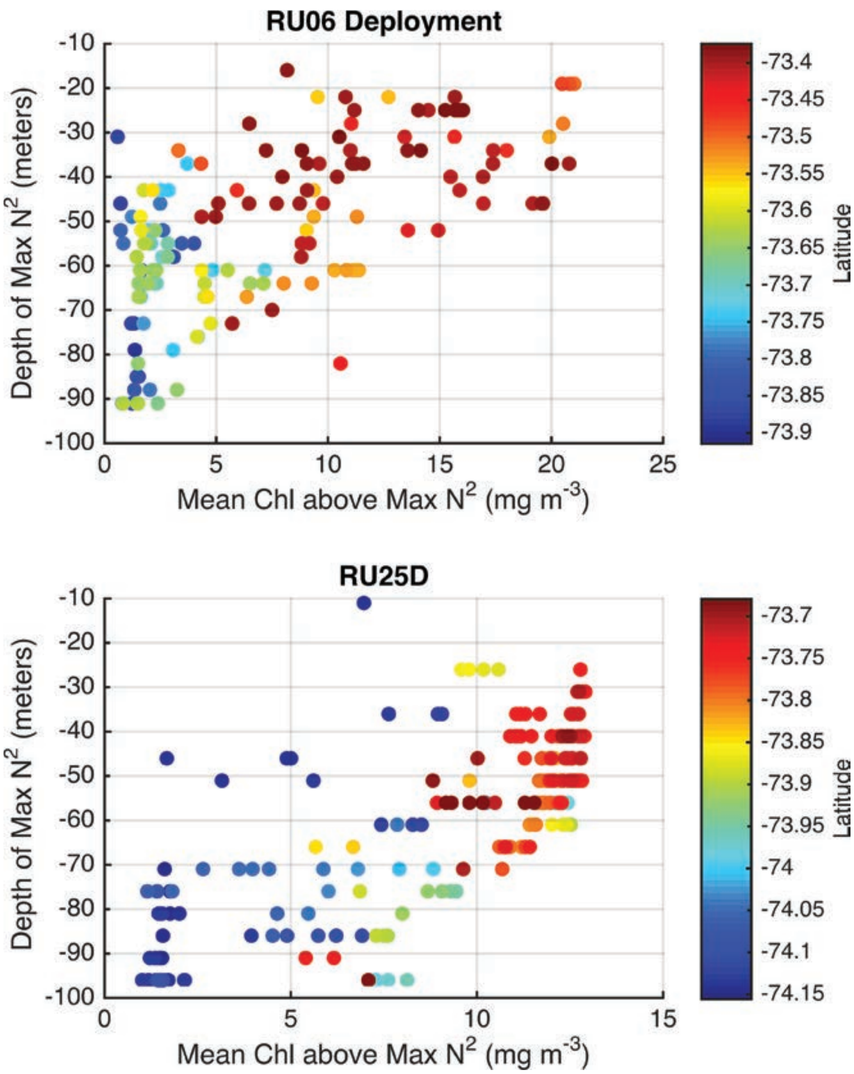

Figure 13

Relationship between depth of maximum water column buoyancy frequency (N^2) and mean chlorophyll concentration.

The relationship between the depth of maximum water column buoyancy frequency (N^2) and the mean chlorophyll *a* concentration (mg m^{-3}) is shown for the water column above the maximum N^2 depicted in Figures 4 and 5. The colors indicate the latitude of the water column measurements. Red colors generally indicate distance away from the ice shelf.

doi: 10.12952/journal.elementa.000073.f013

< 0.001, RU25D R^2 = 0.59 and p-value < 0.001). Higher chlorophyll was associated with lower latitudes (Figure 13) located offshore the ice edge (Figure 1B). The higher N^2 associated with the offshore waters was associated with increased solar warming of surface waters and the increased inputs of freshwater from sea ice melt (Alderkamp et al., 2015).

During ASPIRE, bio-optical data suggested that the nature of the particulate matter was unique in the lower salinity surface water compared to high salinity surface water. While fluorescence-based phytoplankton biomass estimates correlated with optical backscatter (for RU06 and RU25D, R^2 = 0.92 and 0.90, respectively, p-value < 0.001), there was variability in the chlorophyll/backscatter and spectral backscatter ratios (Figure 10, 11). The spectral optical backscatter ratio (470 nm/660 nm) was lower in the AASW. The portions of the water column associated with high values of optical backscatter at 470 nm had low spectral backscatter ratios (470 nm/660 nm; Figure 10). In the high backscatter regions, the 20–30% range in the spectral ratio reflected a flattening in the backscatter spectrum, indicating either a change in the particle size distribution or a change in the organic/inorganic make-up of the particles (Boss et al., 2004). Furthermore, the variability in backscatter spectra suggests that it would be difficult to convert the backscatter data to a particle concentration without information on the particle type and size distribution (Boss et al., 2004). Pigment analyses revealed that the high biomass waters were dominated by prymnesiophyte algae, as indicated by HPLC measurements of 19′-hexanoyfucoxanthin. Microscopic examination identified *Phaeocystis pouchetti* as the dominant species present. The low chlorophyll concentrations were characterized by diatom communities, as indicated by the presence of fucoxanthin. These shifts were consistent with the spatial variability in the optical backscatter ratio.

Discussion

Understanding the physical regulation of primary productivity and community structure along ice shelves and polynyas is critical to understanding the regional ecology and biogeochemistry. Polynyas in the Amundsen Sea region are characterized by large phytoplankton blooms (Arrigo et al., 2012; Lee et al., 2012) and are experiencing change due to climate forcing (Holland, 2014). Phytoplankton studies in key polynyas to date have focused on defining the relative importance of nutrient versus light regulation (Lee et al., 2012), with numerous efforts focusing on the importance of iron (Fe) in driving phytoplankton growth in polynyas (Buma et al., 1991; Sedwick and DiTullio, 1997; Sedwick et al., 2000; Tagliabue and Arrigo, 2005).

Deckboard incubations during ASPIRE confirmed the importance of Fe in promoting accelerated growth in phytoplankton (Alderkamp et al., 2015). There are several potential sources of Fe reflecting a range of ocean-ice sheet-seafloor interactions. The potential sources of Fe include basal melting of glaciers and beneath ice shelves, sediment resuspension within the sub-glacial cavity and at grounding lines, and direct input from calved icebergs (Gerringa Loes et al., 2012; Yager et al., 2012). While these sources are sufficiently large to support large phytoplankton blooms (Sherrell et al., 2015), deckboard incubations suggest increased input of Fe could increase primary productivity by a factor of 1.7 (Alderkamp et al., 2015).

The mCDW subsurface outflow from the ice sheet appears to be a major source of dissolved and particulate iron to the polynya (Gerringa Loes et al., 2012; Sherrell et al., 2015). Driven by Coriolis and pressure gradient forces, the relatively dense CDW travels along-isobath toward the ice shelves with the coastline to the left of the flow. This warm water mass affects the glaciers and ice shelves, melting ice and forming a modified CDW (mCDW) and meltwater mixture (Jenkins, 1999; Walker et al. 2007; Jenkins and Jacobs, 2008; Jenkins et al., 2010; Jacobs et al., 2011). Presumably the meltwater input increases buoyancy of the mCDW, causing upwelling, while the Coriolis force drives outflows on the southern and western sides of the ice shelves dependent on bathymetric orientation. The micronutrients associated with outflow can fuel productivity if mixing carries the deeper water into the euphotic zone. It has been hypothesized that transport of subsurface water to the surface is driven by horizontal diffusivity (Gerringa Loes et al., 2012), advective eddy transport (e.g., Årthun et al., 2013), mixing along the Dotson trough (St-Laurent et al., 2013), and wind- and iceberg-induced mixing (Randall-Goodwin et al., 2015). Given the slow, calculated *in situ* and deckboard growth rates of the phytoplankton and the observed high biomass, injection of nutrients through destratification of the full water column followed by stratification and subsequent regrowth is unlikely. The injection of micronutrients would thus likely be dominated by horizontal and vertical advection and diffusive mixing. Observations suggest that dissolved iron- and meltwater-rich deep water shoals from the basal ice shelf towards the central polynya and likely supports the bloom there (Sherrell et al., 2015). Recent results in the ice shelf outflow region, showing decreasing optical backscatter with proximity to the seafloor, suggest that particulate matter, which had a linear relationship with meltwater concentration, was sourced from the overlying glacier rather than resuspended sediment (Miles et al., 2015b).

The robust relationship between water column stability and chlorophyll concentration suggests the importance of the light environment in driving phytoplankton standing stock in the ASP. The high concentrations of phytoplankton encountered in this polynya indicate an extremely productive system. Productivity rates are similar to the high productivity rates found along the West Antarctic Peninsula (WAP; Ducklow et al., 2007), with the contrast that along the WAP the high productivity regions are associated with diatoms (Hart, 1942; Moline et al., 2004; Vernet et al., 2008; Montes-Hugo et al., 2009). The high productivity rates associated with *Phaeocystis* in the ASP are consistent with the Ross Sea (Smith et al., 1998, 2003). Additionally, the high concentrations of chlorophyll encountered during the ASPIRE and KOPRI cruises are consistent with past ship (Lee et al., 2012) and satellite studies (Arrigo et al., 2012). Given the high biomass in these waters, satellite estimates of chlorophyll would underestimate the overall biomass significantly, as the depth of the satellite section would span only the upper few meters of the water column, missing the majority of the phytoplankton biomass (Kirk, 2011).

The ASP with its high biomass conditions represents a unique environment in which the interplay between nutrient availability and light limitation is extremely complex (Dubinsky and Schofield, 2009). Phytoplankton populations are capable of photoacclimating to low light conditions and measured photosynthesis-irradiance curves during ASPIRE indicated the cells were low light-adapted (Alderkamp et al., 2015); however cells were still often chronically light-limited. This was especially true as the upper mixed layer was often deeper than the euphotic zone (defined as the 1% light level). The net result is that in the high biomass waters any small shift in the mean position of phytoplankton in the water column (meters) could shift a cell from being light-saturated to being light-limited; therefore, cell motility and/or mixing within the turbid upper mixed layer waters must play a predominant role in determining the overall water column productivity and corresponding growth of the phytoplankton (Kroon and Thoms, 2006; Dubinsky and Schofield, 2009; Schofield et al., 2013b).

Given that a relatively constant biomass of phytoplankton spanned the upper mixed layer (Figure 12) which was often over 10-fold deeper than the depth of the 1% light level, active movement of the phytoplankton in the upper mixed layer might be required to maintain growth rates in upper mixed layer. While many phytoplankton species exhibit significant movement through swimming (Blasco, 1978) and/or buoyancy regulation (Walsby et al., 1997), there is no evidence that *Phaeocystis* exhibits capabilities for significant vertical motility. The few available laboratory studies on *Phaeocystis* suggest that cells are either neutrally or slightly negatively buoyant under light-limiting conditions (Wang and Tang, 2010). Although these studies were not conducted on the Antarctic species encountered during the ASPIRE and KOPRI expeditions, it appears that the rate of mixing within the upper mixed layer and not cell motility is critical to supporting the observed accumulation of phytoplankton biomass.

Phytoplankton photosynthesis can be extremely efficient in turbid conditions if mixing promotes the "fluctuating light effect" (Phillips and Myers, 1954; Myers, 1994). The "fluctuating light effect" describes when phytoplankton exposed to dynamic light intensities can have photosynthesis rates and biomass yields that are higher than cells grown under a constant photon dose, due to differences in the slow kinetics of the xanthophyll cycle relative to the mixing rate (minutes-hours; Demmig et al., 1987; Demmig-Adams, 1990), thereby allowing cells to operate at maximal photosynthetic efficiencies. Past studies in turbid plumes have demonstrated that not accounting for mixing in the upper mixed layer could lead to large errors (as large as 40%) for traditional static biological measurements of phytoplankton productivity (Schofield et al., 2013b). Therefore, improved understanding of the phytoplankton ecology will require measurements of turbulent mixing rates to define the light environment for cells within the upper mixed layer.

Conclusions

Recent reports highlight that glacial melt in the Amundsen Sea will continue for the foreseeable future (Thoma et al., 2008; Holland, 2014). Continuing glacial melt will increase the delivery of low salinity water into the Amundsen Sea Polynya (Hellmer, 2004), which will have biogeochemical ramifications through potentially increasing the overall productivity of this polynya (Arrigo et al., 2012) if the physical integrity of the system is otherwise maintained. Glider results from two different expeditions support this interpretation, as low salinity plumes associated with pycnoclines shallower than 50 m corresponded to regions of highest phytoplankton biomass. Additionally, the overall regulation of the phytoplankton biomass must be strongly influenced by mixing within the upper mixed layer, as mixing determines the proportion of the community experiencing chronic light limitation. Therefore, there is a critical need to quantify mixing within the AASW to better understand the injection of iron into surface waters and to model the light environment in a turbid high-biomass environment.

***Abstract*—The Slocum Glider is an instrument of efficiency and getting more out of less. When looking at getting the most distance out of a single battery, it is important to consider many different variables. Horizontal speed and flight path planning can both play a part in being able to achieve flight across ocean basins. With the ability to change a glider's velocity, a pilot could determine the quickest speed to fly the glider trans-ocean without depleting the battery. In other words, the pilot could choose the optimal pitch angle for a specific mission. Different pitch angles travel at different speeds while consuming battery power at different rates. One mission may carry great importance on speed rather than energy while another mission would rather go slow-and-steady in order to save as much power possible. Through enabling a pilot to change the speed of a glider through pitch angle, shorter missions can be done much more quickly while longer missions can conserve more energy while flying at a slower pace.**

Additionally, having a flight path that utilizes the currents in the ocean is a method used today to make gliders run efficiently. Making sure all instruments are reading properly is crucial to being able to navigate these currents. The key to this accurate navigation is a properly calibrated compass. Compass calibration can be complicated and frustrating but new methods of calibration have been able to remove a lot of the error that is associated with the compass. One comparison deals with a calibration of hanging a glider with ropes versus a calibration using a wooden tilt cart. Having the glider travel on the correct course between waypoints can cut miles off the overall trip that may add up and waste battery.

Keywords—Battery Consumption; Pitch Angle; Compass Calibration; Autonomous Underwater Gliders;

I. Introduction

Slocum gliders are autonomous under water vehicles that rely on bouyancy changes to slowly move through the ocean within the upper 1000m. Along the way, the gliders sample ocean parameters including temperature, salinity, and in some cases biological measures of phytoplankton occurance, abundance, and health. These gliders are designed in such a manner as to emphasize energy efficiency. By using simple changes in density, the glider is able to travel long distances with minimal power. Since the inception of Autonomous Underwater Vehicles (AUVs), multiple improvements have been made on the design and engineering of the instrument. In 2009, Rutgers University did what has never been done and sent a glider across the Atlantic, starting off the coast of New Jersey and ending at the coast of Spain. Since then, trans-ocean glider deployments have become a common goal in research. The current global glier flights are organized unde the umbrella of the Challenger Project. This project seeks to navigate along the path of the HMS challenger in the late 1800s on the first circumnavigation for science. Legs have been identified in each basin that together will track the path of this improtant science mission. In the South Atlantic, the glider 'Challenger' completed two legs from South Africa to Ascencsion Island and from Ascension Island to Brazil. In July of 2015 the glider was deployed on a mission that extends approximately 6500 kilometers from Ubatuba, Brazil back to Cape Town, South Africa. The current available battery power flying with default parameters will allow for only approximately 7000 kilometers of flight. There is potential to recover the glider, re-battery and deploy from Tristan da Cunha (37.1167° S, 12.2833° W) but this will require a boat trip of at least a month, which is cost and logistically prohibitive. Thus achieving optimum battery life and flight efficiency is critical to completing this mission. As the limits of glider travel are being pushed, designs need to be optimized in order to gain the most out of the increasingly important glider voyages.

A Slocum Glider is a very efficient machine as it currently stands however there is room for improvement. Battery consumption and currents all deal with the efficiency of a glider. Through glider engineering, we can manipulate these factors internally by improving pitch angle and compass precision. Data from previous glider missions along with our

978-0-933957-43-5 ©2015 MTS

own test models can provide the support necessary to prove what advancements will revolutionize the efficiency of the glider. Gliders have the potential to accomplish unimaginable feats without any need to physically change the vehicle.

II. PITCH ANGLE OPTIMIZATION

The glider consumes a variable amount of energy at different pitch angles and different pitch angles led to different horizontal speeds. It has been determined that the most optimal pitch angle to use for the Slocum Glider is about 26 degrees up and down. However, not all glider missions are the same. One glider could be collecting data for a few weeks in the Gulf of Mexico while another is traveling transatlantic for a whole year. Flexibility in speed would lead to getting the most use out of a fully charged glider. Adjusting the glider to a steeper pitch angle would lead to shorter long-distance voyages while maintaining enough energy onboard as a precaution. Here we present steps we have taken to optimze glider flight for the required enegy efficiency to cross an ocean basin.

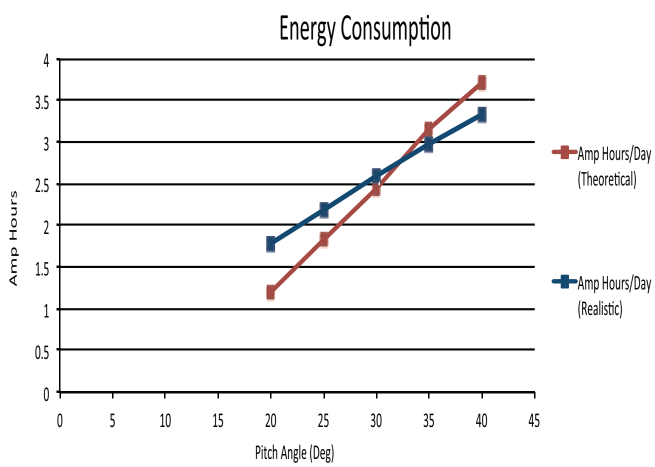

Fig. 1. The energy consumed by the Slocum Glider in Amp Hours at different pitch angles (degrees). The red line shows the theoretical Amp Hours/Day while the blue line shows the realistic Amp Hours/Day.

First, we focused on the rate of energy consumed at a range of pitch angles (Figure 1). Originally, we looked at energy consumption theoretically: using simple trigonometry and the comparison of the number of yos (consequtive upcast and downcast) to amp hours. After that, we computed a realistic trend showing the amp hours per day at different pitch angles using data gathered from the Slocum Glider. The realistic trend shows a smaller slope compared to the theoretical trend, illustrating that measured energy consumption is consistent with theory.

Taking the data retrieved from the Slocum Glider, another trend was calculated to estimate the number of spare days of battery life would be left if completing a 6000 kilometer voyage at different pitch angles (Figure 2). The linear trend indicates that a smaller pitch angle would lead to many more spare days compared to a steeper pitch angle.

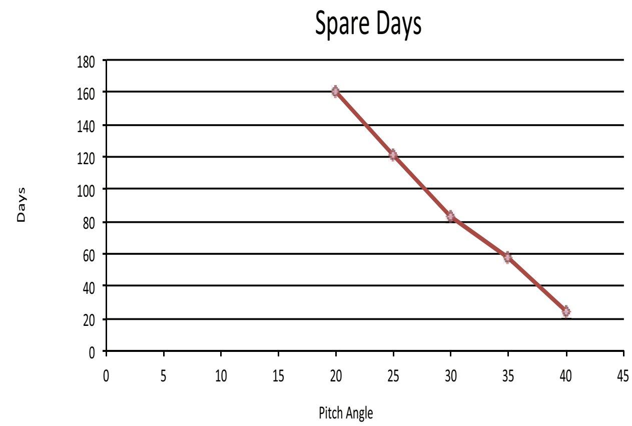

Fig. 2. The spare days of energy left at different pitch angles (degrees).

Next we looked at the horizontal velocities of the glider at different pitch angles. Figure 2 is based on information in Jeffery Sherman's paper, *The Autonomous Underwater Glider "Spray"*. The information describes where the maximum horizontal velocity and maximum range lie on the pitch angle scale. For ocean-wide deployments, the information concerning the horizontal velocity is most essential. According to the Sherman's equation, the maximum horizontal velocity occurs at a pitch angle of about 36 degrees, recommending to remain below it. The range maximized at around 19 degrees, recommending the glider remain above that angle. This window between 19 degrees and 36 degrees is the recommended range that a pilot should consider when flying a glider.

The equations designed by Sherman are derived from the following variables:

ρ	Fluid Density;
u	Horizontal Velocity;
E_0	Energy;
x	Range;
B	Buoyant Force;
C_D	Drag Coefficient;
A_D	Cross Sectional Area of Hull;
U_0	Characteristic Velocity;
X_0	Characteristic Range;

The following equations (1) (2) below describe how to calculate the characteristic velocity U_0 and the characteristic range X_0:

$$U_0 = (\frac{2B}{\rho A_D C_D})^{.5} \tag{1}$$

$$X_0 = \frac{E_0}{.5\rho A_D C_D u^2} \tag{2}$$

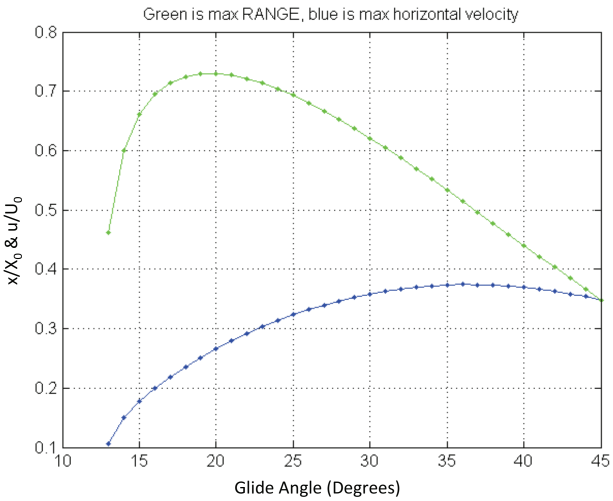

Fig. 3. The ratio between the range of the glider x and it characteristic range X_0 as well as the ratio between the horizontal velocities u and charateristic horizontal velocities are indicated at different pitch angles (degrees).

Comparing this with the information concerning energy consumption, our directive is to find the most optimal pitch angle that allows us to fly fast but safely. With so much spare energy stored in the glider, a pitch angle of 30 degrees may fair for a better transatlantic voyage for RU29.

III. COMPASS OPTIMIZATION

Finally we looked at energy saving opportunities within the glider hardware and software. Given the optimal flight parameters it is important that the glider logic efficiently navigate along its intended path. Deflections from its intended path could lead to energy loss in frequent rudder adjustments. Therefore, the distance traveled on a given day can be optimized with a more precise, properly calibrated compass. With a 6000-kilometer voyage, a simple 5% compass error could lead to a distance error of 300+ kilometer. In order to achieve a more precise compass, effective methods of calibration must be developed and implemented.

Rutgers University generally calibrates Slocum Gliders with a hanging apparatus (Figure 4). This method allows the glider to be rotated in 3D space while suspended, making the calibration process easy and generally effective.

Fig. 4. The hanging apparatus allows the glider to freely move in 3D space with ease. Object such as a tree is required to hang the apparatus.

However, in an environment with limited options to hang a glider (such as tree-less Antarctica), we developed a tilt cart that can be used in many more environments prior to deployment (Figure 5). While testing, the tilt cart prototype did have some issues in rolling the glider, which caused a few errors in our calibration trials. The tilt cart expressed much more error than the hanging method however I hypothesize that if a better method to roll the glider in the tilt cart or a more flexible calibration software was available, the tilt cart could prove to be a very effective method of calibration in the future.

Fig. 5. The tilt cart prototype designed to rotate the glider in 3D space without the necessity of an object to hang the glider from. Limitations in pitch angle exist at about 40 degrees and there is difficulty in rolling the glider in the wooden cradle.

Effective methods in calibration would not be as beneficial without an effective working compass. With both the True North Technologies Revolution Compass and the PNI Corperation TCM3 Compass models at our disposal, we put them to the test to see which model performed better in the hanging apparatus (Figure 6 & 7). Surprisingly, the results from our data show that the earlier TCM3 performed nearly 54% better than the newer Rev compass. More interesting was the errors calculated from the Rev compass as the trends resemble sine curves. We hypothesize that this error could be corrected with a more advanced calibration software however this software is not yet available to us to be tested.

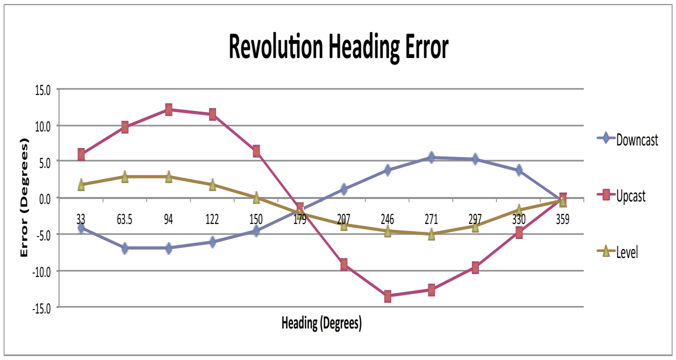

Fig. 6. The Revolution compass error (degrees) rotated around 360 degrees while pitched up 26 degrees, pitch at a level 0 degrees and pitched down at 26 degrees.

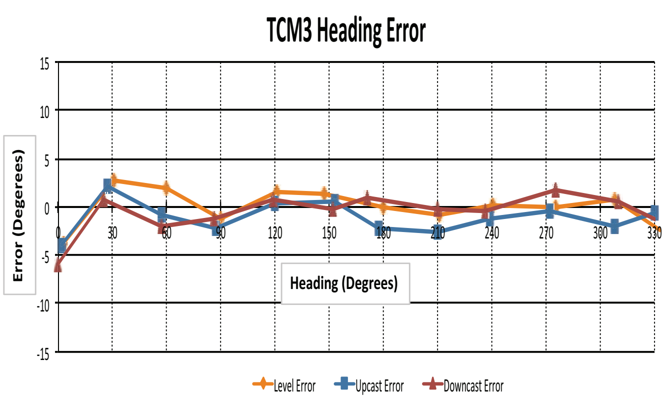

Fig. 7. The TCM3 compass was tested exactly like the Revolution compass by rotating the glider 360 degrees while being pitched up 26 degrees, down 26 degrees and kept level.

As a way to combine our different methods and compasses, we mixed-matched different calibration trials to present each comparison (Figure 8). The first comparison shows how the replacement Revolution compass performs better than the used, original Revolution compass with a 1.1 degree difference in error. The hanging apparatus was our control as our method of calibration. Next, the comparison between the tilt cart and the hanging apparatus provided some insight on how effective our prototype faired. With the replacement Revolution compass as our control, the tilt cart presented 1.3 degrees more error than the hanging method on average. This chart also includes the comparison between the TCM3 and Rev compass from previous.

Type of Compass/Calibration Method	Average Error
RU30 Original Rev Compass/ Hanging Method	4.9
RU30 Replacement Rev Compass/Hanging Method	2.8
RU30 Replacement Rev Compass/Tilt Cart	4.1
RU23 TCM3 Compass/Hanging Method	1.5

Fig. 8. The chart includes the amount of error present when testing a glider with different compasses (Original Rev Compass, Replacement Rev Compass and TCM3 Compass) with different calibration methods (Hanging Apparatus and Tilt Cart).

IV. Disscussion

The optimization of the Slocum Glider is within the ability to change the speed of the glider and pinpoint the best route available. These capabilities depend on the accuracy of the compass and pitch angle of the AUV.

Combining what we know about the horizontal speed of the glider and the rate of energy consumption used at a range of pitch angles allow the pilots to calculate the most efficient way of flight for the specific mission. A glider pilot should decide between the window of 26 and 36 degrees and compare it with the energy consumption at those angles. Any angle between 19 and 26 degrees would be an interesting range to test to see how the glider moves at such low angles. This window enacts as a possible speedometer for the pilot to use in order to operate the instrument for the mission at hand.

Once a pitch angle is agreed upon as the best choice for a mission, the most optimal route must be planned upon as well. A precise compass will allow a pilot to accurately direct the AUV into a favorable waters. For a voyage that is ocean-wide, the smallest compass error could lead to significant distance off course. As of now, the best mode of calibration is through the use of a hanging apparatus however a tilt cart could move in as a substitutable mechanism quite soon. The compass models themselves have shown that the TCM3 performed better than the Rev compass. The solution for the issues with the tilt cart and the Rev compass lies in an effective software. A forgiving calibration program would allow for the glider to halt, tilt and continue moving without presenting an error could allow for a significant drop in heading error. A program to correct the sine error generated from the Rev compass would allow it to compete well with the TCM3.

With more features available to the pilot, a glider could better adapt to the huge variety of environments in the ocean present in a deployment. Control in speed as well as pinpoint compass precision are necessary for anyone operating an AUV. The Slocum Glider has the potential to be so much more efficient with only simple changes in pitch angle and calibration.

V. Acknowledgement

The Challenger Gilder Mission is growing global partnership of gilder operators, scientists, educators and students coordinated by Rutgers University and endorsed by the Challenger Society. The results presented on this paper were initiated in a Rutgers research course and completed by two undergraduate summer interns (Andrenette Morrison and Liam Ramsay) supported by Teledyne Webb Research and six U.S. Naval Academy interns (Martin Arroyo, Kelsey Ashbrook, Olivia Czerewko, Stephanie Lee, Caleb Lintz and Erin Payne). Glider path planning and model/data comparison activites are led by Nilsen Strandskov (Rutgers) and Antonio Ramos (Universidad de Las Palma de Gran Canaria) with cyber infrastructure support provided by John Kerfoot (Rutgers). Glider operators include Chip Haldeman, Dave Aragon, Tina Haskin (Rutgers) and Ben Alsup (TWR).

I. Introduction

Hurricane Gonzalo was 2nd in a series of sequential Atlantic tropical cyclones to hit the island of Bermuda during the 2014 season. Hurricane Fay landed as a Category 1 hurricane October 12 and the resulting efforts helped pre-condition the island for Gonzalo. Less than a week later on October 18, Hurricane Gonzalo made landfall as a Category 2 storm. It had peaked in intensity as a Category 4 storm less than 500 miles south of Bermuda [1].

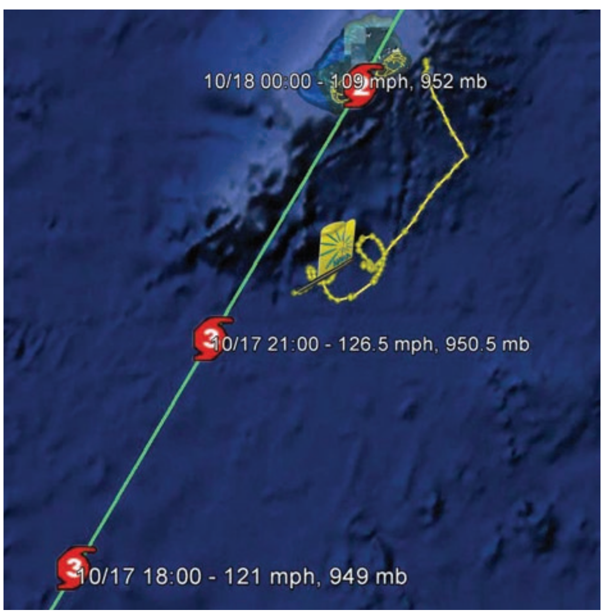

Fig. 1. Hurricane Gonzalo track with wind and pressure. Glider Anna path. (*Google Earth, NOAA*)

A Teledyne Webb Research Slocum G2 glider, owned by BIOS (Bermuda Institute of Ocean Sciences) was opportunistically deployed ahead of the storm, after being recovered before Hurricane Fay. The glider was equipped with CTD, optical backscatter and fluorescence, and a dissolved oxygen meter. The glider flew for a short time before and after the storm giving a snapshot of the post-Hurricane Fay ocean properties and Hurricane Gonzalo induced effects.

Noted during the flight of the glider under the hurricane, was strong turbulence as seen in attitude variables from the vehicle. The measurements were taken using the glider's onboard attitude sensor which measures pitch, roll, and magnetic heading. This turbulence was seen during peak storm intensity as the hurricane crossed over the glider and extending quite deep into the water field. The glider also experienced decreased communication reliability as well as damage to the tail from the storm or debris.

With gliders increasing presence and availability, unique events such as hurricanes will be sampled in ways never before seen. Sensors of greater complexity and quantity are being added to such vehicles and may be susceptible to extreme conditions such as seen during Hurricane Gonzalo.

II. Methods

Gliders have become robust tools for sampling the ocean during both normal and episodic events such as storms [2] [3]. Slocum gliders are capable of operating in shallow waters (5+ meters) to open ocean (up to 1000 m). By changing buoyancy they are able to descend or ascend vertically through the water column. Incorporating a pitch angle into their ascent or descent allows forward progress upwards of 35 cm/s. Steering mechanism and onboard attitude measurements allow navigation underwater for specified lengths of time.

Sensor payloads are added primarily to the center of the vehicle and data is collected during the ascent, descent, or surfacing phase of the glider's flight. Logged at a maximum rate of 1 Hz, gliders provide relatively high density sampling spatially and vertically. Low power allows operation across seasons and certainly during the durations of most storms or episodic events.

The glider deployed from Bermuda's BIOS MAGIC Lab (Mid-Atlantic Glider Initiative and Collaboration) was named Anna. This glider was a deep glider capable of descending to 1000 m. Science payload consisted of 3 oceanographic sensors. A Seabird pumped CTD unit for measuring temperature and salinity is a staple on all gliders. An optical Wetlabs ECO sensor, FLBBCD, measures proxies of phytoplankton abundance (chlorophyll fluorescence), total particle concentration (backscattering), and dissolved organic matter (CDOM fluorescence). An Aanderaa oxygen optode capable of measuring dissolved oxygen are installed at the rear of the vehicle.

Other observations from Bermuda include L.F. Wade airport, NOAA Station BEPB6 - 2695540 - Bermuda Esso Pier, as well as others mentioned in National Hurricane Center's Hurricane Gonzalo Report [1].

III. Results

A. The Ocean, the Storm, and the Robot

The storm approached Bermuda over the slightly cooled waters after Hurricane Fay had passed through. This likely weakened Gonzalo before making landfall, further giving Fay the credit of 'preparing' the island for another hurricane's landfall. Fay had also knocked most loose structures, limbs, and debris loose so that Gonzalo's impacts were limited on the island.

Gonzalo tracked over Bermuda, crossing the glider around 00 GMT October 18. The glider (Anna) was flown about 30 km from storm center. Anna continued to operate an additional 2 days after the storm departed before being recovered by R.V. Atlantic Explorer. At this point it was continuing to profile but was un-steerable due to damage from the- storm, thus recovery was a top priority. It would have been beneficial to continue flying beyond such date.

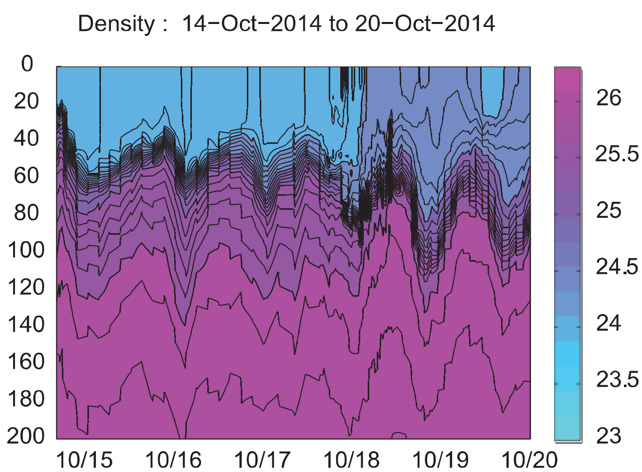

Fig. 2. Anna density, note: mix layer depth (credit: Ruth Curry, BIOS)

The passage of Hurricane Fay cooled the ocean 2-3 degrees C, likely weakening Gonzalo. A curiosity this brings is because both storms had similar tracks, how much effect of the cooling extended further south from the island along their paths. Finally, the mixing and turbulence layers as seen in temperature begin to show the picture of activity as deep as 80 m which affected the glider's attitude. Deeper scientific analysis of the glider data is ongoing and is outside the realm of this paper. This paper intends to focus on the performance of the G2 Slocum glider in an extreme event such as this.

B. Rudder: Lost at Sea

Underwater gliders steer using a variety of methods. Angling the glider about its roll axis (banking) allows gliders to steer during ascents and descents turning vertical motion into heading control. This is analogous to an airplane banking on a landing approach. Another method used is via a rudder or fin allowing the vehicle to turn by yawing. This changes heading much like a rudder in an airplane by rotating the glider about its heading axis. It is important to note vehicles that rely on yaw for heading control have no ability to roll or bank. Their only control methods are pitch and yaw. Roll can be induced by a rudder moment but is outside the scope of this discussion.

The rudder on the Slocum glider is an external moving part, essentially the only one besides an externally inflating and deflating buoyancy diaphragm. This urethane control surface can operate roughly +- 25 degrees for controlling heading. It is housed by a self-contained fin unit called the digifin. Also built into the fin are communication and GPS antennas.

To this date Rutgers University has had no major issues with the digifin system and rudder during its hundreds of individual deployments of gliders. Leading up to rudder loss were numerous reports from the glider that the fin was being pushed around by wind, water, and/or debris. It was expected the rudder would be able to continue to operate normally despite the warnings and conditions.

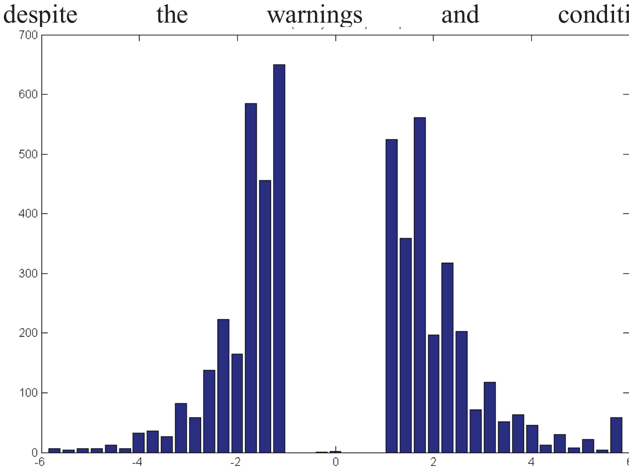

Fig.4. Rudder out of deadband histogram. Degrees rudder was found to be outside of +- 1 degree motor deadband

However, during the passage of Gonzalo over glider Anna the rudder system sustained complete loss minutes after surfacing. The loss occurred (10/17 18:30) several hours before the eye passed directly overhead. It is difficult to conclude the cause of rudder loss: options being biologic, wind driven debris or water. Given the path of the hurricane and wind direction during the loss, debris or flotsam density should be low. Biological loss is an option but would be highly coincidental given the timing and infrequency of rudder losses on previous glider missions.

C. Communications Reliability

Gliders rely on antennas in the top of the digifin (tail assembly) to maintain GPS and communication links. The tail of the glider is elevated out of the water by buoyancy provided from an external air bladder which inflates near the surface. This lifts the tail out of the water for antenna access to GPS and Iridium satellite constellations. The primary means of communication to a glider is via the Iridium system when out of range of radio communications.

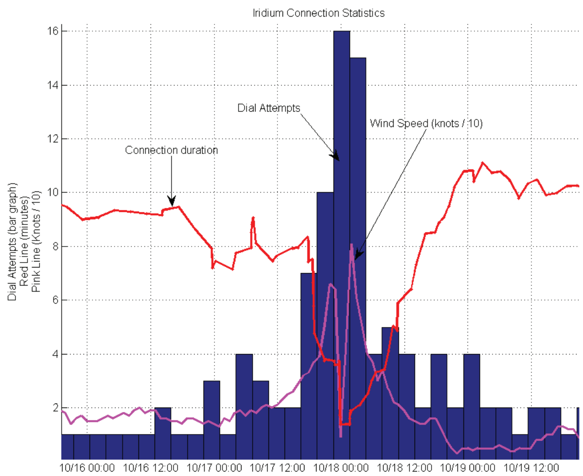

Fig 4. Iridium connection success rate

The mission plan had called for mixed sampling depths between 200 m and 500 m, alternating, during the storm. This was accomplished by changing mission parameters upon each surfacing via an automated scripting routine. Several hours prior to peak storm, communication success rate plummeted and thus dive depth cycling was halted for single 500 m yo's (a yo is a dive and a climb performed by glider) for the remainder of the mission.

Centered on 00 GMT 10/18 by about +- 3 hours, communications hit their low point with connections lasting less than 1-3 minutes. Such short connecting times made changing mission parameters difficult as well as transferring data. This also had an unintended effect of idle surface time perhaps better spent sampling rather than drifting in the dangerous winds.

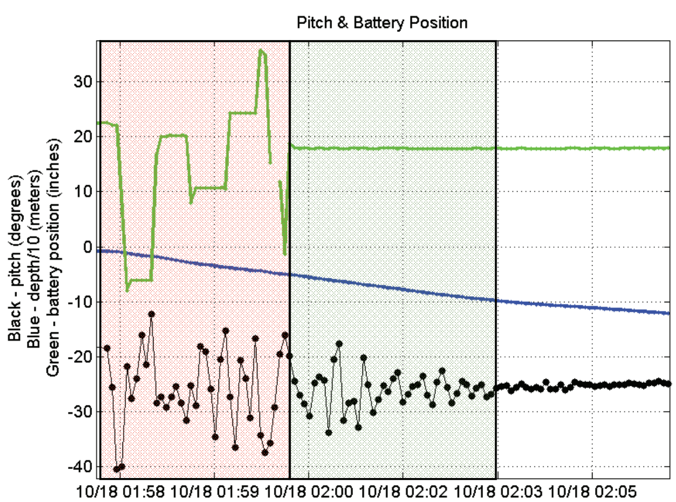

Fig 5. Glider pitch is in green, while depth is plotted in blue. Note even after pitch battery stops moving pitch oscillates down to 100 m

D. Rough Seas: Turbulence

The primary field for which we can look for turbulence in the glider flight is in the roll dimension of the attitude sensor. Roll is important to look at because it is the most independent of the glider's control surfaces. In other words the glider cannot directly control roll, thus most of the roll measurements are the result of the environment itself.

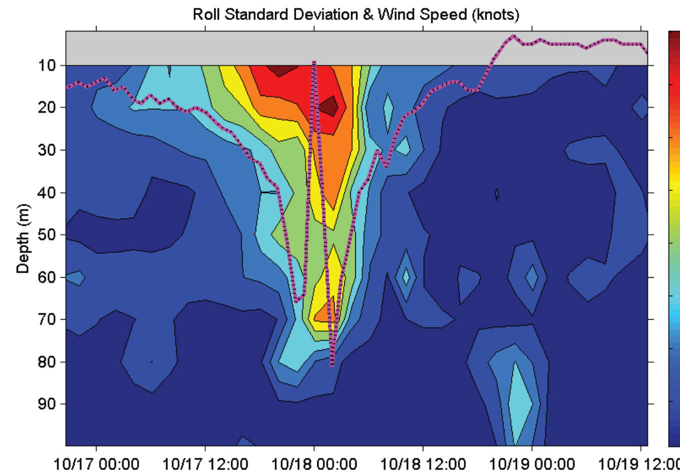

Fig 6. Vehicle roll (degrees) moving standard deviation

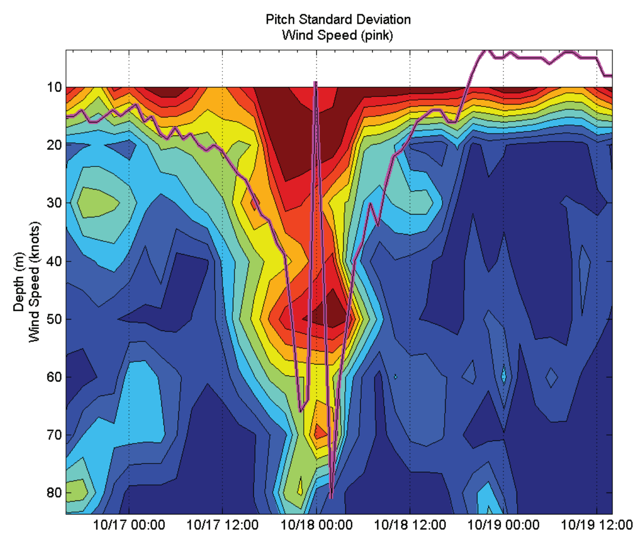

Fig 7. Vehicle pitch (degrees) moving standard deviation

The glider's ideally fly with 0 degrees of roll and outside of any influences should remain at 0 during all operating times. Of course turbulence, inflections, pitch changes, and rudder all create moments which roll the glider. Roll standard deviations of 5-10 degrees were seen during passage of the storm. Periods appeared to be 10-20 seconds in the roll data but further investigation needs to be done.

Pitch shows turbulence as well, but the glider is able to control this surface via a movable mass in the fore of the glider. This 9 kg mass is able to slide forward and aft to adjust the pitch angle. In Anna's case when the pitch error became too large (caused by turbulence) it began to move the pitch internal control surface (battery). Analysis should be done as independent of this as possible. Also worth noting is this may be an unintended consequence of the control system parameters as moving the battery may have contributed to higher pitch errors. A possible solution is flying with a fixed pitch battery or larger pitch deadband.

Pitch errors of +- 10 degrees were seen at depths as great as 80 m. This was centered on the storm and shallowed as the storm approached and departed. For a period of roughly 24 hours the glider showed turbulence in roll and pitch at depth, peaking just hours before the eye passed overhead.

IV. Conclusions

Operating remote platforms such as gliders in extreme events will continue to provide insightful measurements and observations. In parallel advancement, sensor development and integration will bring new sensors to AUV's that will help scientists answer questions they didn't have the means to observe prior.

New sensors often have increasing complexity as well since often scaling down is the largest technical challenge. Early gliders flew just a CTD sensor and that yielded some victories. However, multiple ADCP units by Nortek and Teledyne, as well as water quality sensors such as nitrate, and phytoplankton productivity (FIRE) sensors from Satlantic are all ready for glider use. Turbulence probes such as the Rockland Scientific Microrider can be mounted on top of gliders. Using these complex sensors in extreme events could have unintended effects and should be accounted for in operation. For example large roll and pitch movements could yield errors in ADCP measurements from gliders, especially in vertical water velocities [5]. Proper operation of the vehicle could alleviate some of the effects seen, especially in pitch fluctuations or at least allow predictive behavior. Onboard accelerometers may assist in understanding these effects and provide new insight. Additional understanding as to the response time and accuracy of the onboard attitude sensor will continue to be paramount. Open ocean current profiling gliders could perhaps benefit from upward looking instruments which would sense turbulent water while swimming in still water. This would only have benefits in situations where bottom track would always be impossible.

As the operational numbers of gliders increases so grows the percentage of risk of damage and unintended interactions. Gliders will hopefully continue to harden and become resilient amongst the many conditions they will face. Strong winds and similar incidents that lead to the rudder loss should be accounted for and tested against. Surface time should be limited to reduce risk to the glider.

It is important for scientists and operators of the gliders to understand the lessons from this paper. To summarize the conclusions for missions in the future:

1. Maintain maximum glider stability at all times. This will assist in mitigating external forces creating pitching, yawing, and rolling conditions to the vehicle and attached science sensors. Stability also plays a role in at surface communication success. The goal will be to minimize measurement errors and increase vehicle operability. Stabilizing surfaces are important as well, wings, canards, etc.

2. During episodes of extreme weather, less is more. Prepare to have your glider handle episodes of complete autonomy and make sure it continues to sample. Don't create an overly ambitious operating plan and be sure to sample more than what you need, in this case depths. When probing the unknown you can't predict what you will miss because you don't know what you will be measuring.

3. Limit surface times in the event it can't connect. Time at the surface is not only more dangerous, but it is also un-productive in that little useful data is being collected. Many Rutgers glider missions have had incidents happen at the surface yielding it is a dangerous place to be. Surface control scripts should have told Anna to immediately dive and forego data transfers until passage of the worst conditions.

4. Control algorithms for the glider optimized for normal flight may produce unintended consequences during storm flight. Simplifying or neutering such controls may be beneficial during instances of turbulence and high autonomy (not able to control vehicle). For example, increasing the pitch deadband, setting a fixed pitch battery position, or lowering the control gains could help the glider from trying to dampen turbulence caused pitch oscillations.

V. Future Work

Frequency analysis of the pitch and roll could be helpful to see if it somehow correlated with wave field experienced in the area. Work with a glider and an accelerometer would help augment the suite of useful data collected by the glider. Analyzing the pitch and heading controller during this time period to make a setup for the glider to operate more relaxed during a storm will prove useful.

Acknowledgment

Praise should go to the deployment crew from BIOS and R.V. Stommel who deployed Anna in less than ideal conditions prior to the storm. Also to the recovery team who were able to muster 2 days after the hurricane to rescue an un-steerable glider. This team consisted of the crew and scientists of R.V. Atlantic Explorer. Also special thanks for Ruth Curry and the MAGIC Lab for the opportunity to assist BIOS with their glider operations.

***Abstract*— Underwater autonomous gliders have transitioned from exotic experimental systems to becoming a standard platform capable of collecting data over a critical range of spatial and temporal scales in the ocean. The data are proving to be extremely valuable for addressing a wide range of basic and applied research questions. These communities are growing from distributed research and/or education groups. It is crucial as systems continue to evolve that there is an effort to "harmonize" data products while preserving the diversity of approaches/science/experimentation. As the gliders have matured and new battery solutions provide additional energy, there is an increased focus on the integration of a wider range of sensors to be incorporated into gliders. Many of these new classes of sensors will be particularly effective for characterizing biological processes in the coastal ocean. As biological sensors generally provide proxy estimates of a parameter, developing robust quality control and assurance procedures is critical. These new sensors will be more power intensive thus requiring the development of planning tools for increasing energy efficiency during missions. Given the significant growth in the highly distributed glider community, efforts are now focusing on the development mission planning tools to allow for efficient operation of glider fleets. To further collaboration and standardization of the growing number of glider operators we have initiated a series of community efforts called glider paloozas. We had an exceptional turnout last year, encompassing 18 U.S. and Canadian partners, 28 gliders, 36 glider deployments, and spatial coverage from coastal regions of Newfoundland to the Gulf of Mexico and offshore to Bermuda. The coordinated effort focused on several research themes including continental shelf circulation, fish migrations, and storm activity. The main goals of last year's effort were to produce a seamless flow of real-time glider data into the Global Telecommunications System (GTS) via DMAC and into the regional ocean models and demonstrate the potential of a U.S. national glider network. This is in line with the goal to increase glider data accessibility from Federal and Academic oceanographic modeling communities, the U.S. Integrated Ocean Observing System (IOOS), and other federal funding agencies (i.e., NSF). In order to demonstrate the value and necessity of the planned U.S. national glider network and build on last years successes, we hope to continue these efforts and require that all glider data produced by Gliderpalooza 2015 participants be uploaded by the individual operators to the DAC 2.0 and into GTS.**

Keywords—gliders, coastal oceanography, gliderpalooza, IOOS

I. Introduction

Many basic and applied oceanographic research questions facing humanity require a better understanding of the physical, chemical, and biological interactions in coastal waters. These coastal regions are difficult to sample given numerous turbulent boundary layers and high frequency atmospheric/land forcing. Additionally there are numerous pressures associated with a growing human population, the associated anthropogenic environmental impacts are significant and are only expected to increase as coastal populations continue to grow. Understanding of the ocean's physical, chemical, and biological responses, particularly in the context of anthropogenic forcing (climate change, resource extraction and utilization, waste production and nutrient pollution), remains a difficult problem that limits our ability to predict and manage coastal waters. The data most relevant to understanding/supporting critical coastal processes (ocean productivity, water quality, fisheries, weather, climate, shipping, recreation, and energy production) spans a range of temporal (days to years) and spatial (meters to 1000's of kilometers) scales. These scales cannot be affordably resolved using traditional (ships, moorings) oceanographic sampling approaches alone. There is a greater need to combine monitoring efforts with adaptive sampling in time and space as many of the critical processes of are ephemeral. Autonomous underwater gliders (Davis et al 2003) are mobile platforms that can be steered adaptively from shore and have proven to be a robust that is being taken up by the oceanographic community (Schofield et al. 2015).

Gliders, as currently configured, were first detailed in Doug Webb' s lab book on 2/8/86 (Webb 1986). The concept matured during many backyard discussions with Henry Stommel who, in 1989, publicized his science fiction vision of the future of a smart fleet of instruments being coordinated by

978-0-933957-43-5 ©2015 MTS

graduate students (Stommel 1989). These systems, a cousin to the Argo profiling float, were developed in parallel at several academic institutions and commercial companies through support from the Office of Naval Research in the United States. This progress has been mirrored in Europe, Asia, Australia and Africa They have now matured to the point that they are available for commercial purchase from several companies and there is a large growing community. Due to successes in the field, federal agencies in United States, Europe, Australia, and South Africa have begun to adopt gliders for a range of more applied and operational needs. The community is highly distributed and continues to grow. This evolution has stimulated the community to begin discussions about the potential for a national glider networks for several countries. One example is in the United States, glider community leaders working with NOAA's Integrated Ocean Observing System (IOOS) have been developing a draft national glider plan (http://www.ioos.noaa.gov/glider/strategy/glider_network_whitepaper_final.pdf).

While discussion about a potential national plan continues to evolve, there remains a need to continue to harmonize and accelerate collaboration among the growing glider community. As an example of this community-based coordination, a series of grass-roots regional ad-hoc experiments were conducted in 2013 and 2014. These efforts termed "gliderpalooza" represented coordinated individual experiments, funded by diverse federal and state sponsors, working together to provide regional data to modelers. The data supported their own local objectives while contributing to regional scale questions that could not be addressed by any one institution alone.

II. Path Forward

A. *Moving the glider technology forward*

Increasing the utility of glider technology will be based on increasing a range of activities that include increasing the number of available sensors, coordination of communities of gliders, improved energy efficiency and standardizing quality assurance/control.

An ocean research platform is only as useful as the sensors it can carry. Historically the type of sensor has been limited by the size and energy consumption of the sensor. Fortunately, there is a revolution occurring in instrument miniaturization. Additionally, the increased availability of high-density energy lithium batteries has increased the power availability over traditional alkaline-based batteries. This has opened the door for the potential to integrate a new suite of sensors into gliders in the coming decade. Currently a wide range of physical, chemical, optical and acoustic sensors are being integrated into gliders.

As the number of sensors available for these platforms. As the sensor suite expands, we expect community efforts to shift from mainly hardware/software development to tools that allow for more effective operation of individual or fleets of vehicles. Coordinated fleets will be more common and efficient as it is likely that lifetime costs of gliders will be dominated by the cost of operating them, rather than the cost of purchasing the vehicles.

As the number of gliders sensors increase in oceanography, establishing solid quality assurance and quality control procedures for sensors and data collected from observatory platforms, including gliders, is essential (Fredericks et al. 2009). This includes the production of Standard Operating Procedures (SOPs), quality assurance procedures such as a Quality Assurance Project Plan (QAPP) and QARTOD (Quality Assurance in Real Time Oceanographic Data), validating data, applying quality control in real-time, and developing a data analysis/data management system for future glider monitoring. A QAPP has been successfully implemented for the glider-integrated CTD and monitoring dissolved oxygen using a glider optode (nepis.epa.gov/Exe/ZyPURL.cgi?Dockey=P100IVXI.txt). However, there are still several gliders sensors that do not have established QA/QC protocols. Many teams are actively working to fill the gaps and establish standard operating procedures (SOPs) for quality assurance as well as quality control of real-time glider data. These SOPs should be publicly available. Formal groups such as the MTS or IEEE can and should play a critical role in the facilitating discussion in developing community agreement on the appropriate procedures and QA/QC protocols.

Incorporation of any sensor into a glider results in an immediate new "sink" of power, which limits the lifetime of a mission. Therefore increasing energy efficiency is absolutely critical. Tools that allow for increased efficiency and assist in mission planning are becoming critical as the newer instrument suites tend to have high power requirements. With improvements such as the recent integration of the coulomb meter into the Slocum glider, measuring the discharge of the battery has become more accurate and critical to long duration glider operations. Knowing the rate at which energy is used and how much remains is vital to mission planning. However, the glider's coulomb meter only measures whole vehicle current. To perform more precise mission planning, the energy consumption of individual components (especially power intensive sensors) is necessary. To that end, we have developed a measurement infrastructure, which captures the currents drawn from distinct components of the Slocum Glider. The infrastructure has been deployed in test missions off the coast of New Jersey, and the data collected have been integrated into a Slocum Glider simulator. This measurement board and simulation framework can be used to assist in the planning and decision making of missions and shows possible tradeoffs, for instance, between mission duration, speed, and energy consumption. The simulation environment incorporates energy, speed, seafloor and ocean current models, and is used to predict the flight path, longevity and energy usage of a mission. The simulation environment has been validated against Teledyne Webb's Shoebox simulator and compared to a deployment on the continental shelf off of the coast of New Jersey. Results between the three compared well (Woithe et al. 2010). Mission planning tools such as this will become increasingly important for glider operations in the coming years as more sensors are integrated into the glider.

In situations where the desired sensor activation profile of "everything, everywhere, all the time" is not feasible for the entire duration of a mission, mission planning tools will be particularly crucial. Mission planning tools can help oceanographers to assess the potential tradeoffs between different sensing activities in terms of overall energy consumption and peak power requirements. Sensor activity planning and path planning need to be done together while leaving enough energy reserves to ensure a safe recovery of the glider at the end of a mission. In some cases, the effectiveness of sensing activities can be improved by using lower power sensors to trigger high power sensors only in situations where acquiring expensive sensing data is important. Such trigger chains have been recently proposed with promising results for triggering backscatter sensors of a Slocum glider while flying through a thermocline (Woithe et al. 2015). Simulation results and results from two glider deployments off the coast of New Jersey show energy savings between 34% and 82% without significant loss of scientific relevant data. Mission planning tools have to consider all aspects of sensor activation including the desired spatiotemporal resolution, tradeoffs between sensing activities and their energy/power demands, and the applicability and effectiveness of sensor trigger chains.

B. Moving the community forward

Forming an integrated community will require glider operators share, leverage off the respective experince of individual operators, and optmize/ standardize approaches. It should follow the example of the successful efforts of the ARGO community. To this end, coordinating activities through the MARACOOS community, a regional association of the US IOOS network, there was a concept to conduct a coordinated, but dispartely funded, regional glider experiment. This was to accomplished through a community coordinated event of individual principal investigator efforts which was called a gliderpalooza. The goals were to enable the individual glider missions to meet their specific mission goals but also provide a larger regional glider dataset that could serve a wider range of science and operational needs.

The first gliderpalooza was conducted in 2013. The initial group consisted four of the MARACOOS glider groups (Rutgers, University of Delaware, University of Massachusetts, and University of Maryland). Informal communication and subsequent word of mouth grew the community to eleven institutions (list in Table 1). Listed in Table are the partners, their science funding sources and distances each gliders traveled. In total, the effort resulted in over 7000 kilometers being surveyed through the ad-hoc community effort. The effort faciltated sensor sharing with the Ocean Tracking Network providing Vemco fish recievers to all participants. The effort also helped mature data flow. The community effort

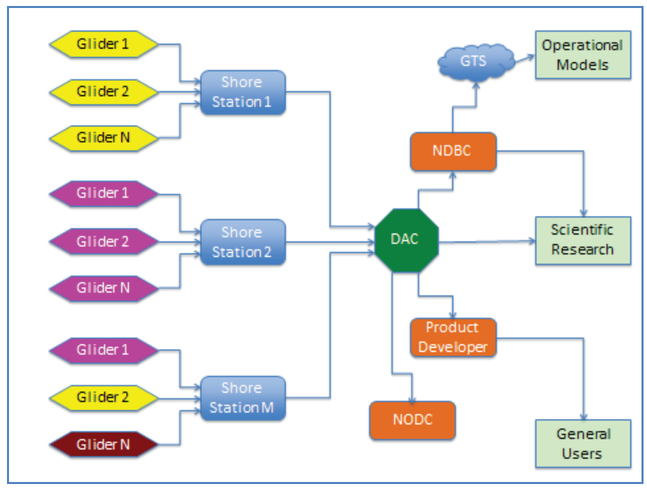

Figure 1. The data flow during the gliderpalooza efforts. During the first two years there was an effort of bringing larger proportions into the data systems illustrated above. The goal for the gliderpalooza in 2015 is to have all the members have their data flow through the NOAA DAC and onto the GTS.

was facilitated with data flow through the national Glider Data Assembly Center (DAC). The data flow through the DAC is illustrated in Figure 1. Efforts were coordinated through weekly telecons/web-ex, the near real-time data collected by the gliders, and regional satallite-HF radar-model datastreams coodinated through the MARACOOS asset map (http://assets.maracoos.org/).

We acknowledge the NOAA Integrated Ocean Observing System program and the Office of Naval Research.

The second gliderpalooza was conducted in 2014. This effort drew a much larger community response. The second

Figure 2. The yellow circles indicate the partners who partook in the 2014 gliderpalooza effort.

gliderpalooza drew communities spanning from the Gulf Mexico to the Bermuda Biological Station (Figure 2). The second effort expanded to 18 partners spanning federal agencies and academic partners. The partners and the number of gliders deployed are presented in Table 2. Glider missions were coordiated through NOAA glider portal which provided a larger framework larger the regional MARACOOS domain. The effort was conducted through the late summer into the Autumn season. As before the effort represented a range of individually funded efforts.

The efforts have continued into 2015. There is a gliderpalooza planned for Fall in the Mid-Atlantic. It was however preceded by another complimentary community effort conducted in the Gulf of Mexico.

The Gulf of Mexico community coordinated a community event in the summer of 2015, which they called an AUV Jubilee. This effort was expanded beyond the gliderpalooza framework by expanding to a larger array of autonomous vehicles. The AUV Jubilee was an inaugural event to coordinate glider and other *in situ* ocean data operations in the Gulf of Mexico for the month of July 2015. The primary goal was to establish an open dialogue and collaboration with scientists across the Gulf, in order to acquire simultaneous ocean observations and leverage off of fellow participants to create a multifaceted and integrated data set. The AUV Jubilee was led by the University of Southern Mississippi's Ocean Weather Laboratory (http://www.usm.edu/marine/research-owx), which hosted a series of webinars to display real-time satellite ocean color and several ocean circulation models (HYCOM/NCOM), as well as maps of product uncertainty to allow the participating scientists to adaptively sample features of interest (e.g. eddies, river filaments, fronts, etc.). This data fusion tool enabled the display of up-to-date locations of various glider and ship/aerial operations while they were deployed, and facilitated near real-time data exchanges in order to further assist in decisions-making for adaptive sampling of ocean features. In addition to real-time operations, all participants were encouraged to submit data to the National Glider Data Assembly Center (NGDAC), so that the data

could be available for assimilation into operational physical circulation models. The list of glider participants is shown in Table 3. The scope of the AUV Jubilee also included an educational outreach component, in which a competitively selected group of highly qualified teachers were brought in for an intensive one week program that included curriculum development, hands on oceanographic experience, and participation in real-time glider operations.

C. Conclusions

The glider community is rapidly growing as the technology has been demonstrated to be a transformative technology. As the platforms have matured, efforts are now focused on expanding the number of sensors, procedures to swarm fleets of gliders, improved/standardized data quality assurance/quality protocols, and extending duration of glider missions through improved energy efficiency. Just as important is the increasing number of open access community events that provide a means to collect valuable data and facilitate community exchange that will mature the community as a whole.

***Abstract*— The exploration of the Earth's oceans is aided by autonomous underwater vehicles (AUVs). AUVs in use today include floats and gliders; they can be deployed to profile salinity, temperature and pressure of the ocean at depths of up to 2 km. Both the floats and gliders typically control buoyancy by filling and deflating an external bladder with a hydraulic fluid delivered by an electrical pump. The operation time of an AUV is limited by energy storage. For floats, such as the Argo float, the operating duration is approximately 5 years with the capability to dive once every 10 days. For electric gliders, such as the deep G2 Slocum, the mission duration can be up to one year with lithium primary batteries. An energy storage system has been developed that can harvest energy from the temperature differences at various depths of the ocean. This system was demonstrated on an Argo style float and has been implemented in a thermal version of the Slocum glider. The energy harvesting system is based on a phase change material with a freeze thaw cycle that pressurizes hydraulic oil that is converted to electrical energy. The thermal Slocum glider does not use an electrical pump, but harvested thermal energy to control buoyancy. The goal for the thermal Slocum glider is for persistent ocean operation for a duration of up to 10 years. A thermal powered glider with an energy harvesting system as described can collect conductivity, temperature, and pressure data and deliver it to the National Data Buoy Center (NDBC) Glider Data Monitoring System and the World Meteorological Organization (WMO) Global Telecommunications System (GTS). Feeding into operational modeling centers such as the National Centers for Environmental Prediction (NCEP) and the U.S. Naval Observatory (NAVO), this data will enable advanced climate predictions over a timespan not currently achievable with present technology. Current testing of the thermal powered Slocum glider is to determine the durability of the technology and quantify the glider system design. Previous issues with this technology included energy storage system management and glider mechanical limitations. Our objective is to learn how to fly an energy harvesting thermal glider that interacts with the ocean environment efficiently. We would also like to establish the latitudinal range of operation. This thermal powered Slocum glider, dubbed Clark, after the famous explorer duo Lewis and Clark, has been deployed off of St. Thomas for flight dynamics and durability testing. The following paper will discuss the deployment and testing of the thermal powered Slocum glider. We will also discuss the advantages of ocean energy harvesting technology for oceanographic research.**

Keywords—glider, thermal glider, thermal recharging

I. INTRODUCTION (*HEADING 1*)

Stemming from a technology development cycle in the early days of the National Oceanographic Partnership Program (NOPP), Rutgers University has maintained a close working relationship with Teledyne Webb Research Corporation (TWRC), often serving as a testbed for new designs, improvements, or enhancements to the Slocum glider. The first prototype of this glider was deployed off the coast of New Jersey in 1999, and Rutgers purchased their first commercially available Slocum Electric glider in 2003. By 2007, Slocum gliders had been declared a viable technology for sustained ocean observations [1]. With the largest fleet of Slocum gliders in the world outside of the U.S. Navy, Rutgers has gained valuable operational experience from over 400 deployments around the world. A first-ever Slocum-TREC (Thermal RECharging) deep ocean glider has been developed through a partnership between Teledyne Webb Research Corporation (TWRC) and the National Aeronautical Space Administration's Jet Propulsion Laboratory (NASA-JPL) for the Office of Naval Research (ONR). Slocum-TREC is a thermal-class glider that can harvest energy from the ocean thermoclines. A photo of the Slocum-TREC "Clark" is shown as Fig. 1. The Slocum-TREC ocean glider was deployed on June 9^{th} 14 miles off the coast of St. Thomas, U.S. Virgin Islands. The goal of Slocum-TREC is to demonstrate the feasibility of the thermal buoyancy drive and TREC energy harvesting system to power deep ocean floats that can operate autonomously for periods of up to 10 years.

II. BACKGROUND

A. Glider Configuration

The Slocum-TREC glider is currently configured to operate with one scientific instrument to measure conductivity, temperature, and depth (CTD). Thermal-class gliders use a thermal engine to directly drive a buoyancy pump that controls the ocean glider's depth and ascent rate. It is capable of diving to 1200 meters and is currently programmed to dive up to 4 times a day. This ocean glider is not limited by battery energy storage.

1) Energy Harvesting System

A functional schematic of the Slocum-TREC energy harvesting and thermal buoyancy drive is shown as Fig. 2. As the glider travels through an ocean thermocline, a phase-change wax in the thermal engine undergoes a freeze-thaw cycle. As the phase-change wax is thawed, the expansion of the wax pressurizes the hydraulic oil in the thermal engine. As the hydraulic oil is pressurized, the energy from pressurization is captured in a high-pressure accumulator. The energy stored in the high-pressure accumulator can then be discharged to the gliders buoyancy drive to provide propulsion [2]. The energy storage in the high pressure accumulator can also be discharged to a power generator to be converted to electrical energy [3]. The electrical energy is used to provide electrical power to the glider to support hotel loads, science and communications. After the oil storage in the high-pressure accumulator is discharged, it is collected in the low-pressure accumulator and fed back to the thermal engine during the phase-change wax freeze cycle.

2) Field test, Energy Harvesting

The energy storage battery voltage of the TREC system during ocean testing is shown as Fig. 3. The TREC energy storage system is configured of two batteries, one battery is being charged by the energy harvested from the ocean by the TREC system, the other is used to provide electrical power to the Slocum-TREC ocean glider. The energy storage batteries are cycling between 13.2 and 13.4 Volts. These battery voltages correspond to approximately 40 to 75% state-of-charge (SOC). Operating the batteries in this SOC range will maximize battery cycle life to meet the program goals of 10 years of operation. The battery set points are controlled from land and can be changed to operate in a SOC range required by a specific mission. An example of a power generation cycle for the TREC system during ocean testing is shown as Fig. 4. A typical generation cycle runs between 40 to 45 seconds. The maximum charge power is approximately 220 Watts. The average energy generated by the TREC system per dive is approximately 1.8 Wh. The estimated energy storage is approximately 1.7 Wh/Dive, this includes the efficiency of the batteries under these charge conditions. In the present operating mode, a battery could deliver approximately 70 Wh electrical energy every 80 generation cycles. This energy can be delivered at power levels as high as 800 Watts. This capability can enable the operation of high-power science instruments on a Slocum-Class ocean glider with the persistence of years of operation.

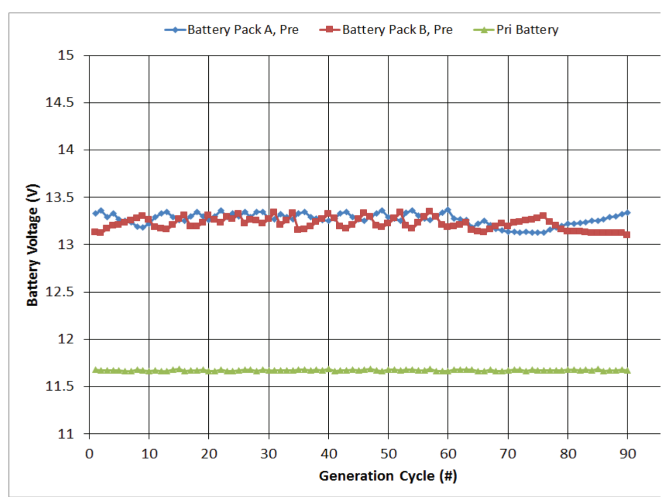

Fig. 3: Energy storage battery voltage of TREC system

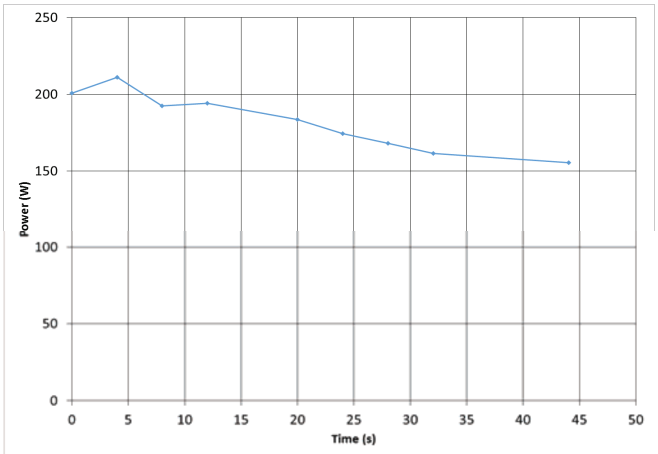

Fig. 4: TREC system energy generation cycle

B. Ballasting and Flight Dynamics

Engineers from TWRC, NASA-JPL, and Rutgers combined their expertise at the University of the Virgin Islands (UVI) in St. Thomas, USVI to assemble, ballast, and deploy the Slocum-TREC for a long duration test flight. The importance of stringent control of ballast is exacerbated by the buoyancy drive; too light and the glider cannot dive to the depths and temperatures it needs to reach to achieve a thermal charge, too heavy and the glider is unable to surface, which ultimately leads to the expulsion of an ejection weight and the end of the mission, requiring an emergency recovery.

Flight characteristics are generally similar to standard electric gliders, but volume and structural differences change the dynamics, giving the Slocum-TREC its own signature flight pattern and nuances. Ballasting was conducted in Brewers Bay, a relatively sheltered patch of water adjacent to UVI's dock, with only a moderate predominate wave and current field. Reliant upon the CTD attached to the Slocum-TREC, data were obtained, density calculations were made, and ballast was adjusted accordingly. Fine adjustments were made at sea, once flight parameters were analyzed following a test dive, by adding small ballast weights externally to achieve a symmetrical yo (dive and climb) pattern. Total symmetry in the yo could not, however, be obtained due to water mass layering. The decision was then made to aim for symmetry in the top water mass, allowing the glider's vertical velocity to slow in the deep water masses; the effects of which are mitigated by compaction of the carbon fiber hull resulting in a lesser volume, and therefore less buoyancy. Further flight dynamics adjustments required recovery and needed to be performed in the lab. Specifically, an inherent roll was noticed that would switch signs from the average on the dive and climb; rolling slightly to port on the dive and hard to port on the climb; this can be seen in the top plot of Fig. 5. A detailed inspection and measurements in the lab uncovered a slight twist between the hull and the thermal engines, effectively turning the entire glider into a rudder. The twist was corrected, and roll has been steady at less than -2 degrees as seen in the bottom plot of Fig. 5.

.

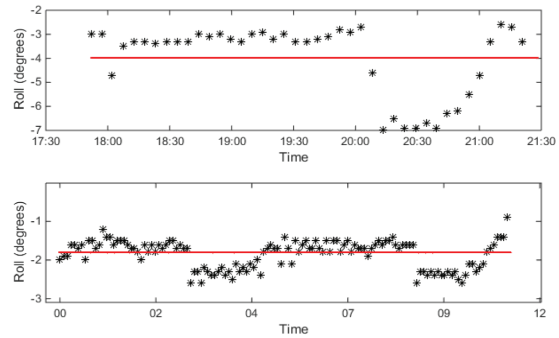

Fig. 5 – Roll before and after fixing the twist in the hull. Red is average roll; -4 degrees prior and less than -2 after.

III. Results

A. Characterization of physical structure – salinity, temperature, and density off the U.S. Virgin Islands

The Slocum-TREC is equipped with a Seabird Electronics (SBE) 41 CP CTD - a low power, 1 Hz continuously profiling flow-through cell CTD originally designed for profiling floats that has proven effective over long periods of unattended operations [4]. This allows for the continual collection of conductivity and temperature data, providing a clear picture of the physical structure of the water column. Initial analysis of the CTD data raised some concerns related to the calibration of the instrument, as results were atypical of the deep water column structure commonly seen in other areas. Once instrument calibration was verified by TWRC, a closer look was taken at the climatology of the area via the Caribbean Coastal Ocean Observing System (CariCOOS.org), a Rutgers partner through the Integrated Ocean Observing System (IOOS). The atypical structure is a subsurface peak of high salinity water nearly 37 psu sitting at a depth of almost 200 m known as the Subtropical Underwater (SUW) mass. The SUW is almost 2 psu higher than the deep water masses in the area, but is more than 15 degrees C warmer, ensuring a stable water column with no density inversions (Fig. 6). The lower salinity top water layer is known as the Caribbean Surface Water (CSW) mass, and, when time shifted, shares a decent correlation to the outflow of the Orinoco River basin in Venezuela [5]. Further freshwater input to the area comes from North Atlantic surface waters and the immense outflow of the Amazon River basin, resulting in a significantly less dense surface water in the top 100 m approximate depth [6]. The CSW exhibits a strong seasonal cycle between the summer and fall in both the depth and intensity of the halocline, corresponding to the lack of or abundance of freshwater input from South America [5]. It is this water mass and its fluctuations that makes its way onto the shelf and impacts marine life in and around the islands. The Slocum-TREC boasts its advantage as a superior platform for sustained ocean observing operations focusing on these types of measurements, as it has the ability to profile continuously for years while actively controlling its location as opposed to Lagrangian-style floats that must ride the predominate currents. Several seasonal cycles could be observed on a single Slocum-TREC deployment, closing data gaps and possibly raising correlations to related climatic cycles.

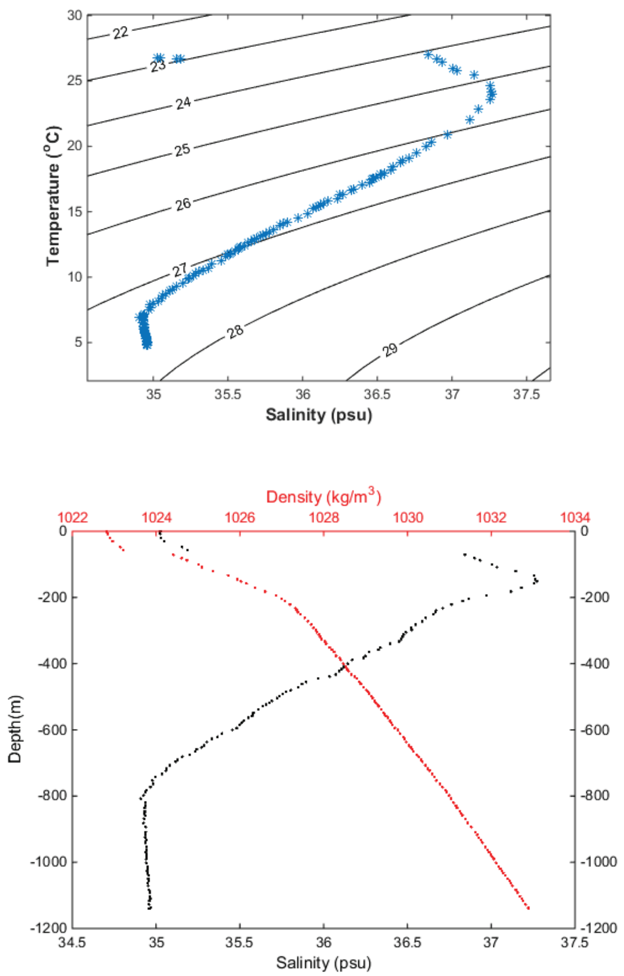

Fig. 6 – T-S diagram, salinity field and density structure showing water column stability. All data transmitted back from "Clark".

B. *Quantification of system design and limitations*

While the Slocum-TREC is currently deployed and fully operational, there are several components of the system that still require quantification. The thermal power generation and energy storage system developed by JPL has been thoroughly tested, measured, and documented, and is described above in detail. Thermal harvesting and power generation has, in fact, been so efficient that the Slocum-TREC has been shunting excess energy, and CTD horizontal resolution has been increased to sample on every dive. The overachieving nature of this system will likely lead to further design improvements as more energy intensive instruments can be integrated to further enhance ocean sampling. Initial musings include increasing sampling resolution in water masses of interest, along with integrating a pumped CTD such as the SBE GPCTD to improve thermal lag calculations in high vertical resolution sampling of strong thermoclines. The latitudinal limits of operation, however – how far north or south the glider can operate while continuing to obtain a thermal charge – are more difficult to discern. The glider requires a thermal difference of at least 12 degrees C between the surface and its maximum dive depth of 1200 m, spending approximately 120 minutes at <8 degrees C for the wax to freeze, plus an additional 120 minutes at >20 degrees C for the wax to melt in order to obtain a thermal charge. While oceanographic models may assist in determining general latitudinal limits, this can change in the short term as currents meander or eddies form and migrate. On a larger time scale, latitudinal limits may expand in the future as oceans continue to warm. One pressing limitation that the Slocum-TREC team has not addressed is a concept familiar to many who have conducted long duration oceanographic studies – biofouling. Ablative paints and other standard antifouling methods have proven ineffective over long durations, and newer technologies such as those resembling shark skin coatings are not yet commercially available. By continuously harvesting thermal energy, the Slocum-TREC has solved the propulsion and energy budget limitations, perhaps thrusting biofouling to the forefront of the list of issues facing long duration ocean sampling.

C. *Data Flow and Implications for the Future*

Currently, data collected by the Slocum-TREC "Clark" is transferred via the Iridium satellite constellation and routed directly to TWRC. This is then synced to a server at Rutgers where data is displayed on the web in near real-time. From Rutgers, this data is ported into the Global Telecommunications System (GTS) for ingestion into oceanographic models by operational modeling centers such as the National Centers or Environmental Prediction (NCEP) and the U.S. Navy (NAVO). NCEP's mission statement refers to delivering climate products essential to protecting life, property, and economic well-being, immediately vesting their interest in the expansion of the collection of accurate, high resolution ocean data. Through the GTS, data collected by gliders, floats, and other assets can be assimilated into models such as the Real-Time Ocean Forecasting System (RTOFS), a global operational model based on an eddy resolving 1/12° global HYCOM (Hybrid Coordinates Ocean Model) developed by the U.S. Navy [7]. Future plans for RTOFS include inputs to hurricane and climate forecast systems, further emphasizing the need for high resolution data collection in sparsely sampled areas. The strengths of the Slocum-TREC become apparent in this context, showcasing the ability to routinely gather high resolution data that can be regularly transmitted ashore for a cost that diminishes throughout the life of the glider. Daily assimilation into models can assist with improving ocean, terrestrial, hurricane and climate forecasting at a level that is unparalleled by any other oceanographic platform.

IV. CONCLUSIONS

Thus far, the Slocum-TREC deployment has been a resounding success. "Clark" has been continually operating in the Virgin Islands Trench, sending full-profile data ashore in user-configurable intervals of anywhere from 6-12 hours; further adjustable if desired. The ocean glider operators, dubbed pilots, since the glider does "fly", are currently in the process of optimizing and adjusting flight and energy storage parameters. The first stage of endurance testing will be complete after 90 consecutive days of deployment. The goal for the second stage of endurance testing is for continued operation greater than 200 days. After the second stage of endurance testing, the glider's flight and energy system data will be evaluated and an extended mission will be proposed. The third mission will likely traverse the Atlantic, including paths suggested by Rutgers undergraduates studying the global ocean models and working on detailed path-planning projects, allowing "Clark's" success to transcend the engineering community and enter the educational community as well.

ACKNOWLEDGMENTS

This work presented here was carried out by Rutgers and Teledyne Webb Research in conjunction with the Jet Propulsion Laboratory, California Institute of Technology under a contract with National Aeronautics and Space Administration. Funding for the project was provided by the Office of Naval Research.

Glider observations and modeling of sediment transport in Hurricane Sandy

Travis Miles[1], Greg Seroka[1], Josh Kohut[1], Oscar Schofield[1], and Scott Glenn[1]

[1]Center for Ocean Observing Leadership, Department of Marine and Coastal Sciences, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, New Jersey, USA

Abstract Regional sediment resuspension and transport are examined as Hurricane Sandy made landfall on the Mid-Atlantic Bight (MAB) in October 2012. A Teledyne-Webb Slocum glider, equipped with a Nortek Aquadopp current profiler, was deployed on the continental shelf ahead of the storm, and is used to validate sediment transport routines coupled to the Regional Ocean Modeling System (ROMS). The glider was deployed on 25 October, 5 days before Sandy made landfall in southern New Jersey (NJ) and flew along the 40 m isobath south of the Hudson Shelf Valley. We used optical and acoustic backscatter to compare with two modeled size classes along the glider track, 0.1 and 0.4 mm sand, respectively. Observations and modeling revealed full water column resuspension for both size classes for over 24 h during peak waves and currents, with transport oriented along-shelf toward the southwest. Regional model predictions showed over 3 cm of sediment eroded on the northern portion of the NJ shelf where waves and currents were the highest. As the storm passed and winds reversed from onshore to offshore on the southern portion of the domain waves and subsequently orbital velocities necessary for resuspension were reduced leading to over 3 cm of deposition across the entire shelf, just north of Delaware Bay. This study highlights the utility of gliders as a new asset in support of the development and verification of regional sediment resuspension and transport models, particularly during large tropical and extratropical cyclones when in situ data sets are not readily available.

1. Introduction

At midnight on 29 October, Hurricane Sandy made landfall near Brigantine, NJ devastating New York and New Jersey coastal communities through a combination of high winds and historic storm surge [*Blake et al.*, 2013]. This storm caused significant coastal erosion [*Hapke et al.*, 2013], and showed a distinct seabed signature at an inner-shelf site [*Trembanis et al.*, 2013] but little is understood about broader regional sediment resuspension and transport on the continental shelf. A unique data set from a Teledyne-Webb Slocum glider equipped with a Nortek Aquadopp Current profiler deployed ahead of the storm in combination with the Regional Ocean Modeling System (ROMS) allow us to assess regional patterns of sediment resuspension and transport throughout Hurricane Sandy.

Storms are important episodic events that redistribute sediment on continental shelves [*Cacchione and Grant*, 1987; *Drake and Cacchione*, 1992; *Sherwood et al.*, 1994; *Ogston et al.*, 2000; *Keen and Glenn*, 2002; *Styles and Glenn*, 2005; *Teague et al.*, 2006; *Warner et al.*, 2008a]. Many of the field programs over the past two decades used benthic landers and tripods equipped with a suite of optical and acoustic sensors at a single location to understand sediment resuspension and transport dynamics [*Trowbridge and Nowell*, 1994; *Agrawal and Pottsmith*, 2000; *Harris et al.*, 2003; *Styles and Glenn*, 2005]. These sensor platforms have provided a wealth of information that have aided in the development of one-dimensional bottom boundary layer models (BBLMs) that take into account combined wave and current interactions [*Grant and Madsen*, 1979, 1986; *Glenn and Grant*, 1987; *Madsen and Wikramanayake*, 1991; *Madsen*, 1994; *Styles and Glenn*, 2000, 2002; *Warner et al.*, 2008b]. These one-dimensional models generally require input of wave and current data and a significant amount of tuning in order to accurately predict sediment resuspension and transport at a specific location.

In the past decade, these one-dimensional BBLMs have been coupled to three-dimensional hydrographic models to understand broader scale erosion and deposition at regional scales [*Blaas et al.*, 2007;

Papanicolaou and Elhakeem, 2008; *Warner et al*., 2008b; *Hu et al*., 2009]. With the development of these regional scale sediment resuspension and transport studies new technologies are necessary to supplement single point measurements of sediment resuspension and transport on continental shelves. Many of the sensors included on tripods and benthic landers have now been developed for autonomous platforms such as Teledyne-Webb Slocum gliders [*Davis et al*., 2003; *Schofield et al*., 2007; *Glenn et al*., 2008]. A study by *Glenn et al*. [2008] presented data from two gliders deployed on the New Jersey shelf during storm conditions, one during stratified summer months and the other after the fall transition to well-mixed winter conditions. The stratified summer deployment showed sediment resuspension throughout the bottom layer, restricted by thermal stratification, during a summer hurricane, while the deployment after the fall transition identified full water column sediment resuspension that followed a Rousian distribution [*McLean*, 1991], where suspended sediment concentration decreased logarithmically with height above the bed. A follow up study [*Miles et al*., 2013] used two simultaneously deployed gliders during a northeaster in fall of 2009 to identify spatial variability in sediment resuspension and transport.

The present work builds on previous sediment resuspension and transport work by using a combination of model predictions and glider observations to identify idealized broad spatial patterns of sediment resuspension, transport, and deposition on the New Jersey (NJ) continental shelf during Hurricane Sandy in October of 2012.

A detailed description of observational and model setup is given in section 2. The synoptic atmospheric and oceanic conditions, as well as the observed and modeled sediment resuspension and transport response along the glider track are detailed in section 3. Section 4 provides a broader regional look at sediment transport throughout the storm and highlights the atmospheric and wave forcing that lead to shelf wide patterns of erosion and deposition. A final summary and conclusions are provided in section 5.

2. Methods

2.1. Gliders

Teledyne-Webb Slocum gliders have become robust tools for sampling storm conditions [*Glenn et al*., 2008; *Ruiz et al*., 2012; *Miles et al*., 2013]. These instruments are mobile sensor platforms that profile through the water column using a combination of buoyancy and a set pitch angle to move vertically and horizontally in a sawtooth pattern. Data are logged every 2 s on downcast and upcast with vertical speeds of $\sim$20 cm/s resulting in high data density relative to traditional shipboard techniques. A single hour long sampling segment may include approximately 5–10 profiles depending on water column depth. After each segment is complete the glider surfaces and relays its position and data back to Rutgers using an Iridium satellite phone in the aft section of the glider. Further details of Rutgers glider operations can be found in *Schofield et al*. [2007].

The glider used in this study was RU23, a first generation shallow (100 m rated) glider equipped with a suite of oceanographic sensors. RU23 included three science sensors, a Seabird unpumped conductivity temperature and depth (CTD) sensor, two Wetlabs triplet sensors and an externally mounted Nortek Aquadopp current profiler. One Wetlabs triplet was an optical backscatter puck (bb3) that measured the volume scattering function (VSF) at three wavelengths 470, 532, and 660 nm in the 117° back direction. We converted from the VSF to estimated backscatter coefficients following *Boss and Pegau* [2001]. For our analysis, we use the 660 nm channel as it is less impacted by absorption effects than the shorter wavelength channels (E. Boss, personal communication, 2014). These instruments respond linearly to increased suspended particulate matter concentrations [*Boss et al*., 2009], but are also sensitive to variability in particle size, shape, and composition; similar sensors were used onboard previous glider observations of storm driven sediment resuspension and transport [*Glenn et al*., 2008; *Miles et al*., 2013]. The second Wetlabs triplet was an ecopuck that we used primarily to measure chlorophyll fluorescence.

The Nortek Aquadopp was a three-beam 2 MHz system with a 0.2 m blanking distance that collected data in 10 1 m bins in beam coordinates. The Aquadopp was externally mounted in an upward looking position, with a custom glider head that measured 0° pitch at a nominal glider pitch angle of 26.5°. Data were logged internally and downloaded postdeployment. This instrument served two purposes: the first was to estimate realistic water column velocities following a shear least squares method originally developed for lowered acoustic Doppler current profilers [*Visbeck*, 2002] and recently adapted to use on glider platforms [*Todd et al.*, 2011a, 2011b]. The shear least squared method is used to solve the following equation:

$$(u,v)_r=(u,v)_w-\ (u,v)_g \tag{1}$$

where $(u,v)_r$ is the measured water velocity relative to the glider, $(u,v)_w$ is the real ocean velocity, and $(u,v)_g$ is the velocity of the glider. The measured water velocity relative to the glider is taken directly from the vertical profile of the horizontal shear of the velocity profiles above the glider. Glider velocity is dead-reckoned [*Davis et al.*, 2003] using a combination of pre and postsegment GPS fixes, pitch angle, heading, and depth. These two measurements are then used to solve for the real ocean velocities using least squares, which are described in detail in Appendix B of *Todd et al.* [2011a].

The second purpose was to provide acoustic backscatter observations coincident with optical measurements. Acoustic return (*Amp*) strength along each beam was converted to echo level (*EL*), with units of decibels (dB) following *Lohrmann* [2001]:

$$EL=Amp\times 0.43+20\log_{10}(R)+2\alpha_w R+20R\int \alpha_p\times dr \tag{2}$$

where R is the range along each beam, α_w is the water absorption in db m^{-1}, and α_p is the particle attenuation in db m^{-1}. Previous studies [e.g., *Lynch et al.*, 1997] have used colocated optical and acoustic backscatter sensors on bottom tripods to assess the relative contribution of small and large sediment particles. The difference in acoustic and optical response to different size classes is most clearly illustrated in *Lynch et al.* [1997, Figure 4], with an optical backscatter sensor and a 1 and 5 MHz acoustic backscatter sensor. An Aquadopp is most sensitive to particles with a $k*a=1$, where k is the acoustic wave number and a is the particle radius [*Lohrmann*, 2001; *Thorne and Hanes*, 2002]. For a 2 MHz system, a k*a value is most sensitive to particles with a 0.25 mm diameter with a reduction in sensitivity raised to the fourth power for particles smaller than a and inversely proportional for particles with a diameter larger than a. Optical backscatter sensors generally respond to the cross-sectional area [*Bunt et al.*, 1999] and have been shown to have large increases in observed optical backscatter for similar concentrations of small versus large particles, thus in the presence of significant concentrations of small suspended particles these sensors are largely unresponsive to additional concentrations of large particles (C. Sherwood, personal communication, 2014).

As the glider was deployed over a broad spatial region with varying bottom types, sediment types and optical properties we did not attempt to calibrate either optical or acoustic backscatter sensors using in situ sediment, but rather focus on intercomparison of the suite of sensors to estimate sediment resuspension and transport throughout the deployment.

2.2. Additional Observational Assets

We use National Oceanographic and Atmospheric Association (NOAA) buoy 44025 and 44009 data to supplement glider data and validate numerical model results. NOAA buoy 44025 is located at 40.250°N and 73.167°W off of Long Island, New York, and NOAA buoy 44009 is located at 38.461°N and 74.703°W offshore of Delaware Bay (Figure 1). Buoy data included in this study are hourly wind speed and direction collected at a height of 4 m, barometric pressure, significant wave height, dominant wave period, wave spectra, and mean wave direction from buoy 44025 only.

2.3. Hydrodynamic Model

The Regional Ocean Modeling System (ROMS) [*Shchepetkin and McWilliams*, 2005, 2009; *Haidvogel et al.*, 2008] version 3.6 was used to simulate the ocean response to storm forcing. ROMS is a free surface, sigma coordinate primitive equation model that is widely used for coastal applications. The configuration here is a modified version of the Experimental System for Predicting Shelf and Slope Optics (ESPreSSO) (http://www.myroms.org/espresso/) with 5 km horizontal resolution and 36 vertical levels, which extends from Cape Cod, MA, to Cape Hatteras, NC, and near shore to beyond the shelf-break (Figure 2). The ESPreSSO domain has been used extensively on the MAB to study a diverse array of physical and biological processes [*Cahill et al.*, 2008; *Haidvogel et al.*, 2008; *Hofmann et al.*, 2008; *Zhang et al.*, 2009; *Wilkin and Hunter*, 2013; *Xu et al.*, 2013]. We used the original assimilative ESPreSSO four-dimensional variational data assimilations (IS4DVAR) output as an initial condition starting on 25 October and ran the model forward including boundary

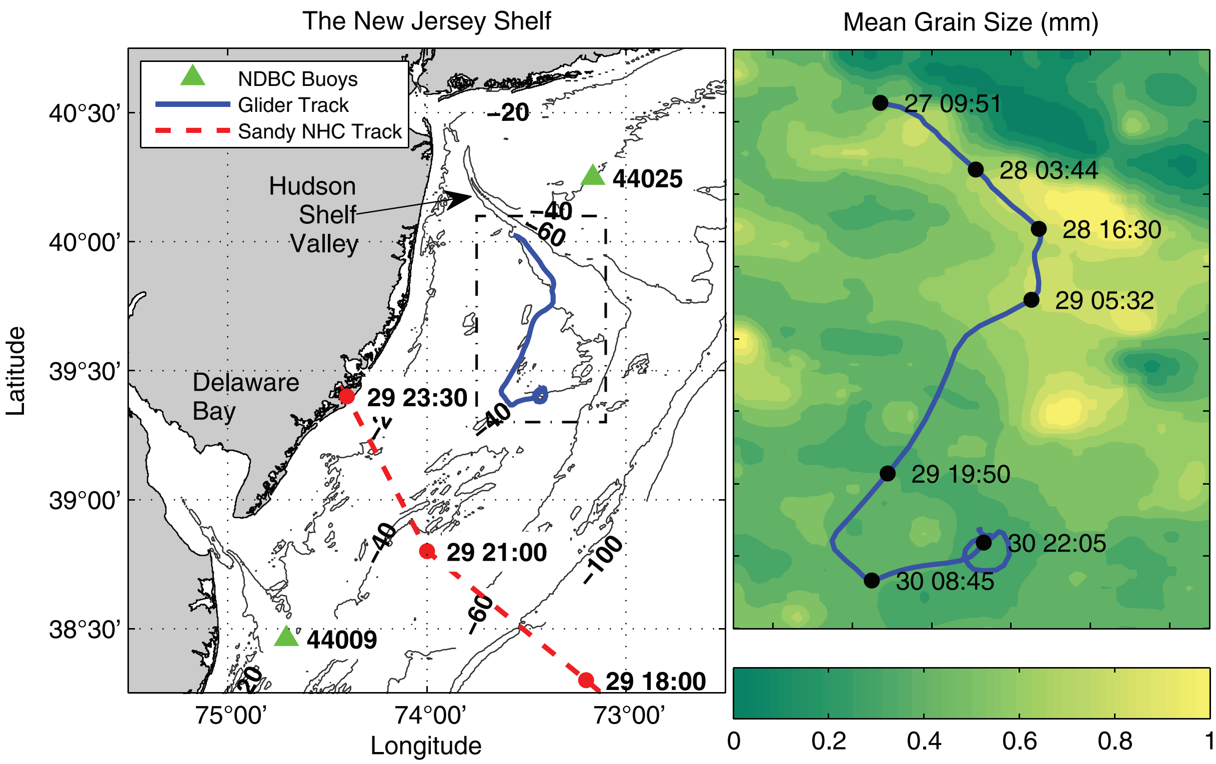

Figure 1. Map of the (a) New Jersey shelf, with locations of buoys (green diamonds) 44025 and 44009, (blue line) RU23 glider sampling track, the (red dashed line) Hurricane Sandy track from the National Hurricane Center (NHC) with associated time points. (b) A map of mean bed grain sizes over the area defined by the dashed box in Figure 1a in millimeters compiled from the usSEABED project, with a (blue line) track of the glider consistent with Figure 1a overlaid with times in the format of day hour:minute on 27 October through 30 October 2012.

conditions from HYCOM-NCODA (http://hycom.org/), tidal boundary conditions from the ADCIRC tidal model (http://adcirc.org/).

For this study, we modify the standard ESPreSSO setup in a number of ways: we replace the standard ESPreSSO atmospheric forcing from the National Center for Environmental Prediction (NCEP) North American Mesoscale (NAM) model with our own Weather Research and Forecasting (WRF) model detailed in section 2.4; by turning on the sediment features detailed in section 2.5; and the BBLM detailed in section 2.6; and drive this BBLM with the wave information from NOAAs, WAVEWATCH III model detailed in section 2.7. While numerous studies have used the Coupled Ocean Atmosphere Wave Sediment Transport (COAWST) system [*Warner et al*., 2010; *Olabarrieta et al*., 2012] for sediment transport, which includes a coupled wave and atmospheric model, for simplicity we use the Rutgers ROMS ESPreSSO domain as it has a robust history of reproducing realistic circulation over our study region [*Wilkin and Hunter*, 2013] and required minimal adjustment from the standard setup to run for the purposes of this study.

2.4. Atmospheric Model

Default atmospheric forcing for ROMS ESPreSSO is from the NCEP NAM model, which is an operational version of the WRF Nonhydrostatic Mesoscale Model (WRF-NMM) run at 12 km horizontal resolution with standard output every 3 h. In order to provide ROMS with higher spatial and temporal resolution atmospheric forcing, we used our own implementation of the Advanced Research WRF (WRF-ARW), Version 3.4 [*Skamarock et al*., 2008]. WRF-ARW is a fully compressible, nonhydrostatic, terrain-following coordinate, primitive equation atmospheric model that is used for many different weather and climate applications.

Our WRF-ARW simulations were run at 6 km horizontal resolution with 35 vertical levels, using the Global Forecast System (GFS) 0.5° model for lateral boundary conditions. To provide continuous near-analysis atmospheric forcing, we used hourly output from a series of six short 36 h WRF-ARW hindcasts. These hindcasts were initialized at 00:00 GMT each day starting on 25 October 2012. For each run, excluding the first

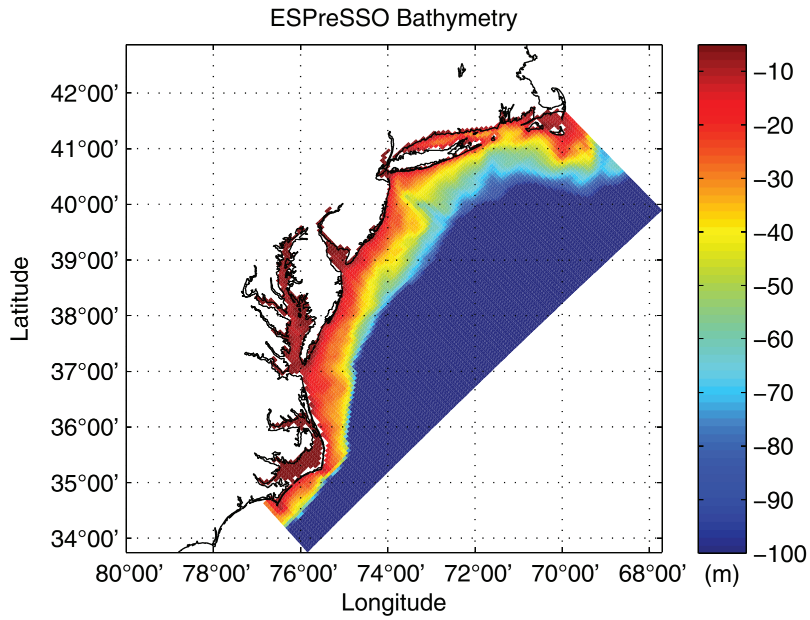

Figure 2. A map of bathymetry for the ESPreSSO model domain (gridded region) with the maximum plotted depth of 100 m. Depths beyond 100 m are present in the model domain but are plotted as blue here.

and last runs, only data from hours 7 to 30 were retained in an effort to minimize the impact of model reinitialization on wind forcing. The first run included hours 1 through 30 and the last run included hours 7 to 36 in an effort to maximize coverage.

For bottom boundary conditions over water, we used a high-resolution sea surface temperature (SST) composite product. This daily SST product has a resolution of 2 km and is a 3 day coldest dark pixel composite of regionally declouded daytime scans from the Advanced Very High Resolution Radiometer (AVHRR) aboard the NOAA-18 and NOAA-19 satellites. Through these techniques, normally unresolved coastal upwelling and tropical cyclone cold wake processes are preserved. For each simulation, we initialize SST with the daily composite described above and leave it fixed until the next simulation's initialization. Model validations in section 3.3 indicate that this model setup adequately represents storm forcing for our purposes, but future model runs may benefit from coupled ocean and atmospheric modeling.

ESPreSSO air-sea heat and momentum fluxes were calculated using the bulk formulae of *Fairall and Bradley* [1996] and *Fairall et al*. [2003] using the ESPreSSO model sea surface temperature and WRF-ARW sea level air temperature, precipitation, pressure, relative humidity, and 10 m winds.

2.5. Sediment Model

We used the Community Sediment Transport Model (CSTM) to simulate sediment resuspension and transport. A detailed description of the CSTM can be found in *Warner et al*. [2008b]. The CSTM requires input of user-defined sediment size classes, critical shear stress values, fall velocities, densities, and erodibility constants. We initialized with an idealized spatially uniform single, 15 m deep, bed layer with two noncohesive size classes of 0.1 mm and 0.4 mm to represent fine and medium grain size sands found in the glider sample region (Figure 1b). According to a map generated from data collected by the usSEABED project [*Goff et al*., 2008] on 29 October 2012 during peak storm conditions, the glider was sampling over a region with approximately 0.4 mm mean grain sizes. Additionally, a recent publication [*Trembanis et al*., 2013] collected grab samples on the southern region, near buoy 44009 and identified mean grain sizes of approximately 0.3 mm prior to Sandy impacting the region. Based on the 0.1 and 0.4 mm diameters and 2650 kg m^{-3} densities, we use settling velocities and critical shear stresses of 5.7 mm s^{-1} and 0.14 N m^{-2}, respectively, for the 0.1 mm sediment and 52 mm s^{-1} and 0.23 N m^{-2} for the 0.4 mm sediment and erodibility constants of 5×10^{-4} kg m^{-2} s^{-1} for both sediment types. This uniform bed setup is used to only generally represent sediment resuspension and transport on the continental shelf, and is primarily used for simplification of data interpretation and comparison of large and small grain size particles with glider data. This setup will not address the potential impact of realistic sediment distributions and bed armoring on sediment resuspension. For more detailed analysis, we recommend using a broader array of sediment types, higher spatial resolution model grids, and coupled ocean-atmosphere-wave model routines.

At each time step, the model uses sediment bed properties to calculate bed roughness at each grid point and passes this information to the bottom boundary layer model to calculate bottom stress (τ_{sf}) from combined waves and currents. If critical shear stresses (τ_{ce}) are exceeded sediment is resuspended into the water column and transported as a tracer similar to temperature and salinity, but with an additional source and sink term, based on the erosional source and settling velocity, respectively. From *Warner et al*. [2008b]:

$$C_{source,m} = \frac{\partial w_{s,m} C_m}{\partial s} + E_{s,m} \tag{3}$$

where s is the vertical coordinate for the advection diffusion equation in ROMS, w_s is the vertical settling velocity prescribed by the user for each size class m, C is sediment concentration, and E_s is the erosion source, which follows[*Ariathurai and Arulanandan*, 1978]:

$$E_{s,m} = E_{0,m}(1-\phi) \frac{\tau_{sf} - \tau_{ce,m}}{\tau_{ce,m}} \quad \tau_{sf} > \tau_{ce,m} \tag{4}$$

where again, s is the vertical coordinate in ROMS, E_s is the surface erosion mass flux, E_0 is a bed erodibility constant, ϕ is the bed porosity of the uppermost bed layer and τ_{sf} τ_{ce} are the defined above. For the purposes of this study, we only consider suspended load transport for direct comparison with glider observed suspended load transport, though for realistic studies of sediment transport bedload transport must be considered. Bedload transport routines are also available in ROMS [*Meyer-Peter and Müller*, 1948; *Soulsby and Damgaard*, 2005].

2.6. Bottom Boundary Layer Model

The standard ESPreSSO setup uses a quadratic drag law with a drag coefficient expression to represent bottom stress. For sediment resuspension and transport, a more detailed calculation of bottom stress is needed as realistically, large gradients in velocity and sediment concentration occur near the bed. For this study, we use the ssw_bbl model, which follows *Madsen* [1994] for combined waves and currents and the moveable bed routines from *Wiberg and Harris* [1994] and *Harris and Wiberg* [2002]. The ssw_bbl routine used in this study is covered in detail in *Warner et al*. [2008b]. Parameters required for the ssw_bbl model include sediment characteristics described in the previous section to determine bed roughness, near-bottom reference velocities, u and v taken as the velocity in the lowest model grid, wave orbital velocities u_b, wave period T, and wave direction θ.

2.7. Wave Model

The wave parameters used for this study are derived from the third generation NOAA WAVEWATCH III (WWIII) (http://polar.ncep.noaa.gov/waves/index2.shtml) operational wave model. We specifically use data from the hindcast reanalysis version 2.22, with 3 h output. We use two WWIII data sets for this study, with 4° and 10° min resolutions that cover the study region. The 4 min resolution data does not cover the entire ESPreSSO domain but provides higher resolution in near shore shallow water regions. Both the 4 and 10 min resolution data are interpolated to the standard ESPreSSO grid with a nominal 5 km horizontal resolution. While this may not be an ideal methodology for detailed analysis of coastal change or long-term studies on the continental shelf, interpolation of these readily available products were sufficient for a first-order comparison of glider optical data to modeled suspended sediment at the midshelf. WWIII model hindcasts do not include the full wave spectra as the operational and forward run products. To calculate bottom orbital velocities from WWIII data without spectral information, we use linear wave theory and follow the method of *Wiberg and Sherwood* [2008] using an assumed Joint North Sea Wave Project (JONSWAP) spectrum. Matlab® codes for this calculation are included in the reference and validation of the calculated product of both buoys is presented in section 3.3.

3. Results

3.1. Storm Conditions

On 28 October, when winds and waves began to steadily increase on the MAB (Figure 3) the center of Hurricane Sandy was located nearly due east of the Georgia and South Carolina. On 29 October, the storm began

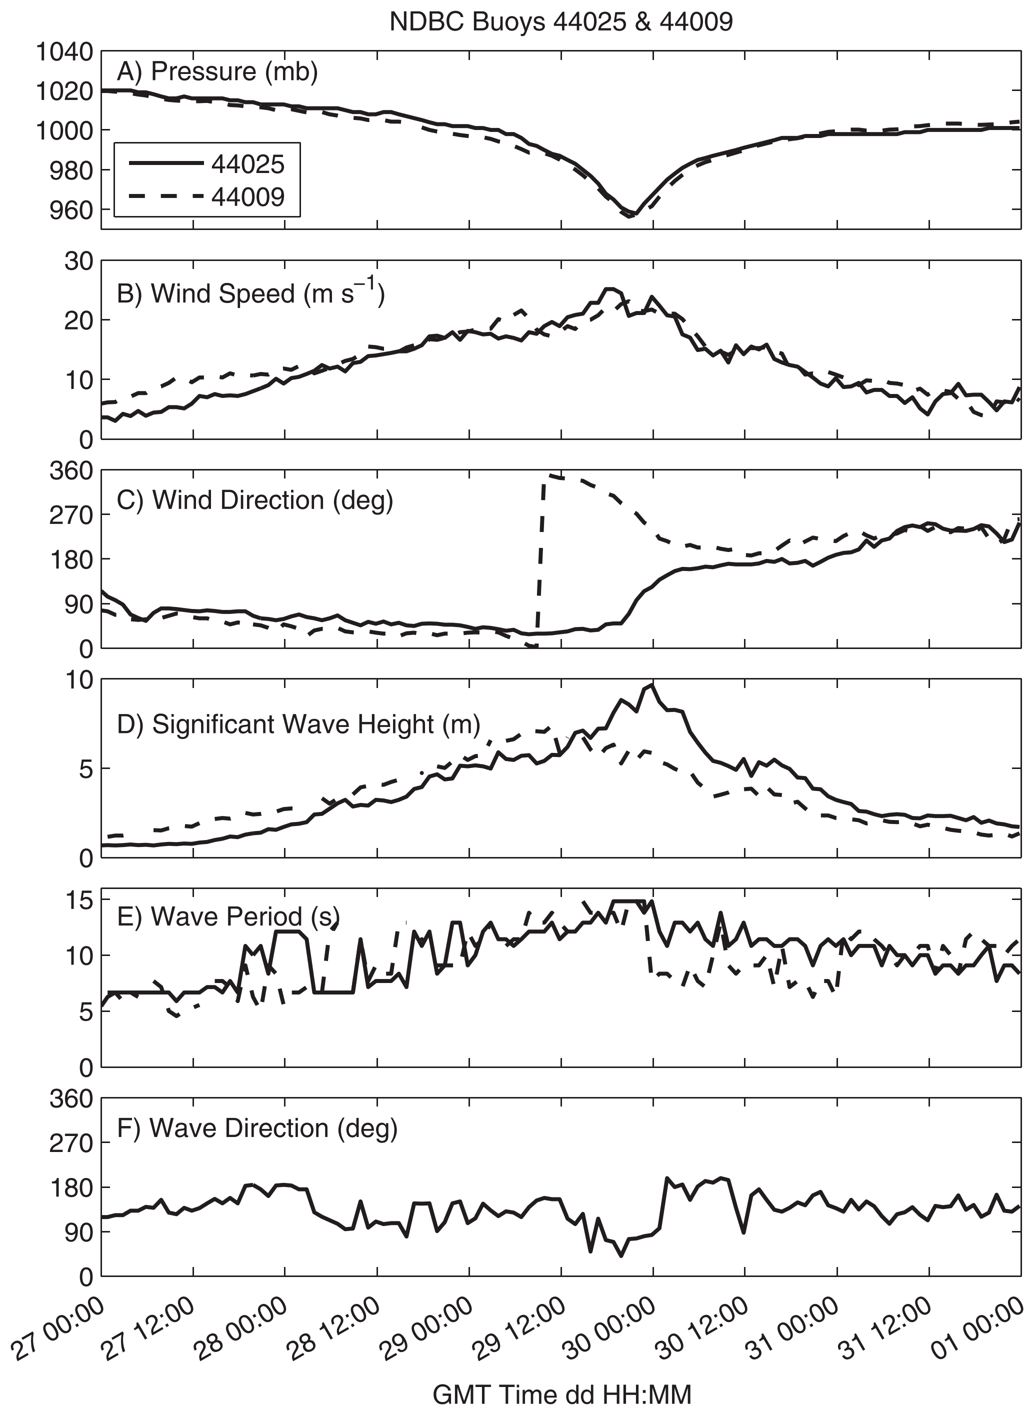

Figure 3. Buoy (solid line) 44025 and (dashed line) 44009 (a) pressure, (b) wind speed, (c) wind direction from north, (d) significant wave height, (e) wave period, and (f) wave direction from north at buoy 44025 only. The *x* axis is in days hour:minute for October 2012.

a left hand turn toward the New Jersey coastline and made landfall near Brigantine, New Jersey at 23:30 GMT (Figure 1a) [*Blake et al.*, 2013]. Buoy 44025 and 44009 were located to the north and south, respectively, of the storm track as it crossed the shelf (Figure 1a). Minimum sea-level pressure at 44025 and 44009 was below 960 at both locations, and maximum wind speeds peaked over 20 m s^{-1} (Figure 3). Winds were initially downwelling favorable from the northwest at 44025 and north at 44009. Winds shifted counterclockwise to be more northeasterly at 44009 on 29 October as the storm center crossed the shelf. Winds at 44025 maintained a northwesterly direction until just prior to landfall when they shifted clockwise to be

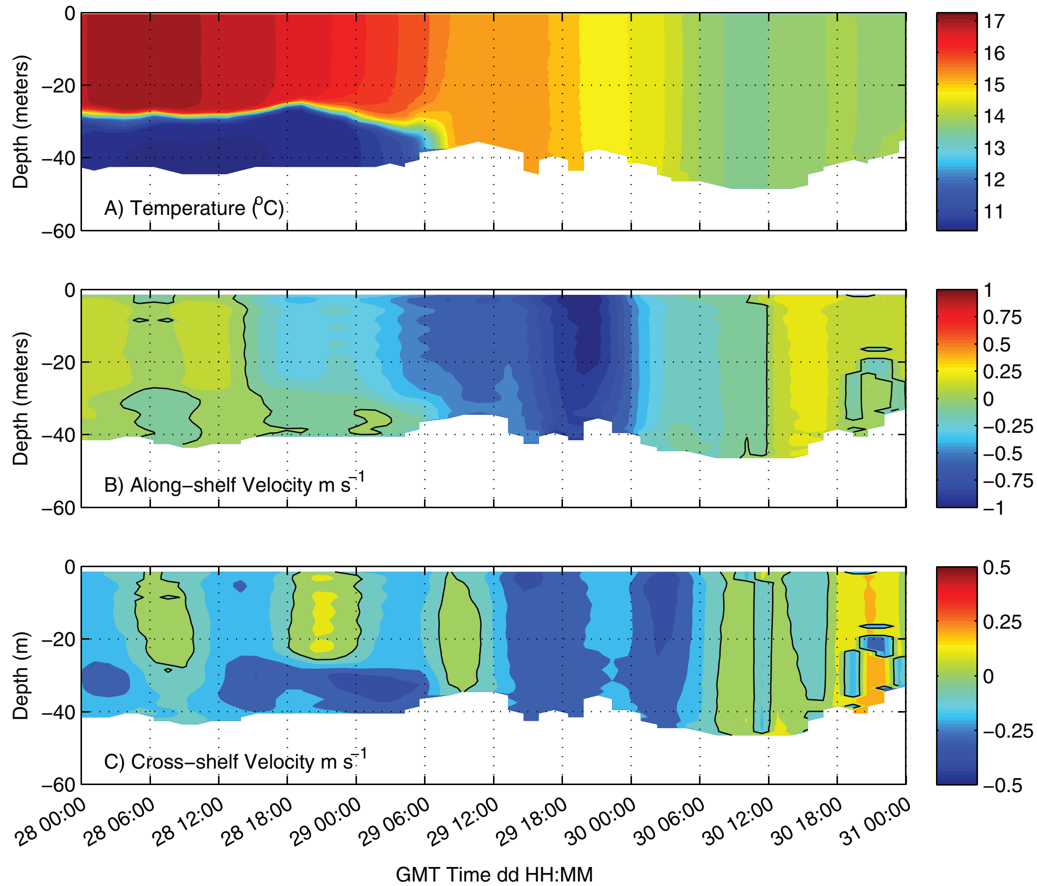

Figure 4. Cross sections along the glider track of (a) temperature, (b) along-shelf currents, and (c) cross-shelf currents with the black contour representing 0 m s^{-1}. Directions are toward and rotated 30° clockwise from north to be approximately along and cross-shelf, where positive is toward the northeast and offshore, respectively. Times on the *x* axis are as in Figure 3.

from the southwest as the eye passed between the two stations. Significant wave heights first peaked on the southern MAB at 44009 near 7 m approximately 12 h before they peaked at 44025 near 10 m. Dominant wave periods at both buoys reached 15 s near landfall. Wave periods dropped immediately following eye passage at 44009, likely due to the rapid shift in wind direction. While no wave direction data were available at 44009, mean wave direction at 44025 was generally in agreement with wind direction.

3.2. Glider Deployment

Glider RU23 was deployed on 25 October approximately 15 km off of northern New Jersey, on the southern flank of the Hudson Shelf Valley (Figure 1a). RU23 progressed southeastward in an effort to exit a coastal shipping lane prior to storm conditions. During the initial storm forcing period from 28 October at 00:00 GMT to the 29 October at 06:00 GMT, the water column observed by the glider was highly thermally stratified with surface temperatures of near 18°C and bottom temperatures as low as 10°C separated by a sharp thermocline (Figure 4a). During the stratified phase currents measured by the Nortek Aquadopp showed two-layer cross-shelf flow consistent with downwelling circulation on the shelf (Figures 4b and 4c), with offshore flow near the bottom and onshore flow near the surface. On 29 October at 06:00 GMT, the system transitioned from two to one-layer with a uniform water column temperature of ~15°C and strong alongshore flow toward the southwest. As glider horizontal speeds are on the order of 0.2–0.3 m s^{-1}, the glider was rapidly advected alongshore with the mean current until after the eye passed on 29 October at 23:30 GMT.

3.3. Model Validation

To validate the meteorological and wave forcing parameters, we calculated correlation coefficients and root-mean-square-error between modeled and observed winds, sea level pressure, wave height, and calculated bottom orbital velocities at buoy 44025 and 44009. We focused the comparison on the storm

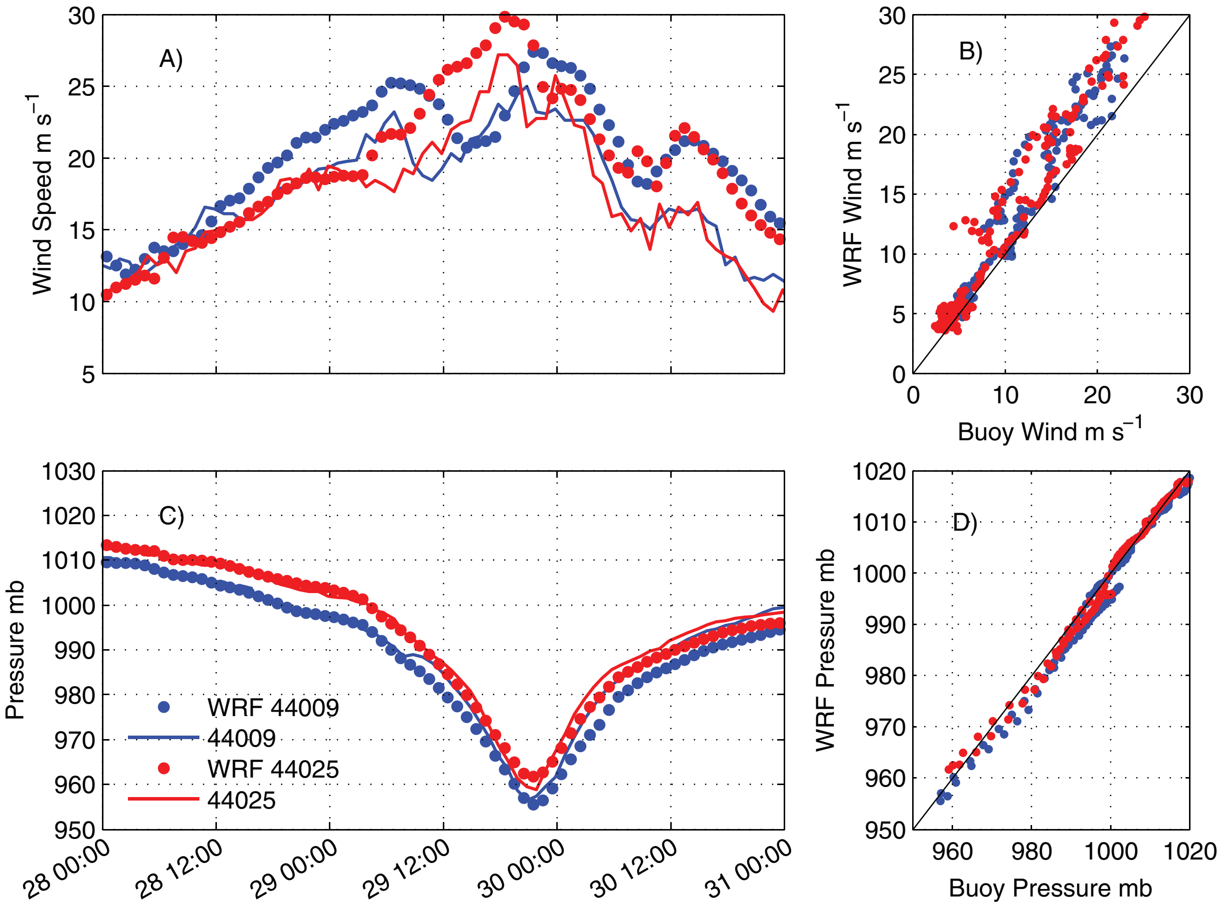

Figure 5. Comparisons of (dots) WRF and (lines) buoys (blue) 44009 and (red 44025) of (a and b) wind speed and (c and d) pressure during the storm forcing period. WRF versus buoy winds had a root mean square error (RMSE) of 4.25 and 4.14 m s^{-1} and correlation coefficients of 0.87 and 0.90 for 44009 and 44025, respectively. WRF versus buoy pressures had RMSE of 2.75 and 1.74 mb and correlation coefficients of 0.99 and 0.99 for 44009 and 44025, respectively. Time on the *x* axis is consistent with Figure 3.

forcing period between 28 October at 00:00 GMT and the 31 October at 00:00 GMT so as not to bias the validation to fair-weather conditions. Quantitative comparisons are detailed in the captions for Figures 5 and 6.

Qualitatively, the WRF hindcast wind speed and pressure (Figure 5) were in good agreement with observations at buoy 44025 and 44009. Modeled wind speeds (Figures 5a and 5b) appear to be overpredicted, likely due to WRF winds being instantaneous values extracted hourly while observed winds were hourly averages. Despite the high values, WRF winds followed along closely with the observations except for a late drop in winds at buoy 44009 on the 29 October at 12:00 GMT. Model predicted pressure was extremely close to the observations with similar trends and minimums below 960 millibars, indicating that the storm track and strength were well represented in the model.

WWIII simulated wave heights (Figures 6a and 6b) were underpredicted at both locations ahead of the storm, particularly at 44009, with peak observed wave heights occurring nearly 12 h ahead of peak modeled wave heights. Wave heights between 29 October at 12:00 GMT and 31 October at 00:00 GMT were well represented at both locations and peak modeled and observed wave heights occurred at approximately the same time at buoy 44025. Simulated bottom orbital velocities at 44025 were similarly underpredicted but generally in good agreement with the observations (Figures 6c and 6d). Differences between modeled and observed waves are likely due to the lack of spectral information included with the archived WWIII model data and coarse resolution. These properties would likely be improved by use of operational WWIII products with full spectral information or by using a modeling system such as COAWST, which includes three-way coupling between ROMS, the simulating waves near-shore (SWAN) model, and the weather research

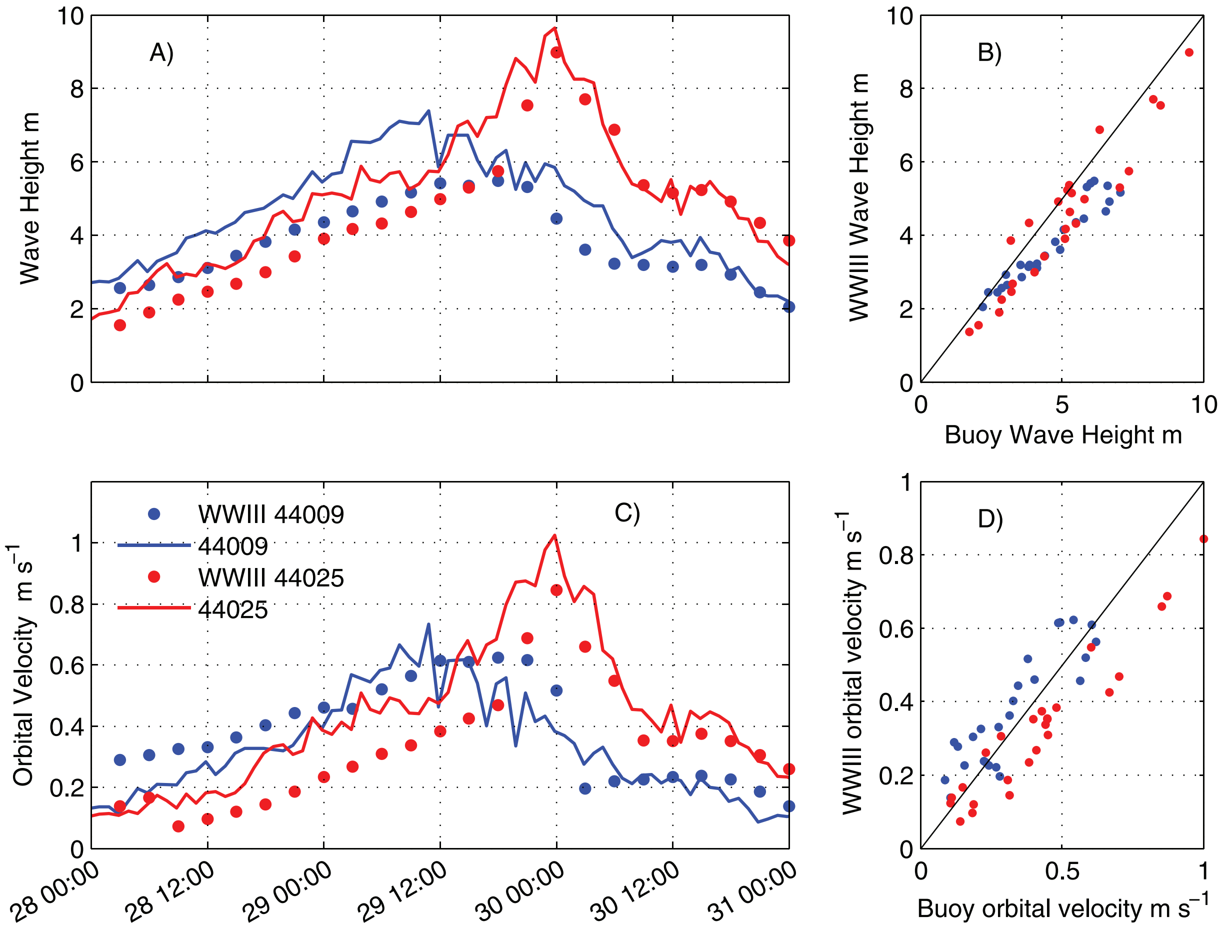

Figure 6. Comparisons of (dots) WWIII and (lines) buoys (blue) 44009 and (red 44025) of (a and b) wave height and (c and d) bottom orbital velocities during the storm. WWIII versus buoy waves had RMSE of 0.98 and 0.83 m and correlation coefficients of 0.96 and 0.95 for 44009 and 44025, respectively. WWIII versus buoy bottom orbital velocities had RMSE of 0.09 and 0.12 m s^{-1} and correlation coefficients of 0.88 and 0.96 for 44009 and 44025, respectively. Time on the *x* axis is consistent with Figure 3.

forecasting (WRF) model [*Warner et al.*, 2010]. Comparisons between the model and observations were sufficient for analysis of concurrent glider and model data north of the eye.

In order to assess modeled ESPreSSO currents, we compared depth-averaged values along the glider track to depth and time-averaged glider currents calculated using dead-reckoning [*Davis et al.*, 2003]. ESPreSSO currents were extracted hourly from the nearest grid point to each hourly glider surfacing. Both glider and ESPreSSO currents were rotated clockwise 30° from true north to align approximately alongshore and cross-shore at the glider location. ESPreSSO currents were in good agreement with the observed dead reckoned glider currents for the majority of the deployment (Figures 7a and 7b). The complex correlation coefficient between the model and glider was 0.90 with ROMS velocities rotated 8.1° counterclockwise of glider data. Cross-shore currents were generally well represented, though predicted velocities were slightly slower during the main forcing period from 29 October to at 00:00 GMT to the 30 October at 06:00 GMT. Both model predicted and observed alongshore velocities reached peak values near 1 m s^{-1} at landfall. Glider dead-reckoned currents are sensitive to accurate compass calibration. While, the compass was calibrated prior to flight and offsets from true compass direction were accounted for in postprocessing this remains a source of uncertainty in the model and observation comparisons and will require careful consideration in future deployments.

3.4. Glider and Modeled Sediment Resuspension and Transport

Typically validation of regional sediment resuspension and transport is done using poststorm surveys or using single point locations but little in situ validation over broad spatial regions and throughout the full

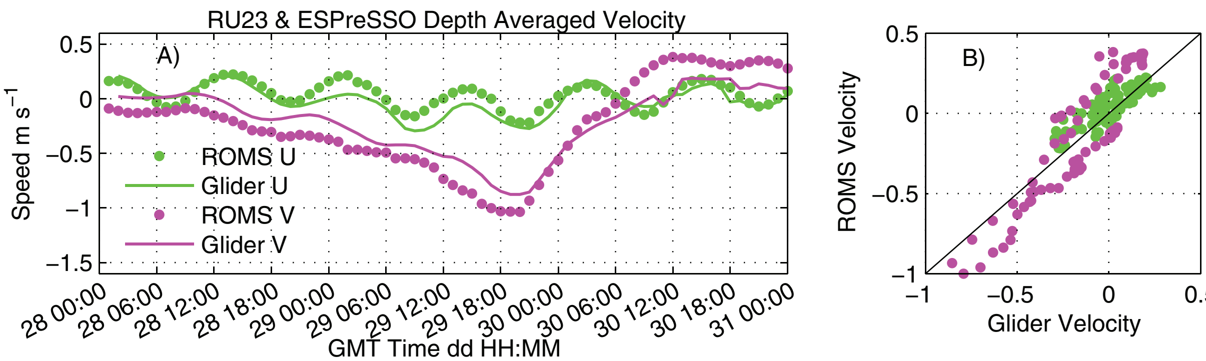

Figure 7. Comparisons of depth-averaged (dots) ROMS and (lines) glider depth-averaged currents calculated along the glider track in the (green) cross-shelf and (pink) along-shelf directions. Positive values indicate along-shelf (cross-shelf) toward the northeast (offshore). The complex correlation coefficient of ROMS versus RU23 depth-averaged currents is 0.90 with ROMS velocities rotated 8.1° counterclockwise of the glider data.

water column has previously been possible from a single set of profiling sensors. As our glider, RU23, was equipped with optical and acoustic sensors we compare along-track sediment resuspension and transport between the model and glider.

Cross sections of model suspended 0.4 and 0.1 mm sediment concentration along the glider track (Figures 8a and 8b) are compared with Aquadopp acoustic backscatter and bb3 optical backscatter (Figures 8c and 8d). Model cross sections of sediment resuspension along the glider track suggest 0.4 and 0.1 mm sediment resuspension initiate in response to storm forcing after 28 October at 12:00 GMT, with concentrations limited to within a few meters of the bed. Full water column resuspension is evident 24 h later, on the 29 October after 12:00 GMT, with large concentrations evident in the lower 10–15 m for 0.4 mm sediment, and throughout the entire water column to the surface for 0.1 mm sediment. Peak values for both grain sizes occur on the 29 October at 19:00 GMT, a few hours prior to landfall, following peak model predicted and observed wave heights and orbital velocities at buoy 44009 but prior to peak values at 44025 (Figures 5a and 5b). This is likely the timing of peak wave heights and orbital velocities at the glider location, which is approximately midway between the two buoys. Larger 0.4 mm particles fall out of suspension rapidly after the eye made landfall on 29 October at 23:30 GMT, while smaller particles had persistent elevated concentrations throughout the water column for 18 h following landfall. Acoustic backscatter (Figure 8c) was significantly different from model predicted values in two distinct ways. First, during early stages of the deployment, between 28 October at 06:00 GMT and 29 October at 00:00 GMT, there is a clear acoustic backscatter signal that fills the lower stratified (Figure 4a) region. Wave heights and orbital velocities were building during this period (Figures 6a and 6b) but were relatively weak compared to peak values. This feature was also present in optical backscatter values (Figure 8d), which indicates that the Aquadopp was likely responding to smaller fine grained sediment in the absence of a significant signal from larger grain sediments near the target 0.25 mm grain size. Cross sections of chlorophyll concentration (Figure 8e) derived from the fluorometer also suggest finer particles or biological material in this lower layer prior to transition from stratified to unstratified conditions. The second deviation from the model predicted suspended sediment is a persistent near surface acoustic backscatter signal, which peaks during peak wave and wind conditions on 29 October at 19:00 GMT. This signal is likely due to bubble entrainment in the surface boundary layer. In the lower portion of the water column acoustic backscatter qualitatively agrees with modeled 0.4 mm suspended sediment, with peak acoustic backscatter near 75 dB just prior to landfall coincident with model predicted peak concentrations. After the storm passed between 30 October at 00:00 GMT and the 31 October at 00:00 GMT, the persistent full water column acoustic backscatter near 55 dB is again likely due to fine particles that remained resuspended after coarse sand fell out of suspension. Cross sections of optical backscatter at 660 nm (Figure 8d) qualitatively agrees with concentrations of 0.1 mm sediment, which were elevated to the sea surface at nearly the same time as observed optical backscatter just prior to 29 October at 18:00 GMT, the peak in 0.1 mm concentrations and optical backscatter occurred in the model and observations similar to the acoustic and model 0.4 mm sand just prior to landfall at 19:00 GMT on 29 October. The optical signal remained high throughout the water column until 30 October near 18:00 GMT, persisting longer than modeled 0.1 mm sand. This suggests that there were likely smaller particles present than those modeled, which remained in

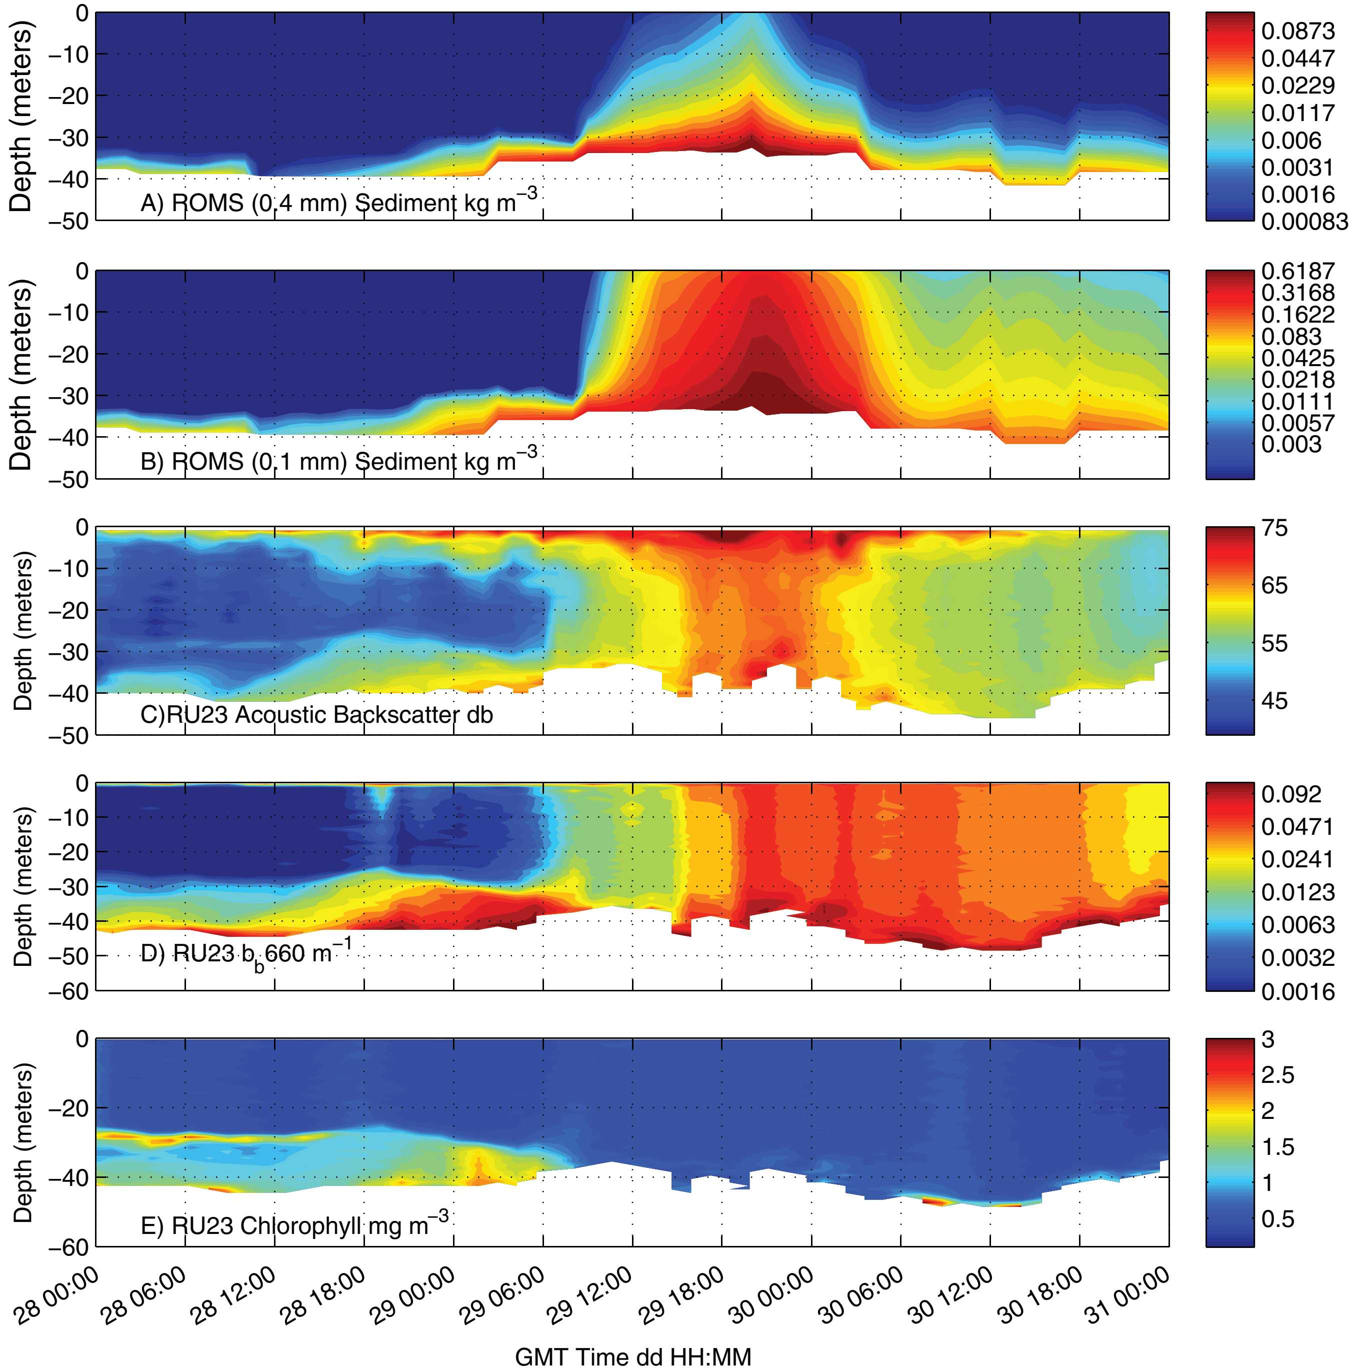

Figure 8. Cross sections of modeled sediment concentrations along the glider track for (a) 0.4 mm grain sizes, (b) 0.1 mm grain sizes and observed cross sections of (c) acoustic backscatter, (d) optical backscatter at 660 nm, and (e) chlorophyll concentration. Times along the *x* axis are as in Figure 3.

suspension well after the storm passed. Profiles extracted from each modeled, acoustic, and optical cross section (Figure 9) provide a more detailed comparison of sediment resuspension at three time periods, prior to the storm on 28 October at 06:00 GMT, just prior to landfall on 29 October at 21:00 GMT and 18 h after the storm on 30 October at 18:00 GMT. Shallow slopes were evident in modeled 0.1 and 0.4 mm grain sizes as well as acoustic and optical measurements prestorm, consistent with limited suspended sediment, though there were two features of the optical and acoustic profiles of note. The optics did not have a linear slope on a log-log scale. The subthermocline signal is likely related to organic material, detritus, chlorophyll, or other

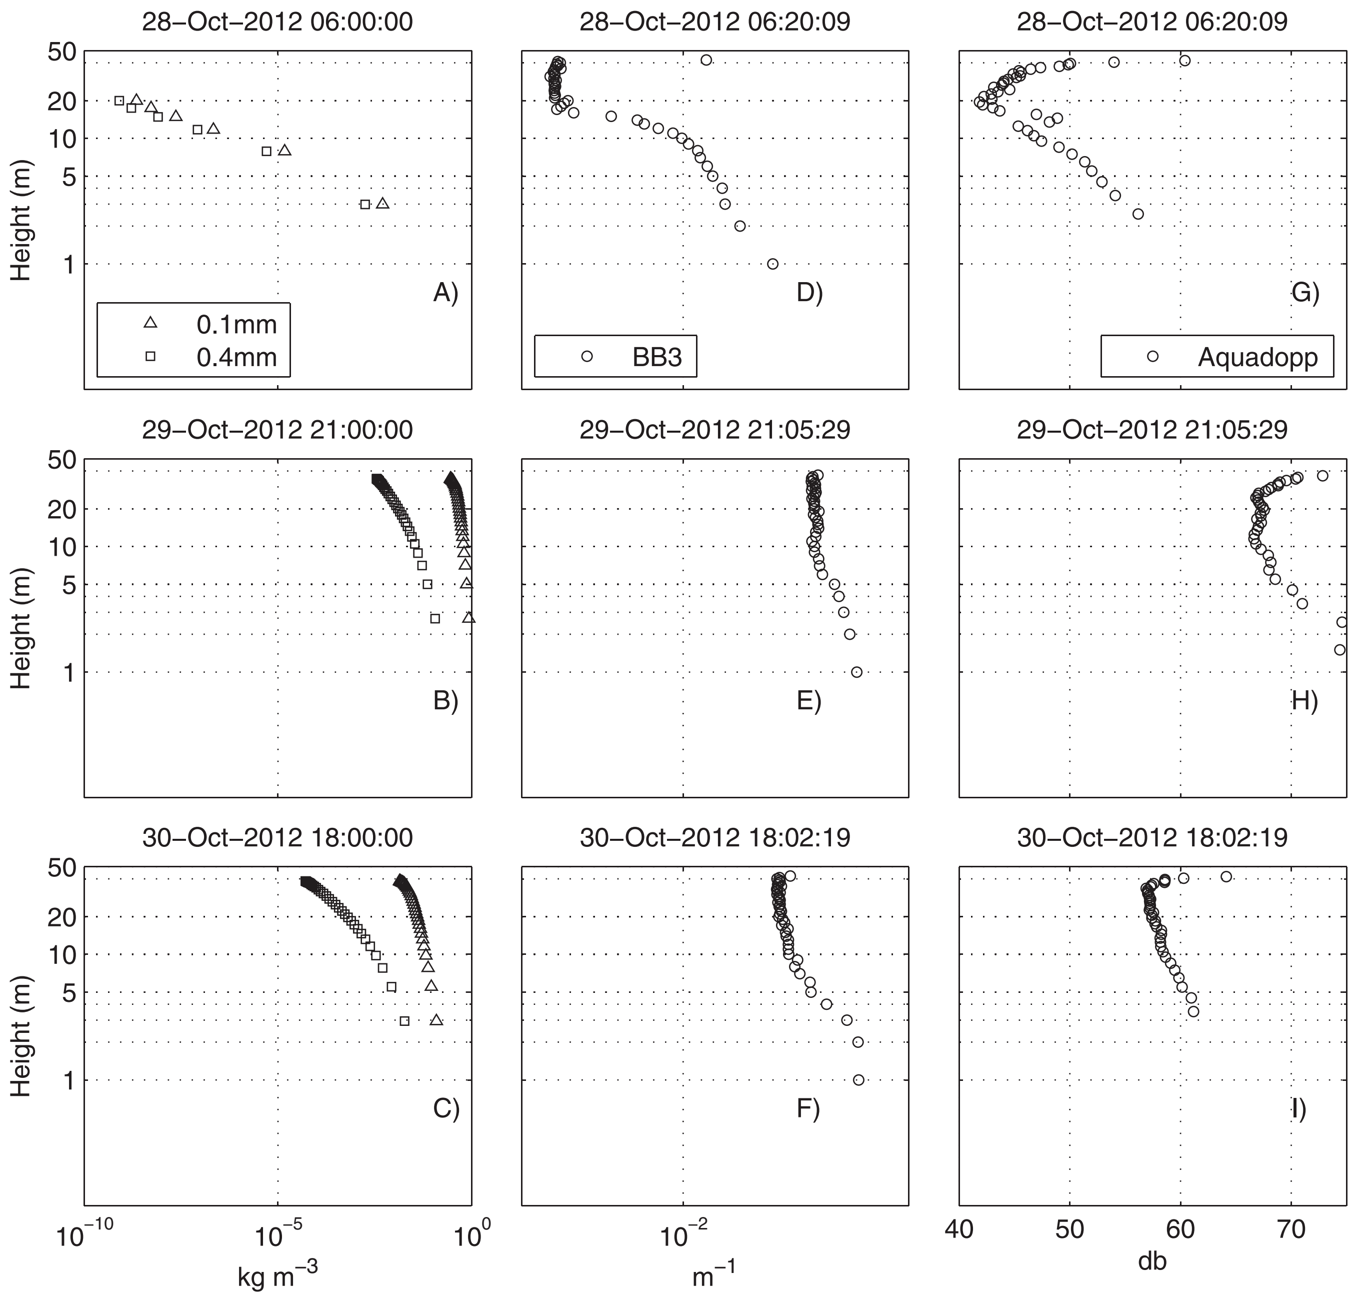

Figure 9. Log-log profiles of modeled 0.1 mm (triangles) and 0.4 mm (squares) (a–c) sediment concentration, (d–e) optical backscatter, and (g–i) semi-log profiles of acoustic backscatter. Acoustic backscatter has a logarithmic response to increased sediment concentration at the target frequency thus values are plotted on a linear db scale. Values below 10^{-10} kg m^{-3} are not plotted in Figures 9a–9c to more easily compare profiles across time points.

fine particulate matter rather than the larger cohesive sediment found on the bottom and was restricted by stratification at 20 m above the bed. Acoustics (Figure 9g) showed a positive slope above the thermocline likely due to bubbles as discussed above. During peak storm conditions model predicted and observed profiles were more vertical consistent with large concentrations of suspended sediment. Above 20 m off, the bed acoustics continued to show a positive slope likely due to bubbles and breaking waves (Figure 9h). Post-storm profiles were shallower than peak-storm but did not entirely return to prestorm conditions consistent with particles continuing to fall out of suspension.

Depth-integrated transport was calculated for modeled sediment concentrations and observed acoustic and optical backscatter. Acoustic backscatter responds logarithmically to increased observed concentration

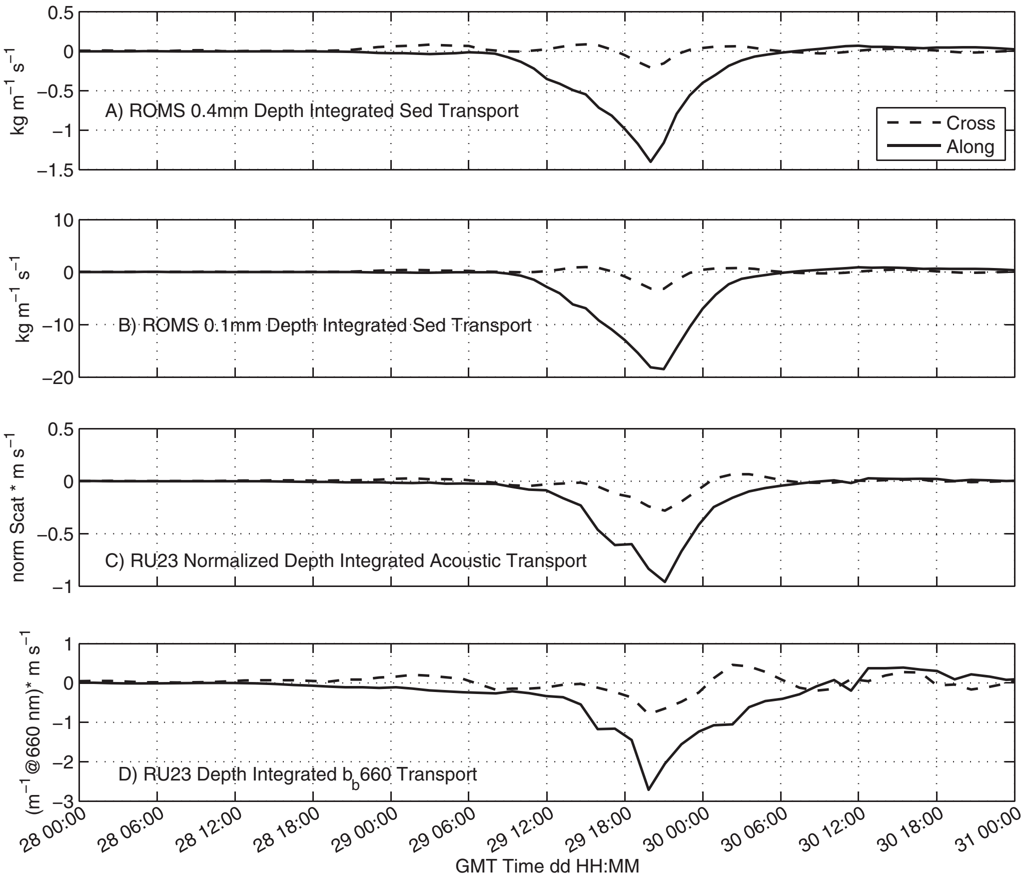

Figure 10. Depth-averaged transports calculated along the glider track for modeled (a) 0.4 mm sediment, (b) 0.1 mm sediment, (c) normalized depth-integrated acoustic transport, and depth-integrated optical backscatter transport in the (dashed) cross and (solid) along-shelf directions. Positive values indicate along-shelf (cross-shelf) toward the northeast (offshore).

[*Lohrmann*, 2001] so values were raised to the power of 10 and then normalized by dividing the maximum observed value. Additionally, acoustic backscatter shallower than 10 m were neglected from the depth integration to reduce the impact of bubble entrainment on relative transport estimates. The timing and direction of peak transport (Figure 10) were consistent between modeled and observed transports, with maximum values in the along-shelf direction on 29 October at 19:00 GMT. Inconsistency between the model predicted and observed cross-shelf currents (Figure 7) during the peak resuspension event is responsible for the limited modeled onshore transport relative to the observations on the 29 October at 19:00 GMT. The model and observations both captured the offshore cross-shelf transport immediately following landfall on 30 October at 3:00 GMT.

3.5. Regional Sediment Resuspension and Transport

Spatial maps (Figure 11) of the model predicted storm conditions over the final 12 h prior to landfall show snapshots of WRF winds (Figures 11a–11c) and WWIII waves (Figures 11d–11e) on 29 October at 12:00 GMT, 18:00 GMT and 30 October at 00:00 GMT. Winds were initially downwelling favorable and alongshore toward the southwest on the NJ shelf. WWIII model predicted wave heights were between 9 and 10 m offshore and decreased with proximity to land. As the storm approached, the coast winds shifted to a more onshore direction on the northern portion of the NJ shelf and offshore in the southern portion. Additionally, waves were near 10 m at the coastline on the northern NJ shelf, and decreased significantly to between 4 and 5 m on the southern NJ shelf as winds shifted toward the offshore direction.

As bottom orbital velocities and ambient currents are primarily responsible for sediment resuspension and transport, respectively, we present maps of the ROMS depth-averaged currents with tides retained (Figures 12a–12c) and WWIII bottom orbital velocities (Figures 12d–11f) on 29 October at 12:00 GMT, 18:00 GMT and

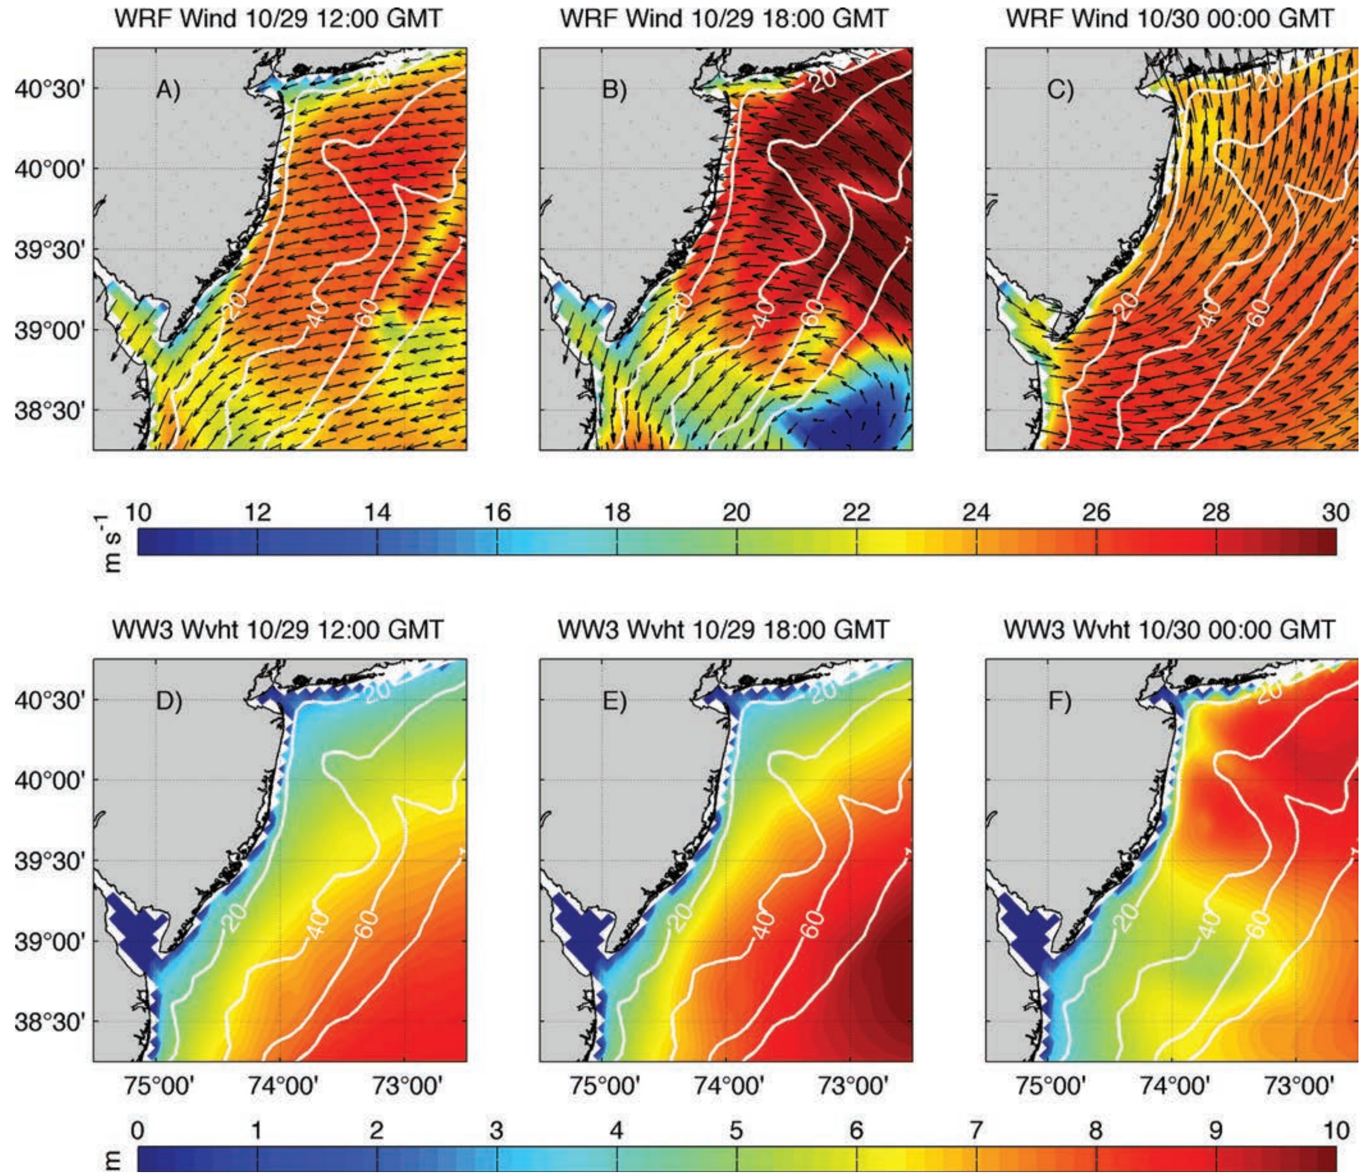

Figure 11. WRF wind on 29 October at (a) 12:00 GMT, (b) 18:00 GMT, and (c) 30 October at 00:00 GMT. WWII wave heights on 29 October at (d) 12:00 GMT, (e) 18:00 GMT, and (f) 30 October at 00:00 GMT.

30 October at 00:00 GMT. Early on 29 October, model predicted currents were highest south of the Hudson Shelf Valley and nearly uniform across the entire shelf except for a region of weak currents outside of Delaware Bay. As the storm crossed the shelf velocities were elevated to near 1 m s^{-1} across the entire domain. Current speeds were quickly reduced as the storm made landfall, likely due to the shift from alongshore winds to the southwest to weaker alongshore winds to the northeast (Figures 13a–11c). Bottom orbital velocities throughout the storm forcing duration were highest near shore south of the Hudson Shelf Valley with largest values, over 1.5 m s^{-1} near the glider deployment location on the northern side of the storm track.

Snapshots of depth-integrated suspended sediment concentration for the 0.4 mm (Figures 13a–13c) and 0.1 mm (Figures 13d–13f) are additionally mapped for the same time periods as in Figures 11 and 12 to show regional model estimates of sediment resuspension throughout the storm. On 29 October at 12:00 GMT, model predicted depth-integrated concentrations on the NJ continental shelf south of the Hudson Shelf Valley were near 1.2 and 10 kg m^{-2} for 0.4 and 0.1 mm, respectively, with highest values in the near-shore region for 0.4 mm and highest values on the central NJ shelf further offshore for the 0.1 mm

10.1002/2014JC010474

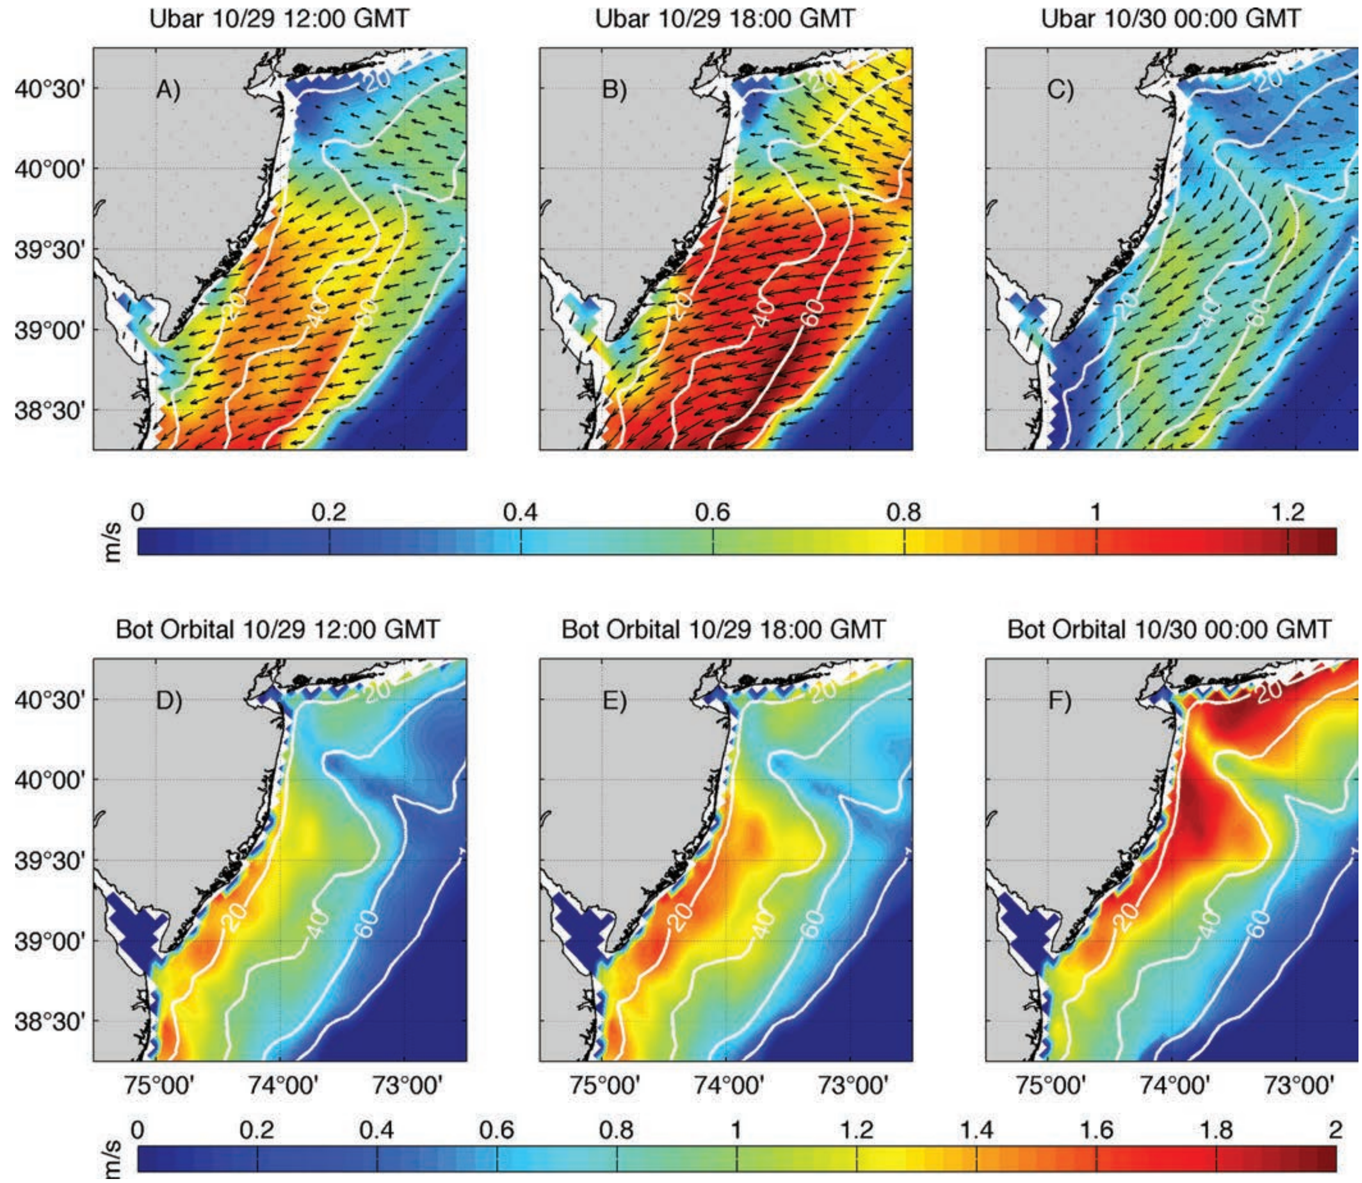

Figure 12. ROMS depth-averaged currents on 29 October at (a) 12:00 GMT, (b) 18:00 GMT, and (c) 30 October at 00:00 GMT. Bottom orbital velocities on 29 October at (d) 12:00 GMT, (e) 18:00 GMT, and (f) 30 October at 00:00 GMT.

sediment. On the 29 October at 18:00 GMT, 0.4 mm sand is resuspended along the entire inner shelf south of the Hudson Shelf Valley, while 0.1 mm sand is mobilized over the entire inner, middle, and outer shelf regions. As the storm made landfall near 30 October at 00:00 GMT, Figures 13c and 13f show that the 0.4 mm sand was resuspended coincident with peak orbital velocities (Figure 12f) and 0.1 mm sand was at a maximum across the entire northern portion of the shelf. Values for both 0.4 and 0.1 mm on the southern portion of the NJ shelf dropped significantly between 29 October at 18:00 GMT and 30 October at 00:00 GMT. This reduction was likely a result of the reduction in wave heights and orbital velocities associated with a reversal of wind direction as Sandy crossed the shelf.

Bed thickness change from the initialization to the end of the model run on 31 October at 08:00 GMT (Figure 14) predicts bed erosion of over 3 cm south of the Hudson Shelf Valley on the northern portion of the NJ shelf. This region is north of the storm track, which had highest waves, orbital velocities, and winds. Deposition of near 3 cm occurred toward the southwest in the direction of along-shelf transport (Figures 12a–12d).

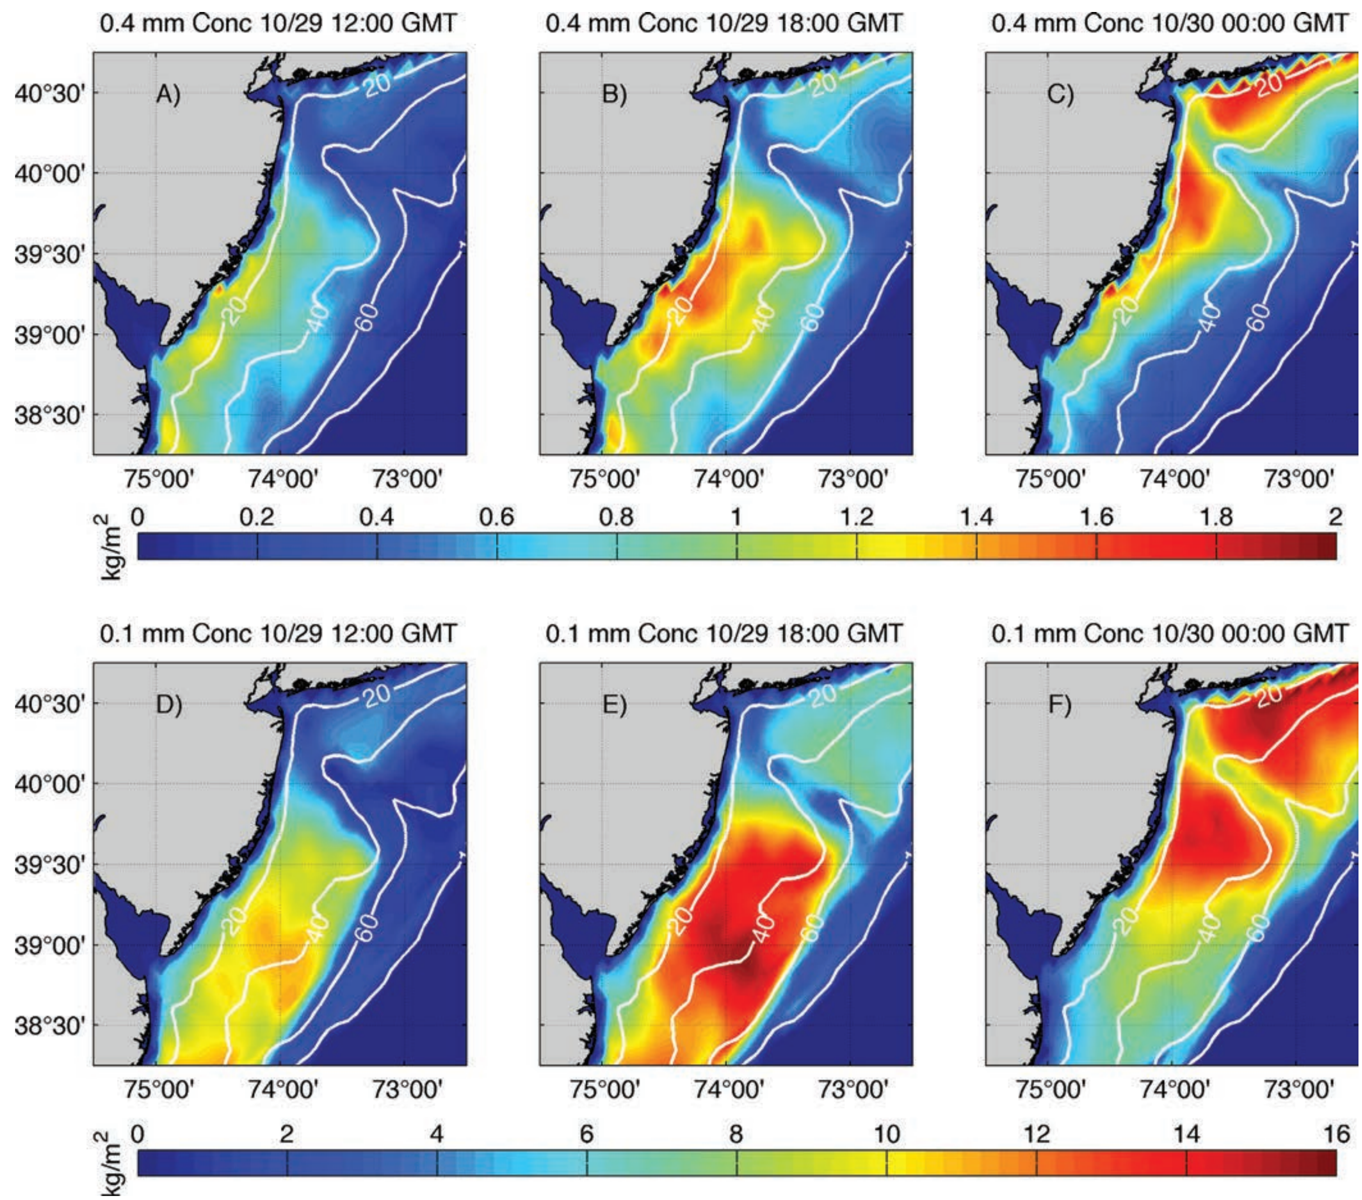

Figure 13. ROMS depth-integrated 0.4 mm sediment concentration on 29 October at (a) 12:00 GMT, (b) 18:00 GMT, and (c) 30 October at 00:00 GMT. ROMS depth-integrated 0.1 mm sediment concentration on 29 October at (d) 12:00 GMT, (e) 18:00 GMT, and (f) 30 October at 00:00 GMT.

4. Discussion

Previous studies have highlighted alongshore transport as the dominant feature of storm driven sediment transport on continental shelves [*Keen and Glenn*, 1995; *Ogston and Sternberg*, 1999; *Styles and Glenn*, 2005; *Miles et al.*, 2013], primarily during winter northeasters in the Mid-Atlantic. The typical offshore track of these storms leads to along-shelf wind stress toward the southwest and waves that increase across the entire NJ shelf [*Keim et al.*, 2004]. While Sandy initially had downwelling favorable along-shelf winds (Figures 11a and 11b), the unique cross-shelf track of the storm [*Hall and Sobel*, 2013] lead to a rotation to offshore winds on the southern portion of the NJ shelf in the 6 h before landfall. This shift on the southern NJ shelf reduced wave heights (Figures 3d and 11f), quickly reduced wave periods (Figure 3e) and ultimately reduced bottom orbital velocities (Figures 6c and 11f), which reduced bottom stress and allowed sediment that was continuing to be transported southwestward to fall out of suspension on the southern portion of the domain.

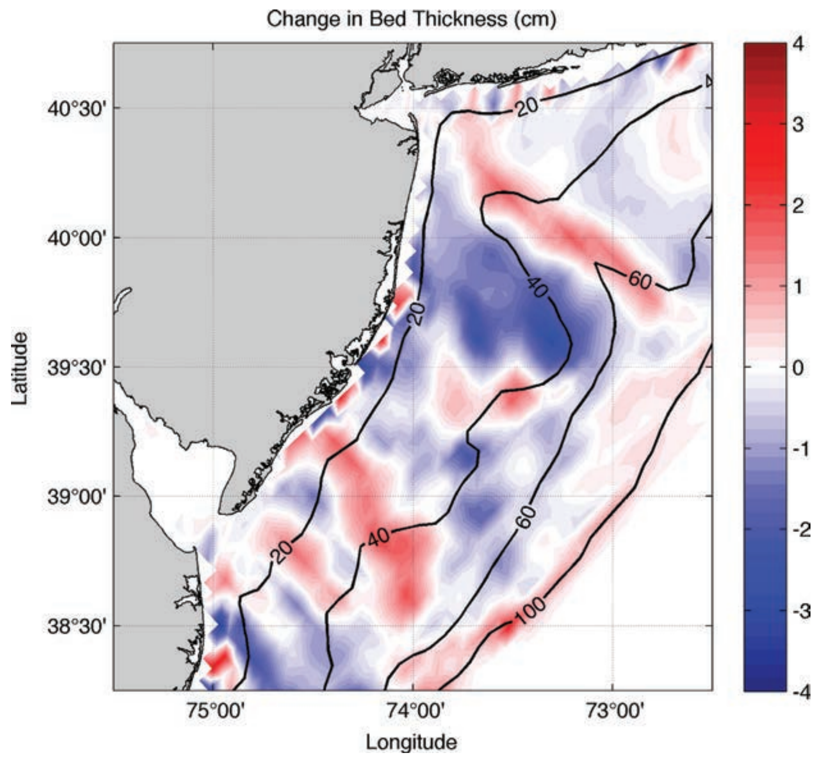

Figure 14. Change in bed thickness between the model initialization on 23 October 2012 at 00:00 GMT and 31 October at 11:00 GMT, with positive values indicating net deposition and negative values net erosion.

The modeled change in bed thickness of over + and − 3 cm on the northern and southern NJ shelf, respectively, should be approached with caution as the idealized model setup did not account for processes such as bed armoring [*Wiberg et al*., 1994], which may have reduced available fine grained sediment for resuspension, or bedload transport, which has been shown to be orders of magnitude larger than suspended sediment transport on the continental shelf [*Styles and Glenn*, 2005]. Regardless, the in situ observations from acoustic and optical sensors mounted on Slocum glider, RU23, support model predictions and suggest that a significant portion of the bed was likely eroded from the northern NJ shelf north of the storm track and deposited along the southern portion of the shelf. This modeled erosion and deposition pattern is likely rare on the New Jersey shelf as the estimated return rate, defined as the occurrence of a sandy-like track with a category 1 or greater under constant climate conditions, is 714 years with a 95% confidence range of 435–1429 years [*Hall and Sobel*, 2013].

Autonomous underwater vehicle and ship-based surveys showed partial recovery of the bed near buoy 44009 five weeks after Hurricane Sandy made landfall [*Trembanis et al*., 2013]. While this suggests that preservation of Sandy's sedimentary signature in the bed is not likely in the active nearshore region, the observed deposition toward the shelf break on the southern portion of the domain may be present as reworking in deeper waters is driven by more episodic wave processes [*Wiberg*, 2000].

While the onshore track, landfall, and resulting erosion and deposition patterns are likely atypical for the Mid-Atlantic, land-falling storms with onshore tracks are typical in other regions. In the Gulf of Mexico hurricanes Camille in 1969 [*Keen et al*., 2004], Hurricane Ivan in 2004 [*Teague et al*., 2006; *Smith et al*., 2013; *Zambon et al*., 2014], and Hurricanes Katrina and Rita in 2005 [*Horton et al*., 2009]. Maximum observed scours poststorm in Hurricane Ivan were as high as 36 cm at the 60 m isobath under the region of maximum winds on the right side of the eye. Along the coast of China typhoons, such as Typhoon Morakot [*Li et al*., 2012] also typically make landfall with an onshore track and resuspend and transport sediment. The continued development of sediment resuspension and transport models is critical to understanding coastal changes driven by land-falling storms across the world. Future studies of sediment resuspension and transport modeling and poststorm sediment analysis will benefit greatly from a suite of observing platforms that include in situ glider data to interpret results over a broad range continental shelves.

5. Summary and Conclusions

In this study, we successfully deployed a Teledyne-Webb Slocum glider in rapid response ahead of Hurricane Sandy on the New Jersey Shelf. This mobile profiling sensor platform proved invaluable in providing in situ sediment resuspension and transport model validation, as well as simultaneous validation of currents in the hydrodynamic models. Predicted resuspension and transport suggested erosion of over 3 cm on the northern portion of the New Jersey Shelf, north of the storm track where waves and currents were highest and deposition of over 3 cm on the southern NJ shelf just north of Delaware Bay. This erosion and deposition pattern was the result of the onshore track of Hurricane Sandy, which is not typical. This study provides a valuable assessment of suspended material in a major storm using coincident acoustic and optical sensors on a glider platform, which builds confidence in the communities' ability to model regional sediment resuspension and transport. Glider technologies now have the ability to compliment invaluable high-resolution near bed measurements from moored and bottom mounted sensors. Future advances that may improve sediment concentration estimates from glider platforms include downward facing acoustic sensors, which will reduce the impact of bubble entrainment near the surface, provide data near the bed where concentrations are highest, and allow for detailed estimates of bottom-stress in situ over a large spatial area.

Acknowledgments
Glider data used in this study are available through the MARACOOS assets page http://maracoos.org/data and http://marine.rutgers.edu/cool/auvs/index.php?did=369 with more detailed data sets available upon request to tnmiles@marine.rutgers.edu. Regional Ocean Modeling System and WRF model results are also available upon request to tnmiles@marine.rutgers.edu. Buoy data and WAVEWATCH III data sets are publicly available through http://www.ndbc.noaa.gov/ and http://polar.ncep.noaa.gov/waves/index2.shtml, respectively. We are grateful for the funding support provided by NOAA grant NA11NOS0120038 as part of MARACOOS, the regional partner of U.S. IOOS and NOAA grant NA13OAR4830233 as part of CINAR, the regional partner of the CIPO. We would also like to thank Teledyne-Webb Research for providing graduate student funding, NortekUSA for providing equipment through a student equipment grant. Additionally, we would like to thank the glider technicians and pilots of the Rutgers University Center for Ocean Observing Leadership; the help of John Wilkin and the research associates of the Rutgers Ocean Modeling group with help setting up the ocean model; and commentary and help setting up the sediment model from Chris Sherwood at the United States Geological Survey (USGS).

***Abstract*- Oceanic forecast models are imperative to understand the Earth's ocean. Current oceanic forecasts assimilate satellite sea surface height and temperature data along with temperature and salinity profiles from Argo networks of over 3000 drifters. Even though assimilation of these datasets are reliable, they have limitations because areas that provide critical data to ocean forecast models are often under sampled. Autonomous Underwater Gliders (AUGs) can be used as a solution to reduce under sampled regions of the ocean. Over the last decade, AUGs have successfully been used to carry out regional deployments to conduct scientific expeditions throughout the Earth's Ocean. Through the Challenger Glider Mission, coordinated flights covering 128,000 kilometers are planned around the five ocean basins. A range of international institutions and agencies can participate in the mission using interactive tools developed by the U.S. Integrated Ocean Observing System (IOOS) and the education outreach tools of the U.S. National Science Foundation's (NSF) Ocean Observing Initiative (OOI). These interactive tools are programmed to display real time glider data with interactive browser-based access, enabling student participation in global ocean exploration and predictive skill experiments. During the summer of 2015, student research teams participated in the second leg of the South Atlantic Challenger Glider Mission (named RU29). The aim is to show the usefulness of RU29's in situ datasets in ocean forecasting by comparing salinity, temperature, and sea surface current observations to the predictive readings of ocean models (RTOFS, MyOcean) and data generated by the Argo Float program. The students' involvement contributes to the assessment of current scientific and oceanographic models, courtesy of the Challenger Glider Mission.**

Keywords – Ocean forecasting; Autonomous Underwater Gliders; Challenger Glider Mission

I. INTRODUCTION

In November 2013, Glider Mission RU29 was deployed in the South Atlantic. It was deployed off Cape Town South Africa, stopped in the Ascension Islands before it was recovered off Sao Paulo, Brazil, ending the 4,420 km crossing in May of 2014. During the summer of 2014, data from RU29 was used to analyze the skill of the American RTOFS ocean model and the European MyOcean ocean model. Students observed the differences between data collected from the glider and the data predicted by the models. This comparison is useful in analyzing oceanographic elements, such as the Brazil Current, that the glider might encounter during its second deployment.

On June 23, 2015, RU29 embarked on its second leg of its circumnavigation of

978-0-933957-43-5 ©2015 MTS

the South Atlantic Ocean. It was deployed from Ubatuba, Brazil and is traveling back to Cape Town, South Africa. This trip is expected to take one year, and will span at least 6,500 kilometers. The glider, subject to ocean currents and necessary energy efficiencies, can travel approximately 7,000 kilometers. If needed the glider will be able to stop at the remote island of Tristan da Cunha for repairs. In order to maximize distance traveled and minimize energy usage, a potential track will be determined for the glider to follow based on the currents predicted with global ocean models, as well as wind and wave forecasts. Throughout RU29's deployment, data collected will be compared to the output from two ocean models, RTOFS and MyOcean, as well as the Argo float program. Based on the analysis of these comparisons, a better understanding of the oceanic conditions within the South Atlantic will be provided to help the glider transit the entire South Atlantic Ocean.

II. METHODS

To assess the forecasting capabilities of existing international suite of oceanic models and devices, the comparison between the US Model, RTOFS, The European model, MyOcean, the Argo float data program and RU29 data was conducted. The collaboration between European countries such as the United Kingdom, France, Germany, and Denmark resulted in the development of the MyOcean model and RTOFS (Real Time Ocean Forecast System) is a United States model created by the National Center for Environmental Predication. Through primarily satellite data assimilation, RTOFS and MyOcean provides integrated oceanic information, which is accessible from internet databases.

In situ data from the Argo floats were compared to both glider and modeled profiles. Argo floats profile the ocean from the surface to as deep as 2000m once every 10 days. Each profile samples ocean temperature, salinity, and density along with other oceanic parameters based on the drifter configuration. There are thousands of Argo floats deployed around the world today including around the area along the glider's track. By comparing a glider and an Argo float profiles to each other, the quality of the glider's measurements of the water column can be determined. These comparisons between RU29 and an Argo float datasets verify the glider CTD data.

RU29 is a G2 glider equipped with a SeaBird pumped Conductivity, Temperature and Depth (CTD) sensor to collect temperature and salinity profiles. Using a process from Kerfoot et al. [5] to correct the thermal inertia of the conductivity sensor, the dataset of RU29 can be compared to an Argo float and sections of the RTOFS and MyOcean models taken along the glider's path (Figure 1). A series of MATLAB scripts facilitated the data processing and profile creations of the temperature and salinity data gathered by the models, the Argo float program and RU29.

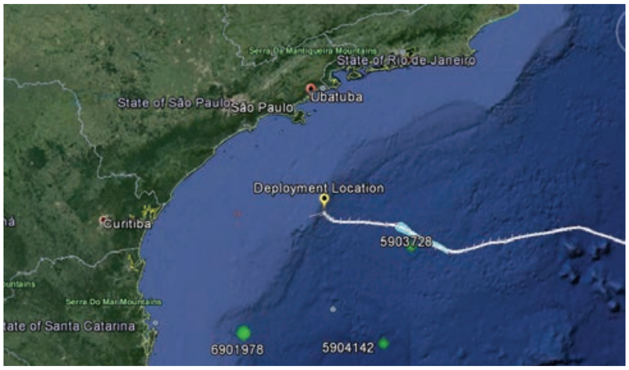

Figure 1: RU29's deployment location and the portion of its track off the coast of Brazil used for the comparison to the models and an Argo float.

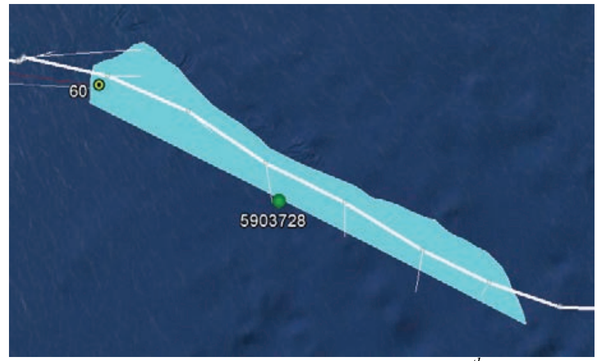

Figure 2: Argo# 5903728 completed its 60th cycle on July 1st approximately 3.44km from where RU29 surfaced on June 29th. The blue shading indicates where RU29's profiles were extracted.

III. RESULTS

On June 29th, RU29 passed by an Argo float (Argo#5903728) that completed its 60th cycle on July 1st several days later. These data were used to compare the glider CTD with RTOFS, MyOcean, and the Argo float (Figure 2). This study will focus on the deeper measurements below the more variable surface layer. In these deeper waters the spatial variability of temperature and salinity are longer. The temperature collected by Argo#5903728 and RU29 did not show any disparity but rather congruency throughout the water column (Figure 3). This cannot be said for salinity. While the profiles compared well in the beginning of the study, on June 30th the glider moved into a water mass with saltier water at depth. Glider profiles 18 to 20 are saltier at depth than the available Argo float data and the profiles sampled by the glider in the days prior (Figure 3).

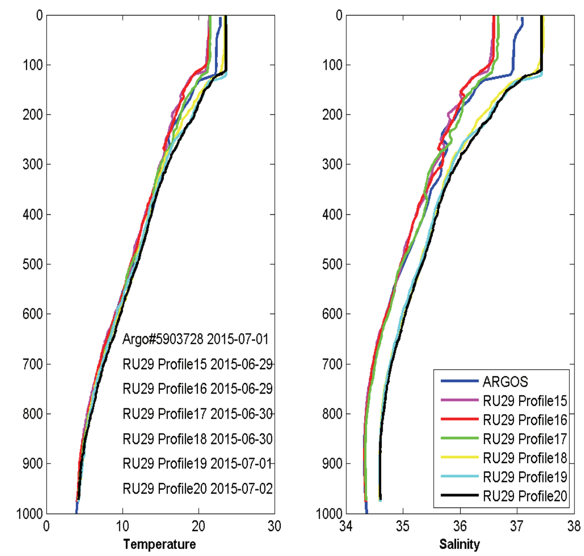

Figure 3: Temperature and salinity depth profile comparison between Argo#5903728 and RU29. Temperature on the left and salinity on the right

The glider highlights spatial changes in the deep water mass not captured by the closest ARGO profile. In the spatial comparisons of the Argo float, glider and models, RU29's profile 18 indicates that at the bottom a significant increase in salinity had occurred (Figure 4). Since Argo#5903728 did not move across this change sampled by the glider and the model grids are courser than the scale sampled by the glider, they could not detect the change. Additionally at the surface, RTOFS predicted lower temperature and salinity than RU29 while MyOcean predicted a slightly higher temperature and salinity than the glider (Figure 4). In the deep ocean, the temperature gradually increases while the salinity stayed constant as the glider continues to travel eastward (Figure 4). Furthermore, Argo#5903728 measured fresher water at depth than RTOFS, MyOcean and the glider and the float and the models report lower temperatures than RU29 (Figure 4). The South Atlantic is characterized with lower precipitation and saltier surface water with strong winds. The spatial comparisons of RU29, Argo#5903728, and the models show that the surface is warmer and saltier than the deep ocean, consistent with the climatology of the South Atlantic (Figure 4).

IV. DISCUSSION

According to observing System Simulation Experiments, additional profile data, especially profile data that cross frontal features, are the most influential at reducing forecast uncertainty. This is evident as RU29's profiles 18 to 20 showed temperature similarities with Argo#5903728 but not in salinity as the glider saw a drastic increase as it moved east along its path (Figure 5). The sudden change in salinity indicates that RU29 crossed a front that the Argo float did not pick up. Since the location of Argo drifters cannot be controlled after they are deployed, they typically do not cross fronts, rather they move along fronts.

Like the glider/ARGO float comparison, the two models and RU29 comparisons highlight the potential spatial considerations needed when evaluating with the higher resolution glider data. The RTOFS and MyOcean models had some similarities with RU29, but they both did not reproduce the frontal structure apparent in the in situ glider data (Figure 6). Since the output of RTOFS and MyOcean are courser than the glider profile data, they do not represent the higher resolution of the Glider or ARGO profile data.

Consequently, the models and RU29 data can show disassociation around sharp oceanic gradients. For instance, RTOFS' June 30th projected currents showed that the RTOFS output compared to the glider was taken in an area of weaker currents in a different feature than the closest glider data and MyOcean output in time and space. (Figure 7). This likely partially explains the difference between the glider and model output. In addition, RTOFS and MyOcean generates average temperature and salinity data of the grid, which limited their ability to resolve the front.

Autonomous Underwater Gliders can be used to assimilate into or evaluate ocean forecast models because of their ability to traverse previously under sampled frontal regions of the ocean. It is crucial to the future of ocean modeling that glider-collected data be incorporated especially where areas of disagreement between the models and an Argo float occur. Over the course of this glider mission we will continue to look at features resolved by the glider to understand how they are represented in the global models. This preliminary analysis focuses on the data deeper than 500 m. As we continue this line of research we will include surface waters associated with these features.

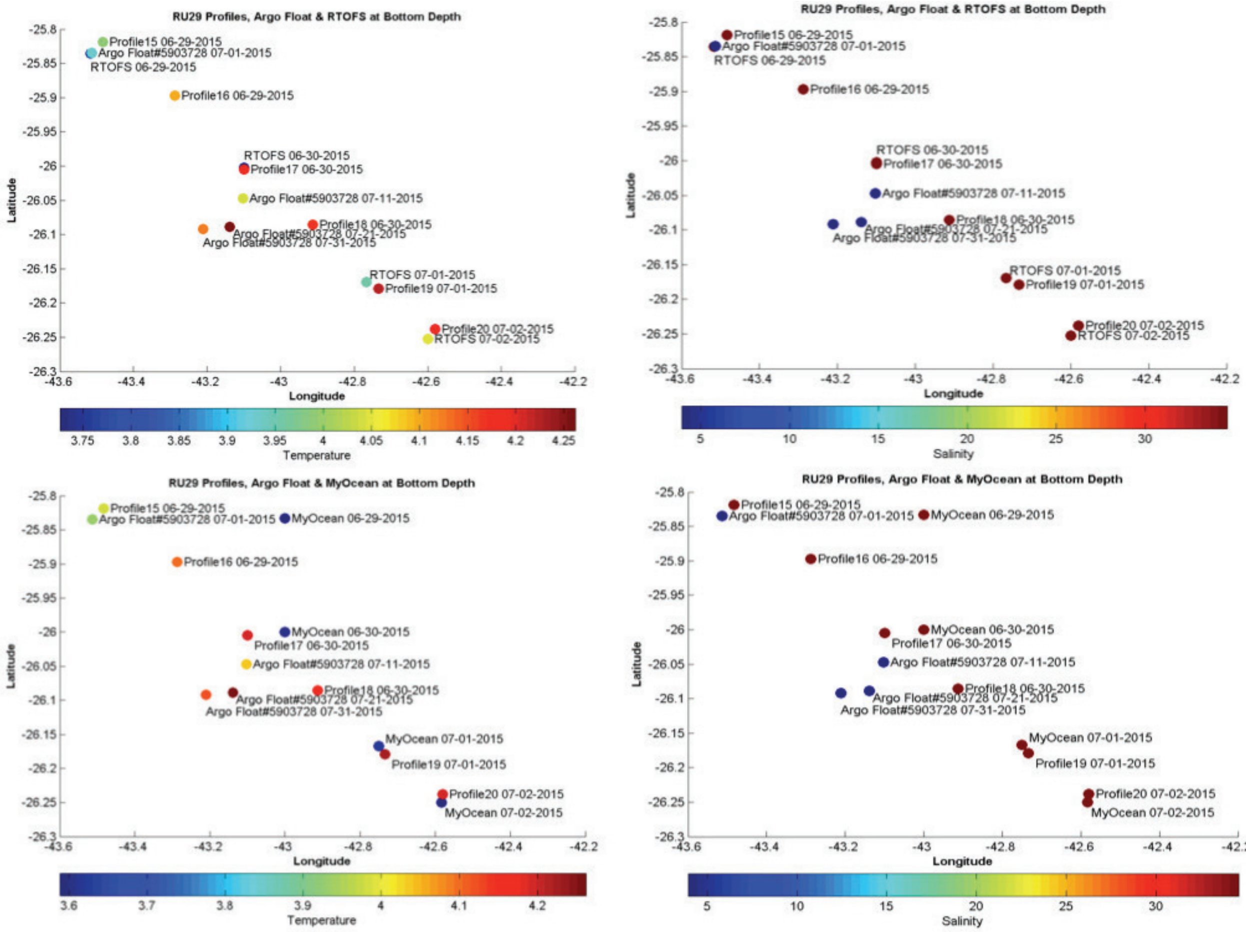

Figure 4: Location, time, and space for RU29, Argo and RTOFS (a and b) and MyOcean (c and d) model data. Time and Sources are indicated (a) bottom temperature with RTOFS, (b) bottom salinity with ROTFS, (c) bottom temperature with MyOcean, and (d) bottom salinity with MyOcean.

V. ACKOWNLEDGMENTS

The Challenger Gilder Mission is growing global partnership of gilder operators, scientists, educators and students coordinated by Rutgers University and endorsed by the Challenger Society. The results presented on this paper were initiated in a Rutgers research course and authored by two undergraduate summer interns (Andrenette Morrison and Liam Ramsay) supported by Teledyne Webb Research and six U.S. Naval Academy interns (Martin Arroyo, Kelsey Ashbrook, Olivia Czerewko, Stephanie Lee, Caleb Lintz and Erin Payne). Glider path planning and model/data comparison activities are led by Nilsen Strandskov (Rutgers) and Antonio Ramos (Universidad de Las Palma de Gran Canaria) with cyber infrastructure support provided by John Kerfoot and Sage Lichtenwalner (Rutgers). Glider operators include Chip Haldeman, Dave Aragon, Tina Haskin (Rutgers) and Ben Alsup (TWR). Argo data was collected and made freely available by International Argo Program and the national programs that contribute to it.

The Ocean is Our Classroom: A 4-Year Research Track for Undergraduate Exploration, Research and Discovery in Oceanography

Scott Glenn, Oscar Schofield, Grace Saba, Travis Miles, Hugh Roarty and Josh Kohut

Center for Ocean Observing Leadership, Rutgers University, New Brunswick, NJ, USA

***Abstract*—Mitigating and adapting to climate change while the global human population continues its projected growth will be the dominant choice challenge confronting the present generation of undergraduates over their professional lifetimes. Today's students should be prepared to develop solutions that will involve the sea, but life-changing at-sea research experiences for undergraduates are limited. The rapid expansion of ocean observatories provides a solution. We have demonstrated in our own observatory how undergraduate student research can be enabled as a year-round activity during a student's full undergraduate career starting on day 1. What began as the Challenger Glider Mission has spread to other observatory technology and science activities both locally and in remote polar regions.**

Keywords — Ocean Observing; Undergraduate Education; Autonomous Underwater Gliders; Challenger Glider Mission.

I. Introduction

Present and future generations will be challenged by the impacts of climate change, including melting of land and sea ice, rising sea levels, ocean acidification and deoxygenation, and increasing extreme weather. This will be combined with the challenges of energy, food and water security as global populations continue to grow while natural and living marine resources are increasingly depleted. An improved multi-disciplinary understanding of the global ocean and its many large marine ecosystems, combined with the ability to observe their present and forecast their future state, is central to providing human society with mitigation and adaptation strategies. A growing constellation of ocean-viewing satellites, and the evolving suite of climate, global and regional scale ocean models, are key advances. Despite the international success of the Argo program, physical, biological and chemical ocean profiles are still among the most sought after datasets for the subsurface ocean, typically requiring expensive ship time countries can no longer afford. Long-duration autonomous underwater gliders, combined with compact sensors on marine mammals, reptiles and fish, can augment the Argo program with additional valuable data to enable discovery, promote scientific understanding, and ultimately improve our ability to forecast the ocean.

Today's undergraduate students will confront the dual challenges of a changing climate and a growing global population over their professional careers, not only the small percentage continuing to graduate school, but increasingly the broader distribution of students as future members of interdisciplinary teams seeking innovative solutions to societal issues within economic constraints. Even though the benefits of undergraduate research experiences are well known, hands-on oceanography remains limited by the availability of time at sea. The global proliferation of ocean observatories provide a means to overcome this issue, increasing undergraduate access to the sea via the Internet.

II. Methods

At Rutgers, we have taken advantage of ocean observatories to provide undergraduates the opportunity to participate in a comprehensive oceanographic research program spanning their entire undergraduate career [1]. Based on the cognitive apprenticeship model, students progress through three levels of participation, frequently described in simple terms as "watch one, do one, teach one". As early as their first semester at Rutgers, interested students can participate in Oceanography House or one of several seminar courses taught by senior level faculty. The seminars introduce students to research opportunities the students may have never envisioned while they are still fulfilling general core course requirements. For those that have already chosen participation in ocean research as an undergraduate goal, Oceanography House provides hands on training in research skills that accelerates the student into the second level of participation, "do one". At the second level, students are

978-0-933957-43-5 ©2015 MTS

taking many of their oceanographic core courses, including a hands-on Ocean Methods and Data Analysis course that includes the use of modern observational technologies on student-directed ½ day research cruises. Additionally, a more data analysis intensive course uses ocean observatory data on student led research. Typical classes of 50-70 students each semester are organized into research teams of 5-7 people led by a more senior student mentor. The semester long research of each group is presented at the end of each semester in a science symposium that features a high level invited speaker to inspire the students in their own future careers. In the final phase, students are taking their oceanography elective courses, and are acting as near-peer mentors to the younger students in the research course. The older students gain valuable mentorship experience including training in how to be a good mentor.

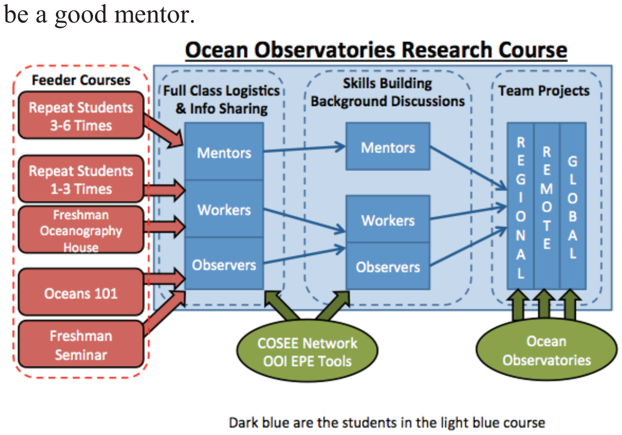

Figure 1: Ocean Observatories Research course that forms the core of the undergraduate research experience.

III. RESULTS

The Challenger Glider Mission is the core field component for the above observatories research course. Student involvement in undergraduate research is enabled by multiple gliders on simultaneous basin-scale missions that over several years are revisiting the historic track of the H.M.S. Challenger, the first dedicated scientific circumnavigation and the beginning of modern oceanography. The scientific questions to be investigated focus on a quality assessment and interpretation of the ensemble of available global-scale ocean models. The mission has already begun with one global-class G2 Slocum Electric glider deployed in the North Atlantic (Silbo) and a second deployed in the South Atlantic (RU29). These two gliders have already completed over 1100 days at sea covering more 22,000 km. The goal is to match the 128,000 km distance covered by the H.M.S Challenger with glider tracks around all 5 ocean basins. The Slocum Electric Gliders Silbo and RU29 will be joined by the Slocum Thermal Glider Clark during the summer of 2015.

The immediate scientific goals are to assess the current capabilities of the existing international suite of global ocean forecast models, and assess the forecast impact on ocean conditions in the vicinity of the glider. The existing global ocean forecast models assimilate satellite sea surface height and temperature data as well as temperature/salinity profiles from the Argo network of over 3,000 drifters. Still, Observing System Simulation Experiments routinely indicate that additional profile data, especially profile data that crosses frontal features, are the most influential at reducing forecast uncertainty. Since the location of Argo drifters cannot be controlled after they are deployed, some regions are critically under sampled, and strong boundary currents are often unresolved. Moreover, even with the SST, altimeter and Argo data, the mesoscale eddy field, the dominant energetic structures for most of the global ocean, are not uniquely or completely resolved by the existing global observation network. Additional data provided by gliders can augment these structures where needed.

A current example is presented here. Glider RU29 recently began Leg 3 of a circumnavigation of the south Atlantic gyre (Fig. 2). Leg 1 ran from Cape Town, South Africa to Ascension Island in 2013. Leg 2 from Ascension to Ubatuba, Brazil in 2014. RU29 is now heading back to Cape Town in 2015 along one of two lines. The orange line is the direct great-circle route back to Cape Town. The red line includes the potential for a stop at the remote island of Tristan da Cunha. The white line is the actual track and current location of RU29, flying somewhere between the red and orange lines.

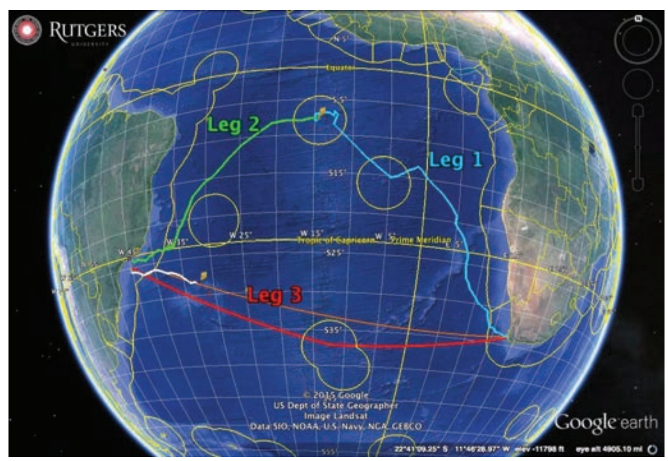

Figure 2: Glider RU29's circumnavigation of the South Atlantic Gyre, with Leg 1 (blue) begun in 2013, Leg 2 (green) in 2014, and potential Leg 3 lines, either directly across (orange) or with a stop in Tristan da Cunha (red). RU29's actual progress on Leg 3 in 2015 is shown in white.

Student-led comparisons between glider data and global ocean models along Legs 1 & 2 have already been reported at previous MTS meetings [2, 3]. Leg 3 is now in the navigation phase, where students must successfully pilot the glider across the basin and investigate interesting features along the way. Figure 4 zooms into the current location of the glider flying generally along the orange line directly towards Cape Town. The average current over the depth of the glider undulations as derived from the NOAA Real Time Ocean Forecast System (RTOFS) are plotted as the green vectors. If RU29 remains on this course along the orange line, RTOFS says it will soon encounter the southern side of a large clockwise rotating eddy (outlined in green) with its adverse currents.

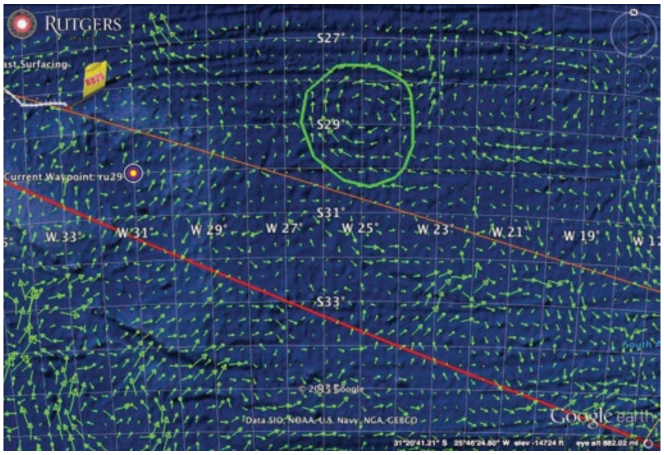

Figure 3: The U.S. RTOFS forecast depth average current field is shown in green. The large clockwise eddy along the orange track is circled with the green line.

However, if one examines the European Copernicus model for the same time period, the depth averaged currents (yellow) indicate a very different situation. Instead of a single clockwise eddy as found in RTOFS (green circle), there are two counterclockwise rotating eddies (yellow circles). The end result, a counter current near the orange direct path to Cape Town, but the reason is totally different. Even though both models are assimilating the same SST, Altimeter and Argo data, the end result on the energetic mesoscale is quite different.

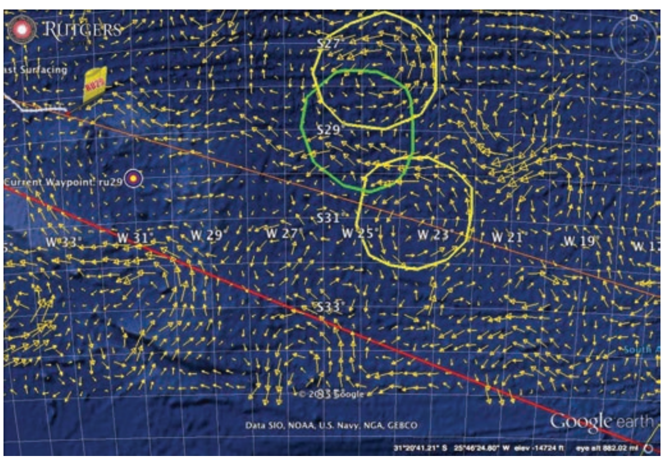

Figure 4: The European Copernicus forecast depth average current field is shown is yellow. The two counterclockwise eddies along the orange track are circled in yellow.

To investigate this, glider RU29 can be targeted to fly through the area of the greatest difference. While both structures produce a counter current to the west along the orange route, the structure between the two yellow eddies from Copernicus and across the middle of the green eddy from RTOFS will be very different. However, to get there, RU29 must first navigate through a field of seamounts (Figure 6), and then line up for a pass through the mesoscale eddies. Differences in the mesoscale eddy structure like this are common.

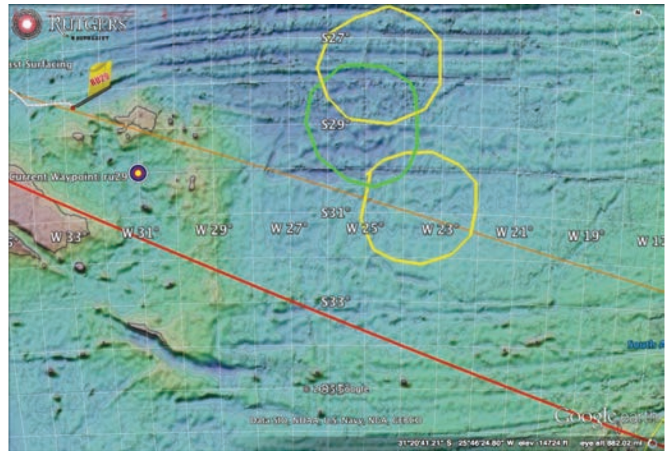

Figure 5: Bathymetry map showing the seamounts RU29 must initially navigate through before lining up for the survey of the differing mesoscale eddy field.

The growth in class size created a new demand for course research projects and intersession research internships. Research projects expanded to include the extensive observatory operated by the Mid Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) as part of the U.S. Integrated Ocean Observing System (IOOS). Research participation ranged from technology improvements to the distributed glider network [4] and the extensive Mid-Atlantic High Frequency (HF) Radar network [5], to scientific applications of the data to homeland security [6.7], fisheries and offshore wind.

School-year research activities are augmented with more intensive hands-on undergraduate opportunities during class breaks. During the summer and winter intersessions, students can commit fulltime to hands-on research in ways not possible during the more class intensive semesters. The shorter winter break coincides with the southern hemisphere summer season. In the Southern Summer Research Institute, in collaboration with projects supported by the NSF Office of Polar Programs, undergraduates have the opportunity to participate in and contribute to research in Antarctica. Over the last 5 years, students have made significant contributions to research on polar research vessels and land based research stations. Students participating in the Northern Summer Research Institute are from Rutgers, the U.S. Naval Academy, and other universities around the country. They come to Rutgers each summer to work full time on team research projects that utilize ocean observatory data. Projects begun during the semester are often pursued in greater detail over the summer. Students are supported through a variety of mechanisms including university contributions, federal grants, and direct industry sponsorship. A major focal point of the Northern Summer Research Institute is the Challenger Glider Mission, where students work with researchers from around the world to validate global ocean models using basin-scale underwater glider missions. The Summer Research Institute uses the MTS/IEEE Oceans process to summarize and present results. Abstracts are submitted early in the summer, and results are documented in Proceedings papers submitted by the students at the end of the summer for presentation at the fall MTS/IEEE Oceans meeting. Over the last 3 years, 8 undergraduate student papers have been submitted to Oceans based on student research in the Summer Research Institute. Papers this year include optimizing glider flight parameters for long-duration missions, comparisons of basin-scale glider data with an ensemble of global ocean models, and the analysis of the first year of HF Radar data from the Western Antarctic Peninsula.

IV. Discussion

We have found that augmenting the standard Marine Science course track with a concurrent research track increases student involvement, retention and diversity. The success of this approach can be assessed by tracking student involvement in the research course established in the fall of 2007. Pre-course levels of undergraduates working in the research lab were consistently at the level of 1 to 3 people per year for 10 years. The research course started with 7 students who began the mission to be the first group to fly an underwater glider across an ocean basin. After the Trans-Atlantic's mission success and publicity in 2009, the course peaked in 2012 with 70 students. Since then, student involvement has leveled off, consistently remaining near 50 students per semester as we continue to fly gliders across ocean basins as part of the Challenger Glider Mission.

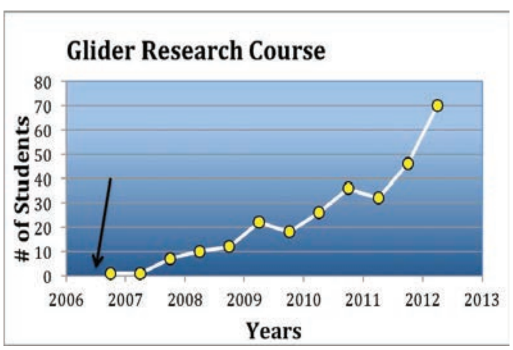

Figure 6: Student involvement in the Ocean Observatories Research course over time since the course was established in 2007.

As the number and diversity of ocean observatories grow worldwide, research courses like the one we teach at Rutgers can be put in place in more locations. One example will be the NSF Ocean Observatories Initiative (OOI). The OOI Education and Public Engagement (EPE) Implementing Organization has already built new software tools to enable undergraduate access to near real time data streams from the OOI. The tools are organized into a Concept Mapper that allows complex concepts to be deconstructed into more elemental components, Data Visualization tools launched from a web browser to reduce computer programming barriers to participation, and a Data Investigation Builder for teachers to produce custom guides for students.

V. Acknowledgements

The Challenger Glider Mission is growing global partnership of glider operators, scientists, educators and students coordinated by Rutgers University and partially supported by the U.S. Integrated Ocean Observing System (IOOS). RU29 mission support is currently provided by the G. Unger Vetlesen Foundation and ONR-Global. Student support is provided by NSF Research Internships in Ocean Science (RIOS) and Teledyne Webb Research. The Ocean Observatories Initiative Education and Public Engagement activities and the Antarctic research activities are supported by the National Science Foundation. The Mid-Atlantic Regional Association Coastal Ocean Observing System is funded by the U.S. Integrated Ocean Observing System through NOAA.

ABSTRACT

Cold wakes left behind by tropical cyclones (TCs) have been documented since the 1940s. Many questions remain, however, regarding the details of the processes creating these cold wakes and their in-storm feedbacks onto tropical cyclone intensity. This largely reflects a paucity of measurements within the ocean, especially during storms. Moreover, the bulk of TC research efforts have investigated deep ocean processes—where tropical cyclones spend the vast majority of their lifetimes—and very little attention has been paid to coastal ocean processes despite their critical importance to shoreline populations. Using Hurricane Irene (2011) as a case study, the impact of the cooling of a stratified coastal ocean on storm intensity, size, and structure is quantified. Significant ahead-of-eye-center cooling (at least 6°C) of the Mid-Atlantic Bight occurred as a result of coastal baroclinic processes, and operational satellite SST products and existing coupled ocean–atmosphere hurricane models did not capture this cooling. Irene's sensitivity to the cooling is tested, and its intensity is found to be most sensitive to the cooling over all other tested WRF parameters. Further, including the cooling in atmospheric modeling mitigated the high storm intensity bias in predictions. Finally, it is shown that this cooling—not track, wind shear, or dry air intrusion—was the key missing contribution in modeling Irene's rapid decay prior to New Jersey landfall. Rapid and significant intensity changes just before landfall can have substantial implications on storm impacts—wind damage, storm surge, and inland flooding—and thus, coastal ocean processes must be resolved in future hurricane models.

1. Introduction

While tropical cyclone (TC) track prediction has steadily improved over the past two decades, TC intensity prediction has failed to progress in a similarly substantial way (Cangialosi and Franklin 2013). Many environmental factors control TC intensity, including the storm track itself, wind shear, intrusion of dry air, and upper-ocean thermal evolution (Emanuel et al. 2004). The last factor underlies all other processes because it directly impacts the fundamental transfer of energy from the ocean to the atmosphere within the TC heat engine (Emanuel 1999; Schade and Emanuel 1999).

Hurricane models often account for track and large-scale atmospheric processes that affect intensity—wind shear, dry air intrusion, and interaction with midlatitude troughs (Emanuel et al. 2004). Some possible reasons include (i) greater attention to the atmosphere in modeling, and (ii) large-scale processes being resolved well, even with less advanced models. However, models do a comparatively less accurate job of representing oceanic processes that govern hurricane intensity because

they are data limited (Emanuel 1999, 2003; Emanuel et al. 2004).

A specific upper-ocean thermal phenomenon that consistently emerges after a TC has passed is a cold pool of water left in the wake of its path, termed a ''cold wake.'' This oceanic phenomenon has been observed behind TCs since at least the 1940s off the coast of Japan (Suda 1943) and since at least the 1950s in the Atlantic, Caribbean, and Gulf of Mexico (Fisher 1958). Observational studies continued into the 1960s (e.g., Leipper 1967) with investigation of potential processes causing the cold wakes, such as upwelling and turbulent entrainment of cold water into the warmer mixed layer. Studies in the late 1970s (Chang and Anthes 1979; Sutyrin and Agrenich 1979) began the use of idealized numerical simulations to investigate the effect of this oceanic cooling on TC intensity, but neglected TC movement. Then, numerical modeling studies in the 1980s (Price 1981; Sutyrin and Khain 1984) and 1990s (Khain and Ginis 1991; Bender et al. 1993; Price et al. 1994) incorporated TC movement and three-dimensional coupled ocean–atmosphere models to further examine the negative SST feedback on storm intensity.

Prior to the 1980s and 1990s, observations of the upper ocean beneath a TC were uncommon due to the unpredictable and dangerous winds, waves, and currents in the storms (D'Asaro 2003). At that point, ocean observations in TCs, summarized by Price (1981), occurred primarily as a result of targeted studies using air-deployed profilers (e.g., Sanford et al. 1987; Shay et al. 1992), long-term observations that happened to be close to a TC's track (e.g., Forristall et al. 1977; Mayer and Mofjeld 1981; Dickey et al. 1998) or hydrographic surveys in a TC's wake (e.g., Brooks 1983). The severe conditions of TCs hampered progress in determining physical processes leading to the previously observed cold wake, as well as specific timing and location of the ocean cooling relative to the TC core. In the 2000s, studies began to provide observational and model evidence that significant portions of this surface ocean cooling can occur ahead of the hurricane eye center (e.g., D'Asaro 2003; Jacob and Shay 2003; Jaimes and Shay 2009), proposing that such cooling is especially important for hurricane intensity.

Even today, the bulk of research efforts have investigated deep ocean processes and their feedback onto TC intensity; indeed, a TC typically spends the vast majority of its lifetime over deep, open waters. However, rapid and significant changes in intensity just before landfall and often in shallow water can have substantial implications on storm impacts (i.e., wind damage, storm surge, and inland flooding). For example, the statistical analysis by Rappaport et al. (2010) finds that category-3–5 hurricanes in the Gulf of Mexico weakened approaching landfall due to both vertical wind shear and hurricane-induced sea surface temperature reductions on the order of 1°C ahead of the storm center. Therefore, attention must be paid to coastal processes as well (Marks et al. 1998), which inherently differ from deep-water processes due to the influence of a shallow ocean bottom and coastal wall, and have been observed to produce SST cooling in TCs up to 11°C (Glenn et al. 2016).

This paper analyzes a recent landfalling storm, Hurricane Irene (2011), using a combination of unique datasets. Hurricane Irene is an ideal case study because in the days leading up to its landfall in New Jersey (NJ), its intensity was overpredicted by hurricane models (i.e., ''guidance'') and in resultant National Hurricane Center (NHC) forecasts (Avila and Cangialosi 2012). The NHC final report on the storm stated that there was a ''consistent high bias [in the forecasts] during the U.S. watch–warning period.'' NHC attributes one factor in this weakening to an ''incomplete eyewall replacement cycle'' and a resulting broad and diffuse wind field that slowly decayed as the storm moved from the Bahamas to North Carolina (NC)—over a warm ocean and in relatively light wind shear. Irene made landfall in NC as a category-1 hurricane, two categories below expected strength.

One hypothesis as to why Irene unexpectedly weakened between the Bahamas and NC involves both aerosols and ocean cooling (Lynn et al. 2016; Khain et al. 2016). Irene crossed a wide band of Sahara dust just north of the West Indies, initially causing convection invigoration in the simulated eyewall and fostering the hurricane's development (Lynn et al. 2016). However, as Irene approached the United States, continental aerosols intensified convection at the simulated storm's periphery. This intensification of convection at the TC periphery can lead to increases in TC central pressure and weakening of wind speed near the eyewall (Lynn et al. 2016 and references within).

This paper's focus is on Irene's time after its NC landfall (Fig. 1) and after it had weakened in intensity due to continental aerosol interaction with convection at the hurricane's periphery and the slight SST cooling in the South Atlantic Bight (SAB). The SST cooling over the Mid-Atlantic Bight (MAB) was at least 3–5 times greater than the SST cooling that occurred in the SAB (Figs. 2 and 3).

While energetic ocean mesoscale features can distort the structure of the TC cold wake (Walker et al. 2005; Jaimes and Shay 2010; Jaimes et al. 2011), during the direct forcing part of the storm, TC cooling in a deep ocean with no eddy features is frequently distributed

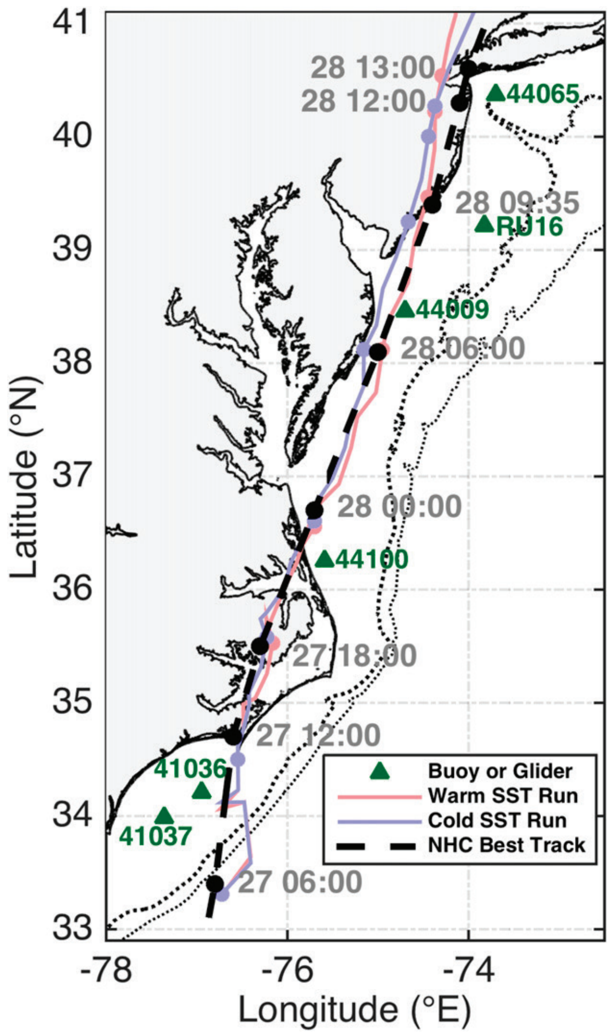

FIG. 1. NHC best-track data for Hurricane Irene in dashed black with timing (DD HH:MM August 2011) labeled in gray. Tracks for warm (red) and cold (blue) SST simulations are also plotted. NDBC buoy and glider RU16 locations are shown with green triangles. The 50- and 200-m isobaths are plotted in dotted black lines.

symmetrically between the front and back half of the storm (Price 1981). This does not include the inertial response in the cold wake. As will be shown in this paper, significant ahead-of-eye-center SST cooling (at least 6°C and up to 11°C, or 76%–98% of total in-storm cooling) was observed over the MAB continental shelf during Hurricane Irene, indicating that coastal baroclinic processes enhanced the percentage of cooling that occurred ahead of eye center (Glenn et al. 2016).

This paper will 1) explore how Irene's predictions change using a semi-idealized treatment of the ahead-of-eye-center cooling, 2) show that better treatment would have lowered the high bias in real-time predictions, and 3) conclude that this ahead-of-eye-center cooling observed in Irene was the missing contribution—not wind shear, track, or dry air intrusion—to the rapid decay of Irene's intensity just prior to NJ landfall.

2. Data and methods

a. Gliders

Teledyne-Webb Research (TWR) Slocum gliders are autonomous underwater vehicles (AUVs) that have become useful platforms for monitoring the ocean's response to storms (Glenn et al. 2008; Ruiz et al. 2012; Miles et al. 2013, 2015). Gliders can profile the water column from the surface to depths of up to 1000 m. They continuously sample every 2 s, providing a high temporal resolution time series from pre- to poststorm and complementing the spatial coverage that multiple concurrent airborne expendable bathythermograph (AXBT; Sessions et al. 1976; Sanabia et al. 2013) deployments can provide. Finally, gliders can be piloted, enabling more targeted profiling throughout the storm, in contrast to Argo (Gould et al. 2004; Roemmich et al. 2009) and Air-Launched Autonomous Micro-Observer (ALAMO; Sanabia and Jayne 2014; Sanabia et al. 2016) floats, which passively move with ocean currents. Because of this, gliders can be directed to steer into a storm and station-keep, providing a fixed-point Eulerian observation time series. A more detailed description of general capabilities of these gliders can be found in Schofield et al. (2007). For storm-specific capabilities of the gliders, see Miles et al. (2013, 2015) and Glenn et al. (2016).

Rutgers University Glider RU16 was used in this study. The glider was equipped with several science sensors, including a Seabird unpumped conductivity–temperature–depth (CTD) sensor, which measured temperature, salinity, and water depth. The top bin in the temperature profiles—0–1-m depth—is used to provide a measure of near-surface temperature at the glider location (Fig. 1). Thermal-lag-induced errors associated with the unpumped CTD were corrected before any data were used (Garau et al. 2011).

b. Buoys

1) NEAR-SURFACE TEMPERATURE

National Data Buoy Center (NDBC) buoys 41037 and 41036 in the SAB and buoys 44100, 44009, and 44065 in the MAB were used in this study (Fig. 1). Hourly water temperatures were used, which is measured at 0.6-m depth at all buoys except 0.46-m depth at 44100. These data provide near-surface water temperatures along and near the track of Hurricane Irene through the SAB and MAB.

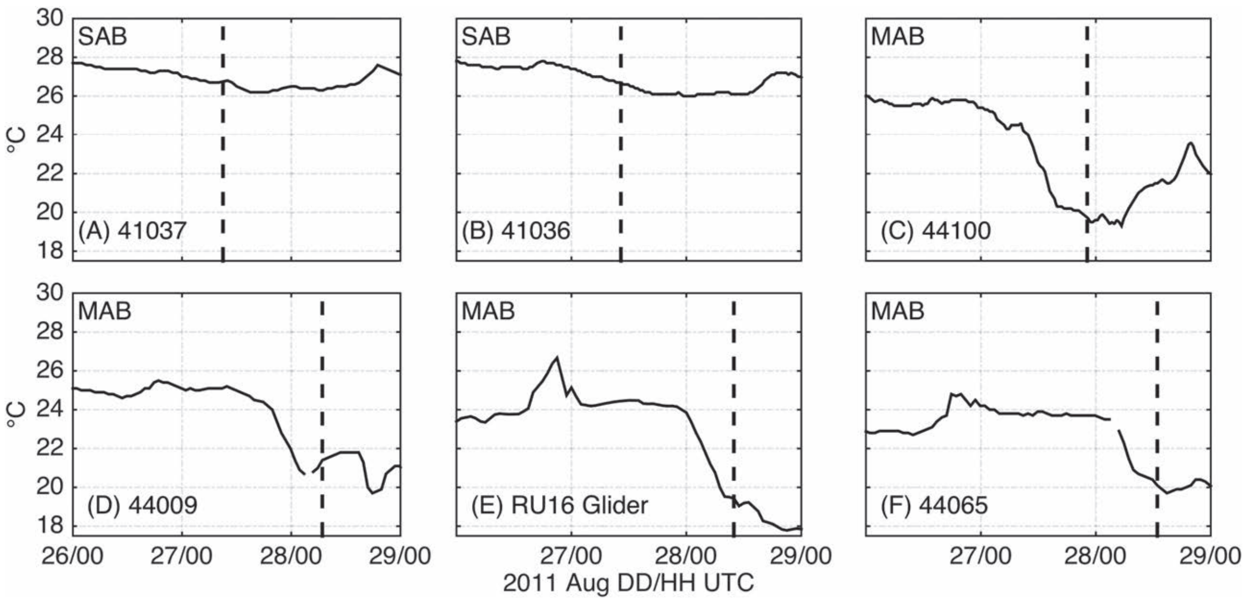

FIG. 2. NDBC buoy and glider near surface water temperature (°C) time series. South Atlantic Bight buoys (denoted by "SAB") from south to north are 41037 and 41036, and Mid-Atlantic Bight buoys and glider RU16 (denoted by "MAB") from south to north are 44100, 44009, glider RU16, and 44065. Timing of Irene's eye passage by the buoy or glider is denoted with vertical dashed line.

2) HEAT FLUXES

NDBC buoys 44009 and 44065 were used for latent and sensible heat flux calculations, which were estimated based on the "bulk formulas" (Fairall et al. 1996):

$$\text{Sensible heat flux:}\quad H = -(\rho c_p)C_H U(\theta - \theta_{\text{sfc}}), \tag{1}$$

$$\text{Latent heat flux:}\quad E = -(\rho L_v)C_Q U(q - q_{\text{sfc}}), \tag{2}$$

where ρ is density of air, c_p is specific heat capacity of air, C_H is sensible heat coefficient [see Eq. (5)], U is 5-m wind speed, θ is potential temperature of the air at 4 m and θ_{sfc} is potential temperature at the water surface, L_v is enthalpy of vaporization, C_Q is latent heat coefficient [see Eq. (6)], q is specific humidity of the air at 4 m, and q_{sfc} is interfacial specific humidity at the water surface.

Neither θ_{sfc} and q_{sfc} are directly computed from interfacial water temperature, but rather computed from buoy temperature measured at 0.6-m depth. During high wind conditions, the difference between skin temperature and temperature at 0.6-m depth is likely small enough to have a negligible effect on the computed bulk fluxes (Fairall et al. 1996).

c. Satellites

1) SEA SURFACE TEMPERATURE

The National Centers for Environmental Prediction (NCEP) Real-Time Global High-Resolution (RTG-HR) is a daily SST analysis used in this study. RTG-HR SST is operationally produced using in situ and AVHRR data on a 1/12° grid (Reynolds and Chelton 2010). The operational 13-km Rapid Refresh (RAP) and the 12-km North American Mesoscale Forecast System (NAM) and its inner nests, including the 4-km NAM continental U.S. (CONUS) nest, use fixed RTG-HR SST. Therefore, RTG-HR is the most relevant SST product for comparison with the 2-km SST composite described next.

Standard techniques to remove cloudy pixels in SST composites use a warmest pixel method because clouds are usually colder than the SST (Cornillon et al. 1987). This tends to reduce cloud contamination but results in a warm bias, which is unfavorable for capturing TC cooling. In this study, a 3-day "coldest dark-pixel" composite method is used to map regions of cooling from Irene. This technique, described in Glenn et al. (2016), filters out bright cloudy pixels while retaining darker ocean pixels.

2) WATER VAPOR

Satellites are also used for a spatial estimate of the intrusion of dry air into Irene's circulation. *Geostationary Operational Environmental Satellite-13 (GOES-13)* water vapor channel-3 brightness temperature imagery is used for these estimates.

d. Radiosondes

Radiosondes, typically borne aloft by a weather balloon released at the ground, directly measure temperature, humidity, and pressure, and derive wind speed and direction. To validate profiles of modeled wind shear and

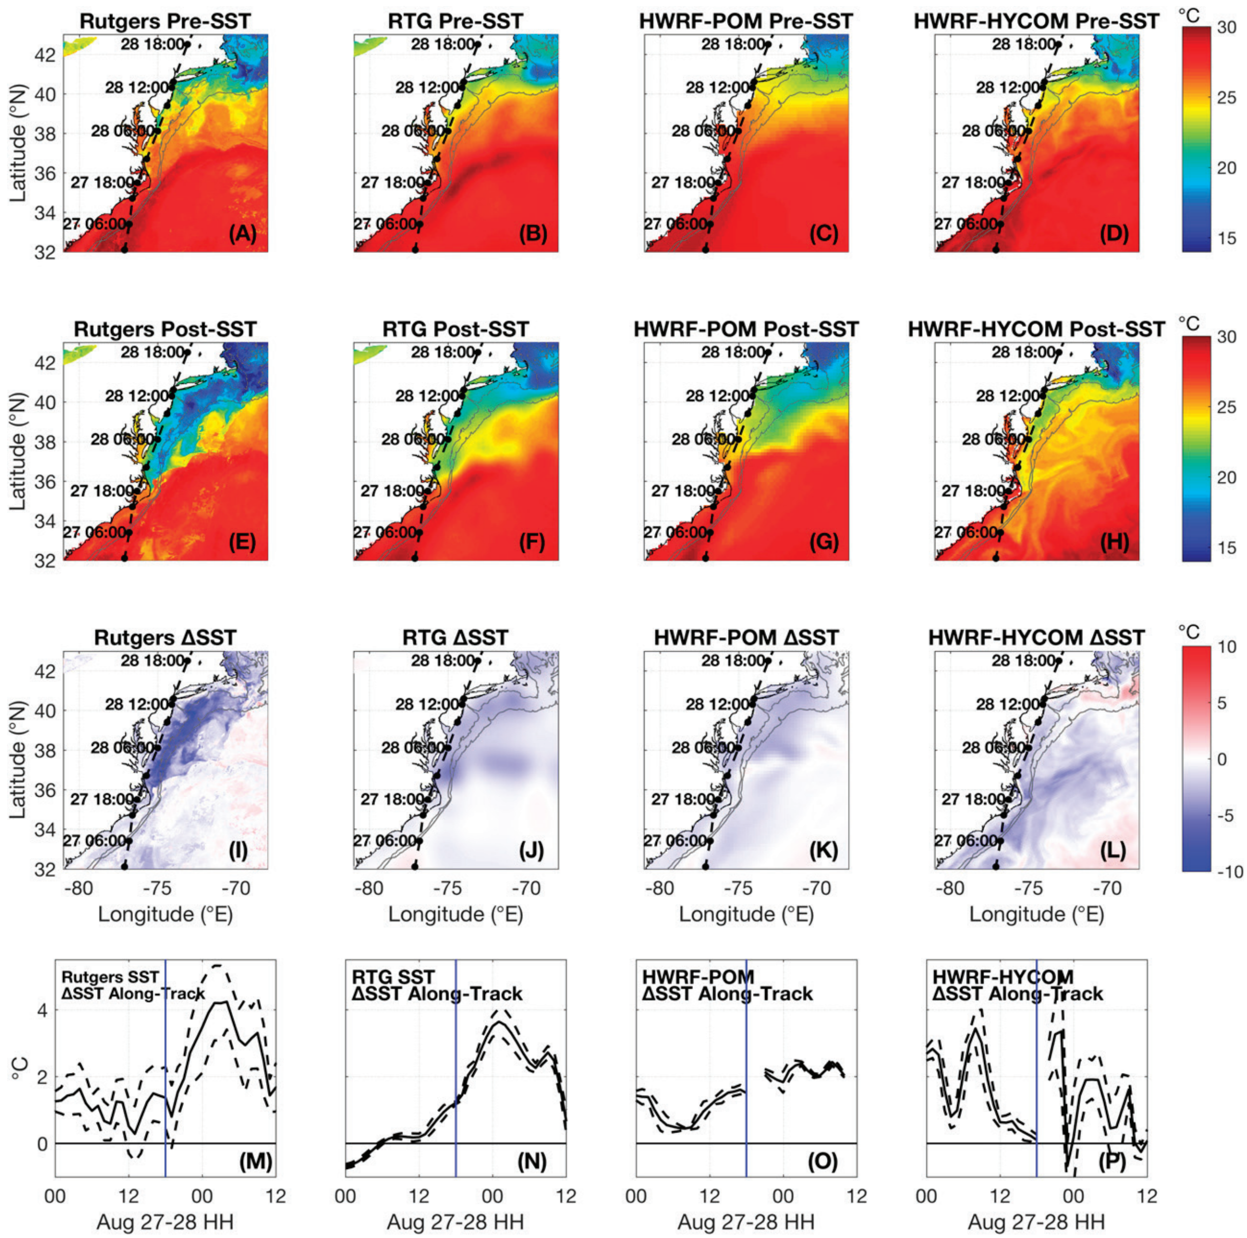

FIG. 3. SST plots (a)–(d) before Irene, (e)–(h) after Irene, (i)–(l) difference between before and after. (m)–(p) Along-track SST change (mean within 25 km of NHC best track in solid black, ±1 standard deviation in dashed black) time series with vertical blue line dividing the first part of the time series when Irene was over the SAB, and the second part of the time series when Irene was over the MAB. (a),(e),(i),(m) The new Rutgers SST composite, as described in section 2c(1); before Irene is coldest dark-pixel composite from 24 to 26 Aug 2011, after Irene is from 29 to 31 Aug 2011. (b),(f),(j),(n) The Real-Time Global High Resolution (RTG HR) SST product from NOAA; before Irene is from 26 Aug, after Irene is from 31 Aug. (c),(g),(k),(o) The operational HWRF-POM from 2011, simulation initialized at 0000 UTC 26 Aug 2011; before Irene is from 0000 UTC 26 Aug, after Irene is from 0000 UTC 31 Aug. (d),(h),(l),(p) The experimental HWRF-HYCOM from 2011, simulation initialized at 0000 UTC 26 Aug 2011; before Irene is from 0000 UTC 26 Aug, after Irene is from 0000 UTC 31 Aug.

dry air intrusion, radiosonde observations of u and v winds are used from Albany, New York (KALB); Chatham, Massachusetts (KCHH); and Wallops Island, Virginia (KWAL), and RH is used from KALB and KWAL.

e. North American Regional Reanalysis

The North American Regional Reanalysis (NARR) is a 32-km, 45 vertical layer atmospheric reanalysis produced by NCEP and provides a long-term (1979–present) set of consistent atmospheric data over North America (Mesinger et al. 2006). The data consist of reanalyses of the initial state of the atmosphere, which are produced by using a consistent data assimilation scheme to ingest a vast array of observational data into historical model hindcasts. NARR is used to evaluate modeled size and structure of Irene, modeled heat fluxes, and modeled wind shear, both horizontally and vertically.

f. Modeling and experimental design

1) Hurricane Weather Research and Forecasting

Output from two different versions of the Hurricane Weather Research and Forecast system [HWRF; Skamarock et al. (2008)] was used in this study: 1) the 2011 operational HWRF, which was the Weather Research and Forecasting (WRF) Model coupled to the feature-model-based Princeton Ocean Model [HWRF-POM; Blumberg and Mellor (1987)], and 2) the same HWRF atmospheric component but coupled to the Hybrid Coordinate Ocean Model [HWRF-HYCOM; Chassignet et al. (2007)].

For the operational 2011 hurricane season, POM for HWRF-POM was run at 1/6° resolution (~18 km), with 23 terrain-following sigma coordinate vertical levels. The three-dimensional POM output files contain data that are interpolated vertically onto the following vertical levels: 5-, 15-, 25-, 35-, 45-, 55-, 65-, 77.5-, 92.5-, 110-, 135-, 175-, 250-, 375-, 550-, 775-, 1100-, 1550-, 2100-, 2800-, 3700-, 4850-, and 5500-m depth (Tallapragada et al. 2011). Near-surface temperatures are pulled from the top level of POM, which occurs at 5 m.

The ocean model component of the 2011 HWRF-HYCOM system is the Real-Time Ocean Forecast System-HYCOM [RTOFS-HYCOM; Mehra and Rivin (2010)], which varies smoothly in horizontal resolution from ~9 km in the Gulf of Mexico to ~34 km in the eastern North Atlantic (Kim et al. 2014). Initial conditions are estimated from RTOFS-Atlantic (Mehra and Rivin 2010) 24-h nowcasts (Kim et al. 2014). RTOFS-HYCOM uses the Goddard Institute for Space Studies (GISS) vertical mixing and diffusion scheme (Canuto et al. 2001, 2002). Near-surface temperatures are pulled from the top layer of HYCOM, which ranges from less than 1 m in shallower regions (approximately 40-m water column depth or less) to 3 m in deeper regions (approximately 100-m water column depth or greater).

2) Regional Ocean Modeling System

The Regional Ocean Modeling System [ROMS; http://www.roms.org, Haidvogel et al. (2008)] is a free-surface, sigma coordinate, primitive equation ocean model that has been particularly used for coastal applications. Output is used from simulations run on the Experimental System for Predicting Shelf and Slope Optics (ESPreSSO) model (Wilkin and Hunter 2013) grid, which covers the MAB from Cape Hatteras to Cape Cod, from the coast to past the shelf break, at 5-km horizontal resolution and with 36 vertical levels.

3) WRF and experimental design

(i) Control simulation

The Advanced Research dynamical core of WRF [ARW, http://www.wrf-model.org, Skamarock et al. (2008)], version 3.4 is a fully compressible, nonhydrostatic, terrain-following vertical coordinate, primitive equation atmospheric model. This ARW domain extends from south Florida to Nova Scotia, and from Michigan to Bermuda (Glenn et al. 2016).

In the experiments, the control simulation has a horizontal resolution of 6 km with 35 vertical levels. The following physics options are used: longwave and shortwave radiation physics were both computed by the Rapid Radiative Transfer Model-Global (RRTMG) scheme, the Monin–Obukhov atmospheric layer model and the Noah land surface model were used with the Yonsei University planetary boundary layer (PBL) scheme, and the WRF double-moment 6-class moisture microphysics scheme (Lim and Hong 2010) was used for grid-scale precipitation processes. The control simulation did not include cumulus parameterization (Kain 2004); sensitivity to cumulus parameterization was tested in a subsequent simulation (see below and in Table 1).

It was critical to ensure that the control simulation had a track very similar to the NHC best track, so as to not include any additional land effects on Irene's intensity as it tracked closely along the coast. Also, because TC translation speed has a large impact on SST response and subsequent negative feedback on TC intensity (Mei et al. 2012), it was critical to closely simulate Irene's translation speed. Several different lateral boundary conditions and initialization times were experimented with before arriving at the best solution (after Zambon et al. 2014a). The resulting initial and lateral boundary conditions used are from the Global Forecast System (GFS) 0.5° operational cycle initialized at 0600 UTC 27 August 2011.

For the control simulation, RTG-HR SST from 0000 UTC 27 August 2011 is used for bottom boundary conditions over the ocean. This is 6 h prior to model initialization, to mimic NAM and RAP operational conditions. All simulations are initialized at 0600 UTC 27 August 2011 when Irene was just south of NC (Fig. 1) and end at 1800 UTC 28 August 2011. By initializing so late, the focus is only on changes in Irene's

TABLE 1. List of model sensitivities, grouped by type. Name of sensitivity is on left, details of sensitivity with WRF namelist option on right. Control run listed last.

Sensitivity	WRF namelist option
A. Model configuration	
1. Horizontal resolution (dx)	3 vs 6 km
2. Vertical resolution (e_vert, eta_levels)	51 vs 35 vertical levels
3. Adaptive time step (use_adaptive_time_step)	On vs off
4. Boundary conditions (update frequency, interval_seconds)	3 vs 6 h
5. Digital filter initialization (DFI, dfi_opt)	On (dfi_nfilter = 7) vs off
B. Atmospheric–model physics	
6–7. Microphysics (mp_physics)	6 (WRF single-moment 6-class) vs 16 (WRF double-moment 6-class) vs 30 (HUJI spectral bin microphysics, "fast")
8–9. Planetary boundary layer scheme (bl_pbl_physics)	5 (Mellor–Yamada–Nakanishi–Niino level 2.5) vs 7 (ACM2) vs 1 (Yonsei University)
10. Cumulus parameterization (cu_physics)	1 (Kain–Fritsch, cudt = 0, cugd_avedx = 1) vs 0 (off)
11. SST skin (sst_skin)	On vs off
12–14. Longwave radiation (ra_lw_physics)	1 (RRTM) vs 5 (new Goddard) vs 99 (GFDL) vs 4 (RRTMG)
15–17. Shortwave radiation (ra_sw_physics)	1 (Dudhia) vs 5 (new Goddard) vs 99 (GFDL) vs 4 (RRTMG)
18–19. Latent heat flux < 0 over water (in module_sf_sfclay)	On vs off (warm SST) On vs off (cold SST)
20. Land surface physics (sf_surface_physics)	1 (5-layer thermal diffusion) vs 2 (Noah)
C. Advanced Hurricane WRF (AHW) options	
21–22. Air–sea flux parameterizations (isftcflx)	1 vs 0 (warm SST) (control run: isftcflx = 2) 1 vs 0 (cold SST) (control run: isftcflx = 2)
D. Sea surface temperature	
23–25. SST	Cold vs warm (isftcflx = 2) Cold vs warm (isftcflx = 1) Cold vs warm (isftcflx = 0)
E. Advanced Hurricane WRF (AHW) options (12-h later initialization)	
26. Digital filter initialization (DFI, dfi_opt)	On (dfi_nfilter = 7) vs off
27–28. 1D ocean mixed layer model (sf_ocean_physics = 1)	On (isothermal warm initial conditions) vs on (glider stratified initial conditions) vs off
29–30. 3D ocean Price–Weller–Pinkel model (sf_ocean_physics = 2)	On (HWRF-HYCOM initial conditions) vs on (glider stratified initial conditions) vs off

intensity occurring in the MAB. Further, as will be shown below, model spinup was a quick 6 h, so the model is already in a state of statistical equilibrium (Brown and Hakim 2013) under the applied dynamical forcing by the time Irene enters the MAB.

A two-part experiment, detailed below, is performed to investigate why model guidance did not fully capture the rapid decay of Irene just prior to NJ landfall. First, >140 simulations are conducted for sensitivities of Irene's intensity, size, and structure to various model parameters, physics schemes, and options, including horizontal and vertical resolution, microphysics [including a simulation with WRF spectral bin microphysics (Khain et al. 2010) to test sensitivity to aerosols], PBL scheme, cumulus parameterization, longwave and shortwave radiation, land surface physics, air–sea flux parameterizations, coupling to a 1D ocean mixed layer (OML) model, coupling to a 3D ocean Price–Weller–Pinkel (PWP) model, and SST (Table 1). These simulations quantify and contextualize the sensitivities of Irene's modeled intensity, size, and structure to SST. Second, a model assessment is performed, specifically evaluating the control run's treatment of track, wind shear, and dry air intrusion.

To conclude the data and methods section, details are provided on a few key sensitivities. These are the following: SST, air–sea flux parameterizations, 1D OML model, 3D PWP model, and latent heat flux < 0 over water.

(ii) Sensitivity to SST

To quantify the maximum impact of the ahead-of-eye-center SST cooling on storm intensity, the control run using a static warm prestorm SST (RTG-HR SST) is compared to a simulation using static observed cold poststorm SSTs. For this cold SST, the 29–31 August 2011 3-day coldest dark-pixel SST composite (described above) is used (Fig. 3e). According to underwater glider and NDBC buoy observations along Irene's entire MAB track (Fig. 1), almost all of the SST cooling in the MAB occurred ahead of Irene's eye center (Figs. 2c–f). The SAB also experienced ahead-of-eye-center SST cooling, but values are on the order of 1°C or less (Figs. 2a,b). Also, the model simulations include only 6 h of storm presence over the SAB. Therefore, the SST simulations described above quantify the sensitivity of Irene to ahead-of-eye-center cooling that occurred only in the MAB.

(iii) Sensitivity to air–sea flux parameterizations

The bulk formulas for sensible and latent heat fluxes are listed above in the buoy heat flux description. The following is the equation for momentum flux:

$$\text{Momentum flux:} \quad \tau = -\rho C_D U^2, \tag{3}$$

where ρ is density of air, C_D is drag coefficient, and U is 10-m wind speed.

Three options exist in ARW version 3.0 and later for air–sea flux parameterizations (WRF namelist option isftcflx = 0, 1, and 2). These parameterization options change the momentum (z_0), sensible heat (z_T), and latent heat (z_Q) roughness lengths in the following equations for drag, sensible heat, and latent heat coefficients:

$$\text{Drag coefficient:} \quad C_D = \kappa^2/[\ln(z_{\text{ref}}/z_0)]^2, \tag{4}$$

$$\text{Sensible heat coefficient:} \quad C_H = (C_D^{1/2})[\kappa/\ln(z_{\text{ref}}/z_T)], \tag{5}$$

$$\text{Latent heat coefficient:} \quad C_Q = (C_D^{1/2})[\kappa/\ln(z_{\text{ref}}/z_Q)], \tag{6}$$

where κ is the von Kármán constant and z_{ref} is a reference height (usually 10 m).

The reader is encouraged to refer to Green and Zhang (2013) for a detailed look at the impact of isftcflx = 0, 1, and 2 on roughness lengths, exchange coefficients, and exchange coefficient ratios C_H/C_D, C_Q/C_D, and C_K/C_D, where $C_K = C_H + C_Q$. Some key points from their paper are that, at wind speeds of $33\,\text{m}\,\text{s}^{-1}$ or greater, isftcflx = 1 has the largest C_K/C_D ratio and shares with isftcflx = 2 the lowest C_D. As a result, they found that for Hurricane Katrina (2005), using isftcflx = 1 produced the most intense storm in terms of minimum SLP and maximum winds.

Therefore, our SST sensitivity effectively changes the variables θ_{sfc} and q_{sfc} in Eqs. (1)–(3) above, while our air–sea flux parameterization sensitivities change the equations for the momentum, sensible heat, and latent heat coefficients [Eqs. (4)–(6)] going into the respective flux Eqs. (1)– (3). Because isftcflx = 1 and isftcflx = 2 both include a term for dissipative heating and isftcflx = 0 does not in WRFv3.4 (Green and Zhang 2013), the air–sea flux parameterization sensitivity between isftcflx = 0 and 1, and between isftcflx = 0 and 2 also test the effect of turning on and off dissipative heating in the model. Although the dissipative heating term was removed as of WRFv3.7.1 due to controversy within the wind-wave modeling community, dissipative heating is still considered an important issue in high wind regimes, and it has been shown to be capable of increasing TC intensity by 10%–20% as measured by maximum sustained surface wind speeds (Liu et al. 2011).

For the air–sea flux parameterization sensitivities, simulations are conducted with isftcflx = 0, 1, and 2 using both the warm (control) and cold SST boundary conditions.

(iv) Sensitivities coupling WRF to 1D and 3D ocean models

Pollard et al.'s [1972; described in WRF context by Davis et al. (2008)] 1D ocean mixed layer model was used to test the sensitivity of Irene to 1D ocean processes. Two different initializations of the 1D ocean model were initially performed: 1) *coastal stratification*: initializing the mixed layer depth (MLD) everywhere to 10 m and the slope of the thermocline everywhere to $1.6°\text{C}\,\text{m}^{-1}$ according to glider RU16's observations (Glenn et al. 2016), and 2) *HYCOM stratification:* initializing the MLD and top 200-m mean ocean temperature spatially using HYCOM. However, there were major issues using both of these options to accurately determine sensitivity to 1D ocean processes. The issue with the first option is its requirement that the initialization is nonvariant in space; the Gulf Stream, which is included in the model domain, is very warm and well mixed down to 100–200 m (Fuglister and Worthington 1951). Initializing the Gulf Stream MLD to 10 m would result in cold water only 10 m deep being quickly mixed to the surface. The issue with the second option of using HYCOM is that due to its poor initialization, the HYCOM simulation used here did not resolve the abundant bottom cold water over the MAB continental shelf that was observed by glider RU16 prior to Irene (Glenn et al. 2016) and that is typical of the summer MAB cold pool (Houghton et al. 1982).

The 3D ocean PWP model (Price et al. 1986, 1994) was used to test the sensitivity of Irene to 3D open-ocean, deep-water processes, including Ekman pumping–upwelling and mixing across the base of the mixed layer caused by shear instability. While the 3D PWP model contains 3D dynamics and is fully coupled to WRF, it does not have bathymetry or a coastline (Lee and Chen 2014); water depth is uniform across the model grid. Therefore, any 3D PWP model run will not simulate the coastal baroclinic processes that were observed in Irene over the MAB continental shelf due to the presence of the coastline (Glenn et al. 2016). In addition, like in the 1D ocean model, initialization must be nonvariant in x–y space.

To ameliorate the issue with mixing the Gulf Stream and still conduct sensitivities on nonstatic 1D and 3D ocean processes, an initialization time 12 h later—1800

UTC 27 August instead of 0600 UTC 27 August—was used for the WRF-1D OML and WRF-3D PWP simulations, because Irene by then was already north of the Gulf Stream and thus would not interact with it, and still south of the MAB (see Fig. 1). Four sensitivities with this initialization time were tested with various configurations of the 1D OML and 3D PWP models. First, the 1D OML model was initialized using the prestorm coldest dark-pixel composite for SST and with a MLD of 200 m, to simulate isothermal warm ocean conditions and the effect of air–sea heat fluxes. Second, the 1D OML model was initialized everywhere using RU16 observed stratification, as described above; this simulated the effect of 1D deep-water mixing processes (the 1D OML model does not have an ocean bottom). Third, the 3D PWP model was initialized everywhere using the same RU16 observed stratification that was used for the 1D OML model simulation but with 400-m full water column depth, to simulate the effect of 3D deep-water processes. Fourth, the 3D PWP model was initialized everywhere using HWRF-HYCOM stratification at the RU16 glider location at 0000 UTC 26 August and again with 400-m full water column depth, to test the sensitivity to a poor ocean initialization. These simulations are summarized in Table 1.

(v) Sensitivity to latent heat flux < 0 over water

In the WRF surface layer scheme code, a switch exists that disallows any latent heat flux $< 0\,\mathrm{W\,m^{-2}}$. (There is also a switch that disallows any sensible heat flux less than $-250\,\mathrm{W\,m^{-2}}$.) WRF convention for negative heat flux is downward, or from atmosphere to land or water surface. This sensitivity involves removing the switch disallowing negative latent heat flux. This switch removal only results in changes in latent heat flux over water, because the subsequent WRF land surface scheme modifies fluxes and already allows for latent heat flux to be negative over land.

Sensitivity tests

1) MOTIVATION

Hurricane Irene developed into a tropical storm just east of the Lesser Antilles on 20 August 2011, strengthening into a category-1 hurricane just after landfall in Puerto Rico 2 days later. Irene continued to move northwest over the Bahamas, intensifying into a category-3 hurricane on 23 August. Soon after, a partial eyewall replacement cycle occurred and Irene was never able to fully recover, eventually weakening into a category-1 hurricane on 27 August as it neared NC. Irene remained at hurricane strength over the MAB until it made landfall in NJ as a tropical storm at 0935 UTC 28 August. As stated above, the NHC final report on Irene (Avila and Cangialosi 2012) conveyed a ''consistent high bias [in the forecasts] during the U.S. watch–warning period,'' which consisted of the time period when Irene was traversing the SAB and MAB (Avila and Cangialosi 2012).

The coastal track of Irene (Fig. 1) over the relatively highly instrumented mid-Atlantic allowed for a comprehensive look into the details and timing of coastal ocean cooling. All in-water instruments employed here provide fixed point data within 70 km from Irene's eye, including station-keeping RU16, providing an Eulerian look at the ahead-of-eye-center cooling occurring near the storm's inner core. RU16 profiled the entire column of water over the MAB continental shelf, providing a view of the full evolution of the upper-ocean response. The rapid two-layer shear-induced coastal mixing process that led to ahead-of-eye-center cooling is described in detail in Glenn et al. (2016).

The buoys in the SAB (41037 and 41036) documented ~1°C SST cooling in the storm's front half, with total SST cooling less than 2°C (Fig. 2). Eye passage at each buoy is indicated by a vertical dashed line and represents the minimum sea level pressure (SLP) observed. For RU16, minimum SLP taken from the nearby WeatherFlow Tuckerton coastal meteorological station was used to calculate eye passage time, and for 44100, linearly interpolated NHC best-track data was used for eye passage time. In contrast to the SAB, the MAB buoys (44100, 44009, and 44065) as well as RU16 observed 4°–6°C SST ahead-of-eye-center cooling, with only slight cooling after eye passage of less than 2°C (Fig. 2). Therefore, the buoys and glider provide detailed evidence that significant ahead-of-eye-center cooling—76%–98% of the total observed in-storm cooling (Glenn et al. 2016)—occurred in the MAB.

While the buoys provided information on the timing of SST cooling, the high-resolution coldest dark-pixel SST composite showed the spatial variability of the cooling, revealing that the cooling was not captured by basic satellite products and some models used to forecast hurricane intensity. The improved 3-day coldest dark-pixel SST composite showed prestorm (24–26 August 2011; Fig. 3a) and poststorm (29–31 August 2011; Fig. 3e) SST conditions along the U.S. East Coast. SST cooling to the right of the storm track in the SAB approached 2°C, and in the MAB approached 11°C at the mouth of the Hudson Canyon (Fig. 3i). Under the TC inner core, within 25 km of Irene's track, SST cooling in the SAB ranged from 0.5° to 1.5°C, while in the MAB cooling ranged from ~2° to ~4°C (Fig. 3m). It is important

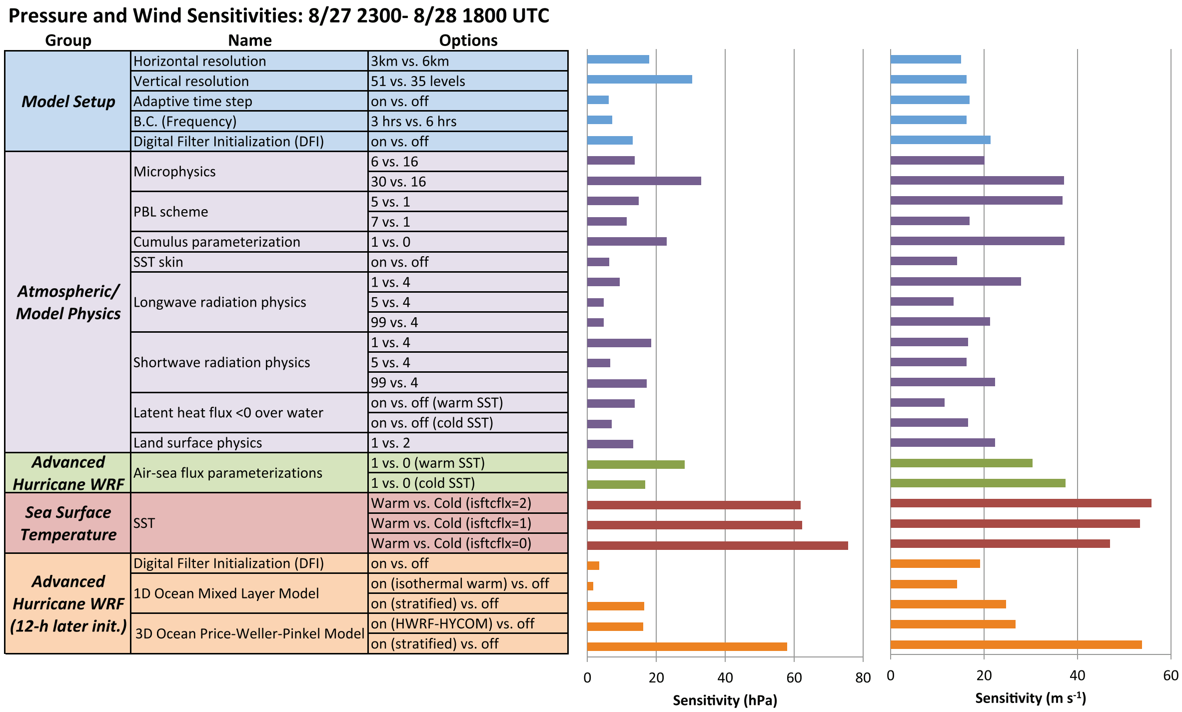

FIG. 4. Cumulative model sensitivity results from 2300 UTC 27 Aug 2011 (entrance of Irene's eye center over MAB) to 1800 UTC 28 Aug 2011 (end of simulation). (left) Group, name, and WRF namelist options with control run namelist option listed last for each sensitivity. (middle) Minimum sea level pressure (hPa) sensitivity and (right) maximum sustained 10-m wind (m s^{-1}) sensitivity.

to note that the SST composite from 3 days after storm passage was used for poststorm conditions. There were, indeed, large cloud-free areas over the MAB 1 day after storm passage, but it took an additional 2 days to fill in the remaining areas over the MAB and attain a cloud-free composite for input into WRF. In the persistently clear areas during this 3-day stretch, no additional SST cooling occurred during the poststorm inertial mixing period after the direct storm forcing.

RTG-HR SST pre- (26 August; Fig. 3b), poststorm (31 August; Fig. 3f), and difference (31 August minus 26 August; Fig. 3j) plots show spatially similar cooling patterns to the coldest dark-pixel SST composite, but cooling magnitudes are lower, especially to the right of the storm track in both the SAB and MAB (Fig. 3j). Similarly, there was no significant additional MAB cooling in RTG-HR SST from 1 day after (not shown) to 3 days after (Fig. 3f) storm passage.

HWRF-POM (Figs. 3c,g,k,o) and HWRF-HYCOM (Figs. 3d,h,l,p) model results are also shown as examples of coupled ocean–atmosphere hurricane models. Prestorm (0000 UTC 26 August) and poststorm (0000 UTC 31 August) times for both model results are coincident with the coldest dark-pixel SST composite and RTG-HR SST composite times, and both model simulations shown are initialized at 0000 UTC 26 August. Therefore, the poststorm SST conditions are 5-day forecasts in both models. Again, there are no significant differences in MAB SST cooling between immediately after and 3 days after Irene's passage in both HWRF-POM and HWRF-HYCOM. Like RTG-HR poststorm SST (Fig. 3f), HWRF-POM (Fig. 3g) and HWRF-HYCOM (Fig. 3h) poststorm SSTs in the MAB are several degrees too warm—the coldest SSTs are 20°–23°C, where they should be 17°–20°C. Therefore, these coupled atmosphere–ocean models designed to predict TCs did not fully capture the magnitude of SST cooling in the MAB that resulted from Hurricane Irene.

2) SENSITIVITY RESULTS

Over 140 WRF simulations were conducted to test the sensitivity of modeled Irene intensity to the observed ahead-of-eye-center cooling and to other model parameters. Only those simulations with tracks within 50 km of NHC best track were retained, leaving 30 simulations (Table 1).

To quantify cumulative model sensitivities, the sum of the absolute value of the hourly difference between the control run minimum SLP (and maximum sustained 10-m winds) and experimental run minimum SLP (and maximum 10-m winds) was taken, but only from 2300 UTC 27 August to the end of the simulation.

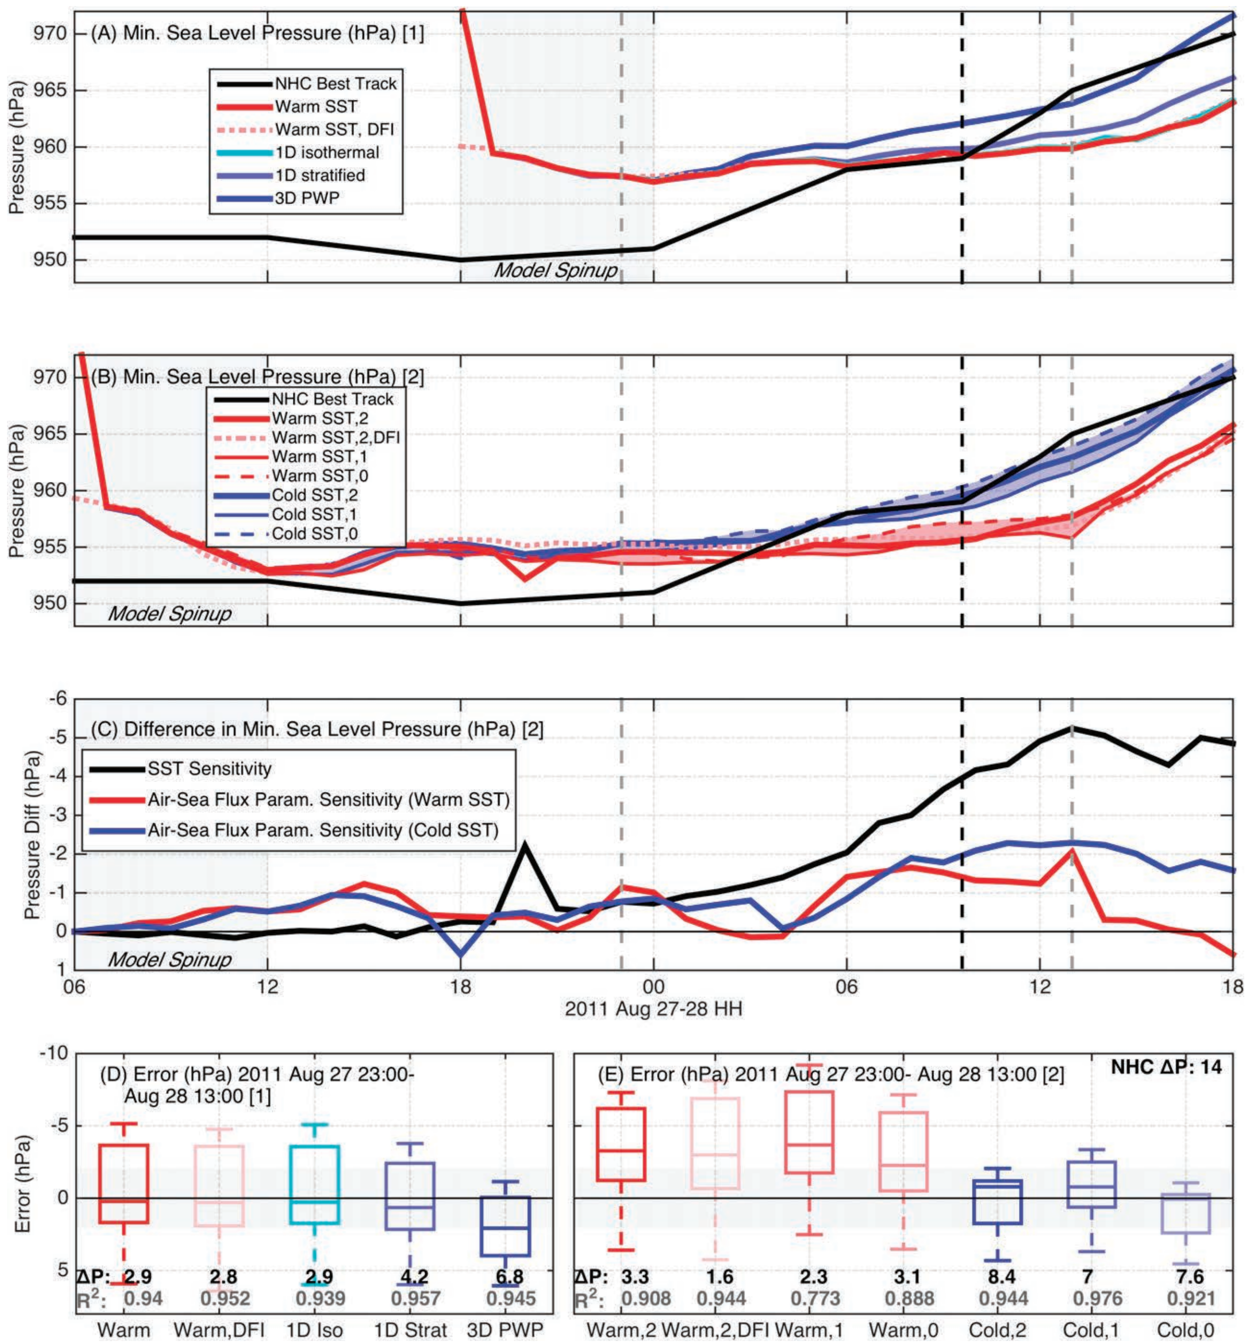

FIG. 5. Minimum SLP (hPa) time series for (a) WRF nonstatic ocean runs with NHC best track in black, warm SST in red, warm SST with DFI in dotted red, 1D ocean with isothermal warm initialization in cyan, 1D ocean with stratified initialization in light blue, and 3D PWP ocean in dark blue. (b) As in (a), but for WRF static ocean runs, with warm SST with isftcflx = 2 in red, warm SST with DFI in dotted red, warm SST with isftcflx = 1 in thin red, warm SST with isftcflx = 0 in dashed red, the three cold SST runs the same as warm SST but in blue lines. Vertical dashed gray lines depict start and end of Irene's presence over the MAB (2300 UTC 27 Aug–1300 UTC 28 Aug), with vertical dashed black line depicting Irene's landfall in NJ. Model spinup indicated as first 6 simulation hours with gray box. Difference in central pressure (c) between WRF static ocean warm and cold SST runs with isftcflx = 2 in black, between isftcflx = 0 and 1 for warm SST in red, and between isftcflx = 0 and 1 for cold SST in blue. (d) Box-and-whisker plots of errors vs NHC best-track data for WRF static ocean runs and (e) nonstatic ocean during Irene's MAB presence with R^2 values in gray and ΔP between 2300 UTC 27 Aug and 1300 UTC 28 Aug in black. NHC best-track ΔP in top right of (e), and uncertainty in pressure from NHC best-track data indicated by gray horizontal ribbon ±0 in (d) and (e).

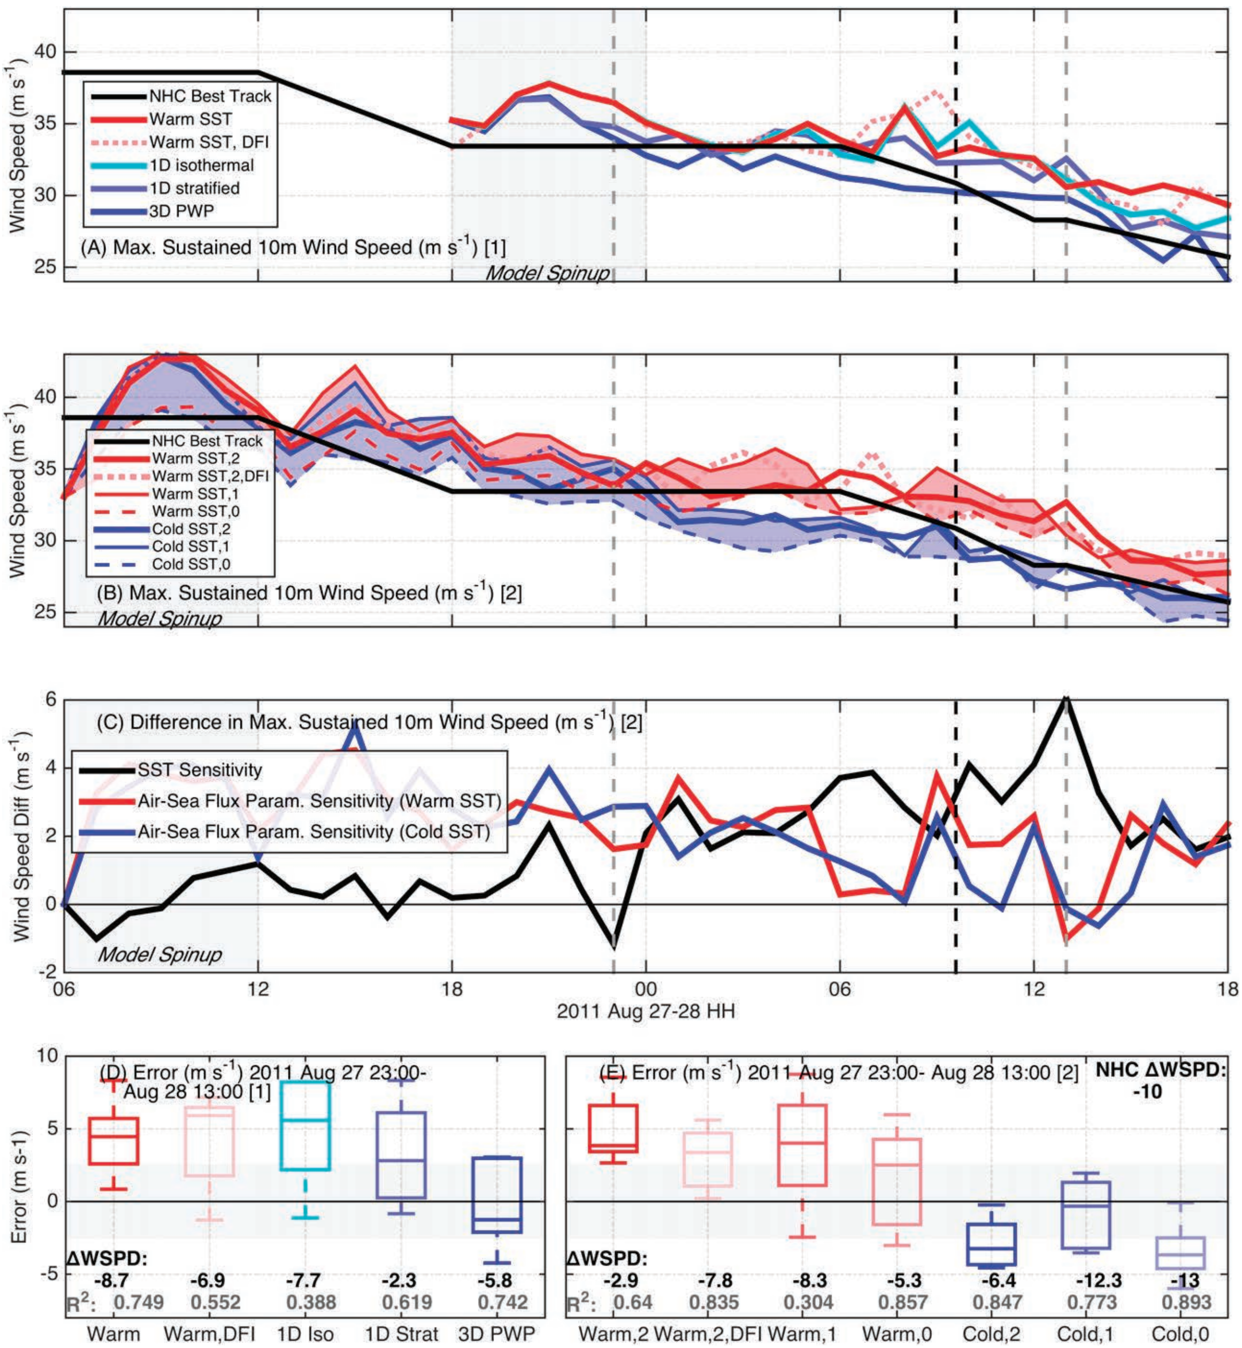

FIG. 6. As in Fig. 5, but for maximum sustained 10-m winds ($m\,s^{-1}$).

This confines the sensitivity to the time period of Irene's presence over the MAB and thereafter. The equation is as follows:

$$\sum_{i=2300\mathrm{UTC27Aug}}^{i=1800\mathrm{UTC28Aug}} |\min \mathrm{SLP}[\mathrm{control}(\mathrm{at\ hour}\ i)] - \min \mathrm{SLP}[\exp(\mathrm{at\ hour}\ i)]|. \quad (7)$$

Figure 4 shows the model sensitivities as measured by minimum SLP (left) and maximum 10-m wind speeds (right). Over the 19 h calculated, the three largest sensitivities when considering both intensity metrics were due to SST with the three WRF air–sea flux parameterization options (isftcflx = 0, 1, 2). On average, for SST over the three options, pressure sensitivity was 66.6 hPa over the 19 h (3.5 $hPa\,h^{-1}$) and wind sensitivity was 52.0 $m\,s^{-1}$ over

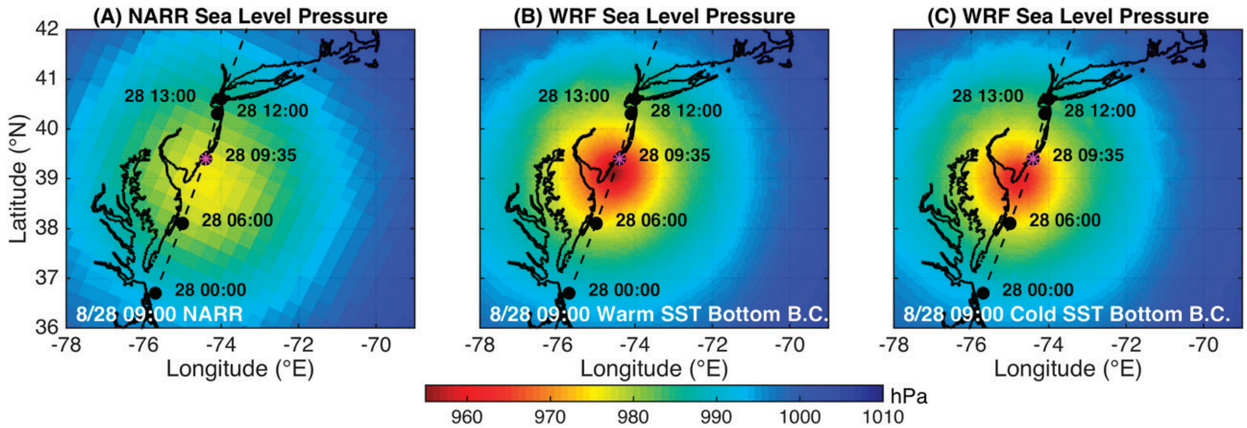

FIG. 7. Spatial plot of SLP (hPa) at 0900 UTC 28 Aug just prior to NJ landfall, with Irene's NHC best track in dashed black: (a) NARR, (b) WRF with warm SST bottom boundary conditions, and (c) WRF with cold SST bottom boundary conditions.

the 19 h (2.7 m s^{-1} h^{-1}). Sensitivity to 3D open-ocean, deep-water processes through the use of the 3D PWP model was comparatively large (Fig. 4). However, caution must be taken with this simulation because the 3D PWP model does not have a coastline and bathymetry, and ended up producing more in storm SST cooling than was observed by glider RU16 (not shown).

The Advanced Hurricane WRF sensitivities for the 12-h later initialization (1D warm isothermal, 1D stratified, and 3D PWP) are presented in time series in Figs. 5a and 6a. The black line indicates NHC best-track estimates of intensity, while the red solid line indicates the fixed prestorm warm SST control run. Note that minimum SLP at initialization is about 973 hPa whereas NHC best track indicates 950 hPa at that time; this difference is due to issues with WRF's vortex initialization (Zambon et al. 2014a), and it only takes 6 h for the model to adjust and drop 13 hPa to 959 hPa. The dotted red line indicates a sensitivity with digital filter initialization (DFI) turned on, which removes ambient noise at initialization. DFI resulted in initial min SLP (maximum winds) to be ~960 hPa (33 m s^{-1})—a reduction of 12 hPa (2 m s^{-1})—with downstream sensitivity negligible, demonstrating that the seemingly significant initialization issue likely has little significant effect on downstream intensity. The remaining sensitivities in Figs. 5a and 6a are the 1D ocean with isothermal warm initial conditions (effect of air–sea fluxes) in cyan, the 1D ocean with stratified initial conditions (effect of 1D mixing processes) in light blue, and the 3D PWP deep ocean with stratified initial conditions (effect of 3D deep-water processes) in dark blue. The air–sea fluxes have a negligible effect on intensity, while the 1D ocean mixing and 3D deep-water processes have a gradually larger negative effect on intensity.

The air–sea flux parameterization sensitivities with the standard initialization time are shown in Figs. 5b and 6b. Again, the black line indicates NHC best-track estimates of intensity, and the simulations have issues with vortex initialization. The DFI sensitivity for this set of runs (dotted red) again effectively resolves this issue. The red lines indicate the three WRF air–sea flux parameterization options using the warm prestorm SST with the area between the isftcflx = 0 and 1 options shaded in red, and the blue lines and blue shading indicate the same but for the cold poststorm SST. Consistent with the results found by Green and Zhang (2013), isftcflx=1 produced the most intense storm using both minimum SLP and maximum winds intensity metrics, for both the warm prestorm SST and cold poststorm SST; again, isftcflx = 1 has the largest C_K/C_D ratio and shares with isftcflx = 2 the lowest C_D.

Figures 5c and 6c show the time evolution of three sensitivities: 1) SST, warm versus cold (black), 2) air–sea flux parameterization with warm SST, isftcflx = 0 versus 1 (red), and 3) air–sea flux parameterization with cold SST, isftcflx = 0 versus 1 (blue). For both intensity metrics, sensitivity to SST gradually increases from about equal to flux parameterization sensitivity upon entrance to the MAB (first gray vertical dashed line) to almost triple it (~5 hPa vs ~2 hPa, 6 m s^{-1} vs ~0–2 m s^{-1}) upon exit out of the MAB (second gray vertical dashed line). Finally, Figs. 5d,e and 6d,e show box-and-whisker plots of simulation error as compared to NHC best track, only during MAB presence (2300 UTC 27 August–1300 UTC 28 August), with uncertainty in NHC best-track data (Torn and Snyder 2012; Landsea and Franklin 2013) shown with gray shading. Correlation coefficient (R^2) values are shown at the bottom in gray, and ΔP and ΔWSPD are shown in black, with NHC ΔP and ΔWSPD values shown in the top right of Figs. 5e and 6e. These delta values, a measure of weakening rate, are calculated by taking the difference in

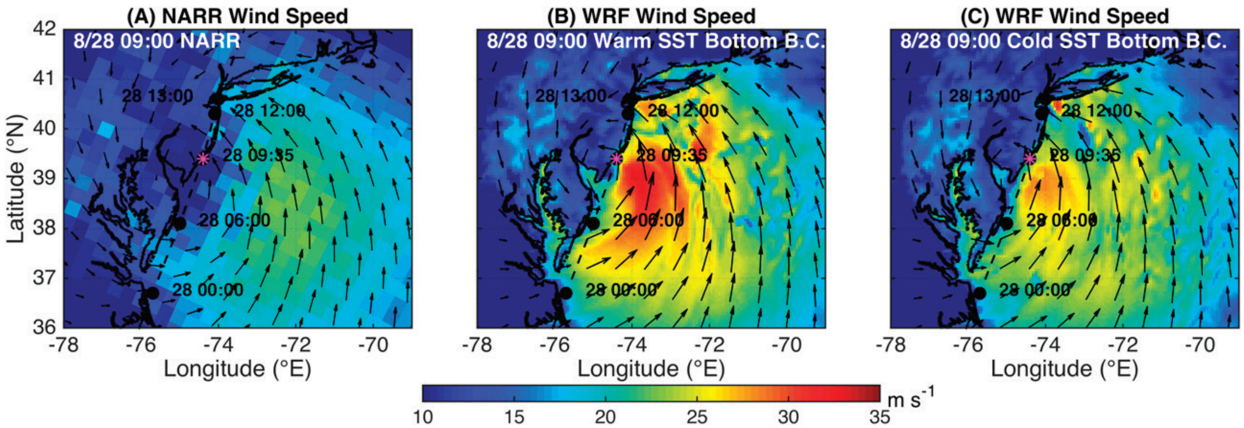

FIG. 8. As in Fig. 7, but for 10-m wind speeds and vectors (m s^{-1}).

pressure and wind speed between exit out of, and entrance into, the MAB.

Although the errors in minimum SLP for the simulations in Fig. 5d are low and the R^2 values are high, the errors in maximum winds are higher and the R^2 values are much lower in Fig. 6d. The four warm SST simulations (Figs. 5e and 6e) have a minimum SLP too low and maximum wind speed too high, while the three cold SST simulations have a minimum SLP closer to NHC best track and a maximum wind speed slightly lower than NHC best track. Because of the high uncertainty (4–5 m s^{-1} for nonmajor hurricanes) associated with NHC best-track wind estimates (Torn and Snyder 2012; Landsea and Franklin 2013), errors from the pressure metric are used. Minimum SLP is also a more certain measure of intensity because it is always at the TC eye center. The highest R^2 values and the ΔP values closest to NHC best-track ΔP were found with the three cold SST simulations. This indicates that a more accurate representation of the ahead-of-eye-center cooling via fixed cold poststorm SSTs lowers the high bias in our model's prediction of intensity. Further, the low ΔP–weakening rate attained using the 3D deep-water PWP simulation (ΔP: 6.8 hPa; rate: 0.5 hPa h^{-1})—which again did not have a coastline or appropriately shallow ocean bottom—suggests that coastal baroclinic processes were responsible for the cooling that contributed to Irene's observed larger ΔP–weakening rate (ΔP: 14 hPa; rate: 1 hPa h^{-1}). These coastal baroclinic processes, which are investigated in detail in Glenn et al. (2016), can be summarized as follows:

(i) front half of Irene's winds were onshore toward the mid-Atlantic coastline;
(ii) ocean currents in the surface layer above the sharp, shallow thermocline were aligned with the winds and also directed onshore over the MAB continental shelf;
(iii) water piled up along the mid-Atlantic coast, setting up a pressure gradient force directed offshore;
(iv) responding to the coastal piling of water, currents in the bottom layer below the sharp, shallow thermocline were directed offshore; and
(v) opposing onshore surface layer and offshore bottom layer currents led to large shear across the thermocline and turbulent entrainment of abundant bottom cold water to the surface; this enhancement of shear and SST cooling occurred in the front half of Irene as long as the winds were directed onshore (hence the term "ahead-of-eye-center cooling").

Therefore, without the coastline in simulations, 1) the coastal piling of water, 2) the offshore bottom counterflow, 3) the enhanced shear at the thermocline, and 4) the rapid surface cooling would not be simulated.

Finally, the deep ocean simulations using the 1D ocean and the 3D ocean PWP model initialized with stratified conditions produced 32% and 56% of the in-storm ahead-of-eye-center cooling at the RU16 glider location, respectively (not shown). Meanwhile, 76% of the observed in-storm cooling at the RU16 glider location—and 82%, 90%, and 98% at 44009, 44065, and 44100,

TABLE 2. Radius of maximum 10-m winds (in km). Warm SST and cold SST simulations compared to b-deck data from the ATCF system database.

	Radius of max wind (km)		
Time	b-deck	Warm SST	Cold SST
0600 UTC 27 Aug	111	107	107
1200 UTC 27 Aug	83	80	80
1800 UTC 27 Aug	83	102	104
0000 UTC 28 Aug	83	72	85
0600 UTC 28 Aug	185	74	74
1200 UTC 28 Aug	185	213	280

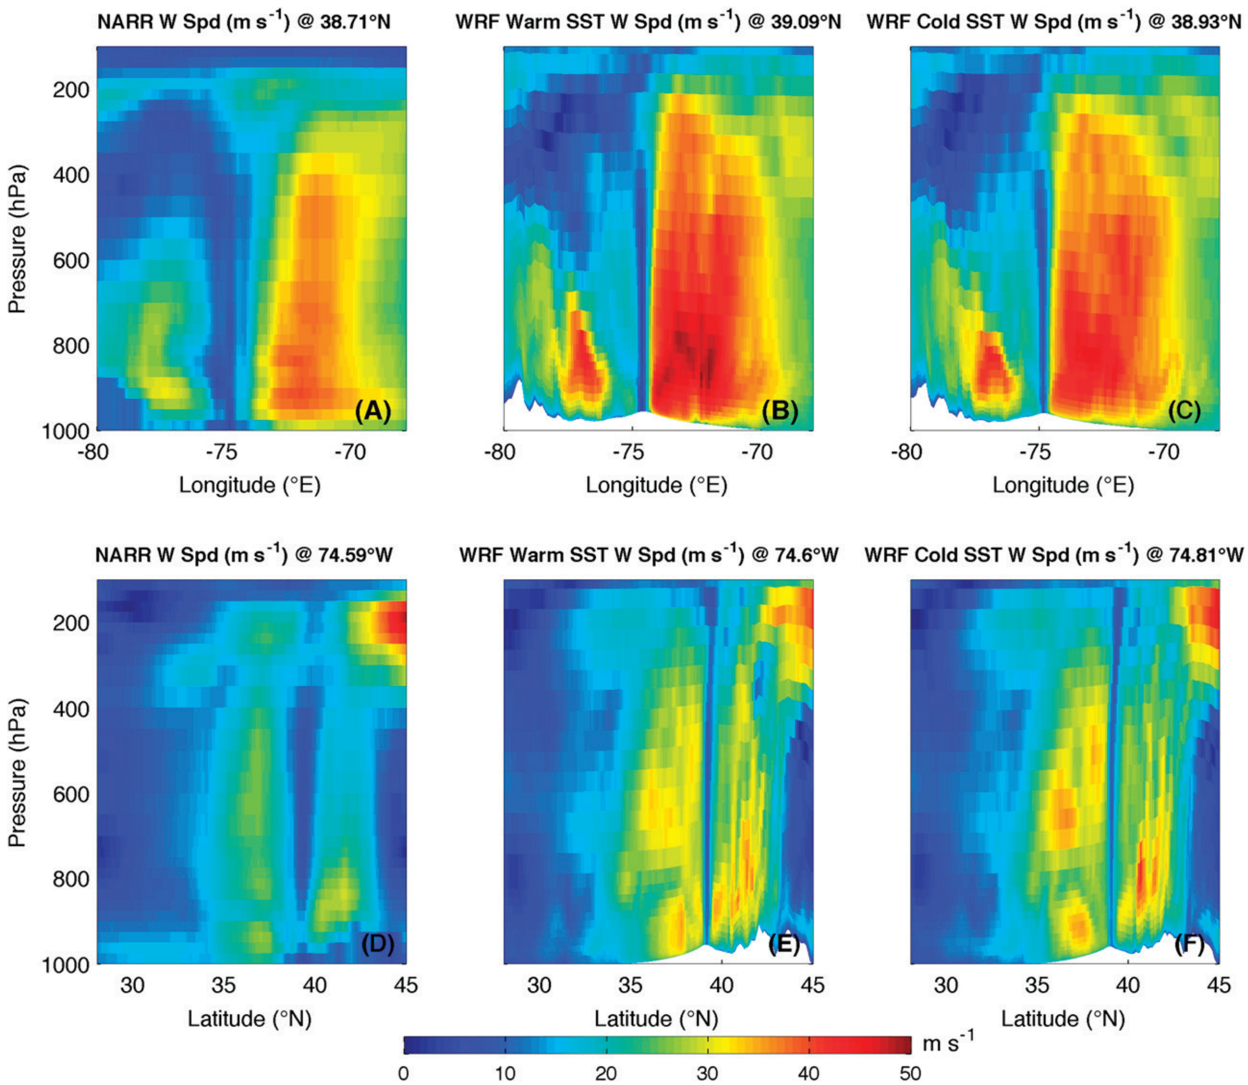

FIG. 9. Vertical cross sections of wind speed through Irene's eye at 0900 UTC 28 Aug, just prior to NJ landfall. (a)–(c) west–east cross sections and (d)–(f) south–north cross sections. For each, the latitude and longitude of eye is determined by locating the minimum SLP for (a),(d) NARR; (b),(e) WRF with warm SST bottom boundary conditions; and (c),(f) WRF with cold SST bottom boundary conditions.

respectively—occurred ahead of the eye center (Fig. 2), further indicating that the nonsimulated coastal baroclinic processes enhanced the percentage of ahead-of-eye-center cooling in Irene.

How sensitive are Irene's size and structure to SST? To spatially evaluate WRF results, NARR SLP and winds are used (Fig. 7). Spatial plots of SLP are shown from NARR (Fig. 7a), WRF warm SST (Fig. 7b), and WRF cold SST (Fig. 7c) runs, at just before NJ landfall. Only slight differences exist between WRF simulations, mainly in Irene's central pressure (warm SST: 955.4 hPa, cold SST: 959.1 hPa); overall size and structure of the storm is very similar between runs. The WRF simulations also compare well in size and shape to NARR SLP, but do not in central pressure (NARR: 975.9 hPa). This is likely due to lower NARR resolution, as the NHC best-track estimate of central pressure at landfall, only 35 min after, is 959 hPa. NARR, at 32-km resolution, is far too coarse to resolve inner-eyewall processes (Gentry and Lackmann 2010; Hill and Lackmann 2009).

Similar results are shown in spatial plots of 10-m winds (Fig. 8). General size and structure, especially over land, agree well among NARR, warm SST, and cold SST runs, but major differences exist over the MAB waters. NARR shows a maximum wind speed of 22.7 m s^{-1}, whereas the WRF warm SST (33.0 m s^{-1}) and cold SST (31.0 m s^{-1}) simulations are much closer to NHC best-track estimate of 30.9 m s^{-1}. Besides a general overall reduction in wind speed in the cold SST simulation, little difference is noted in size of Irene between warm and

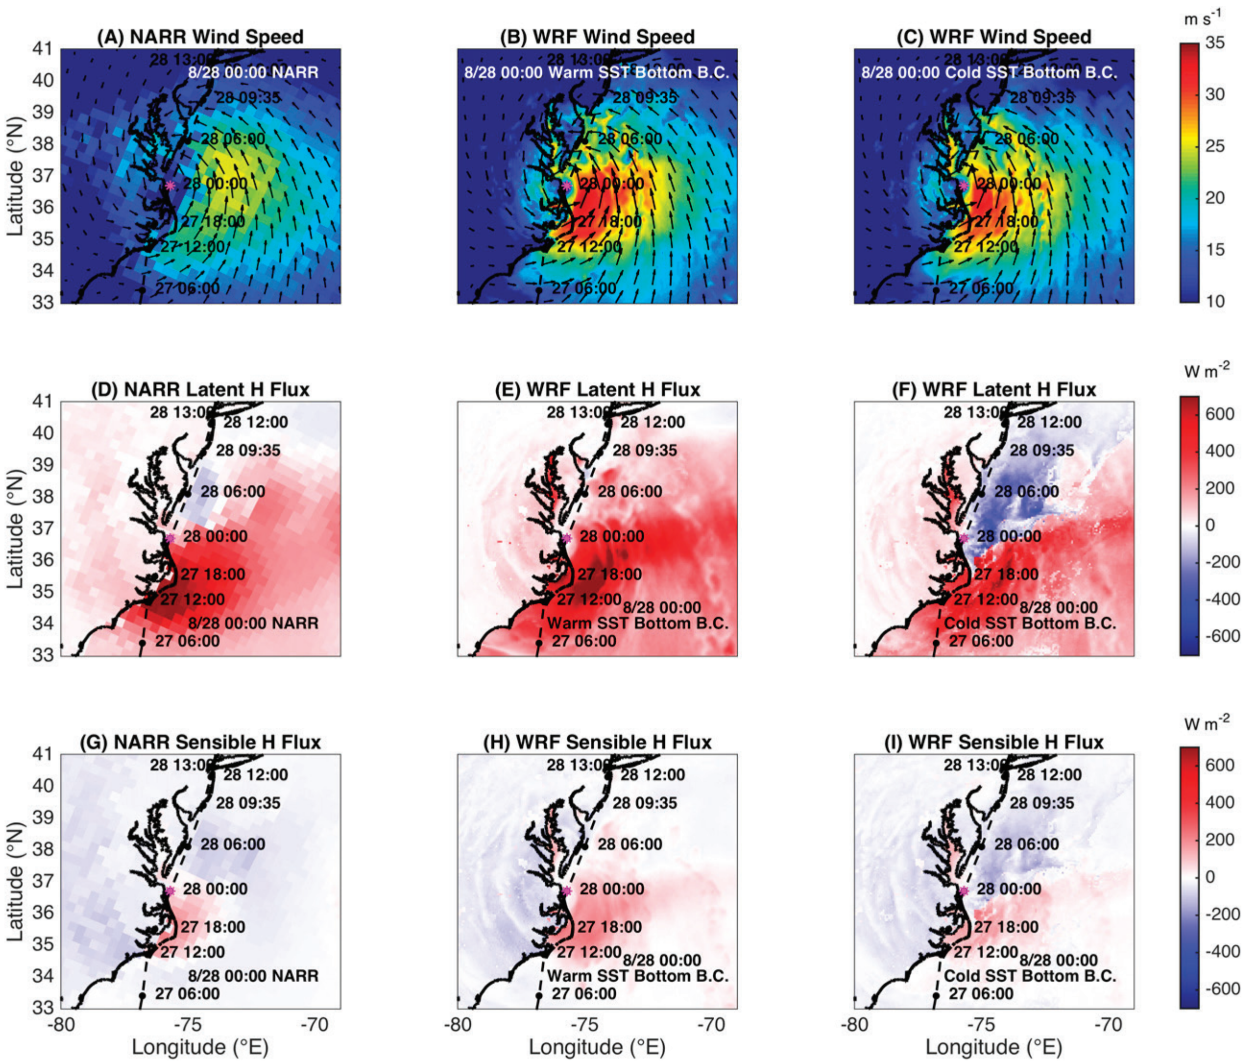

FIG. 10. (a)–(c) Spatial plots of 10-m wind speeds and vectors (m s^{-1}), (d)–(f) latent heat flux at the surface (W m^{-2}), and (g)–(i) sensible heat flux at the surface (W m^{-2}), at 0000 UTC 28 Aug. Fluxes are positive directed from water or land to atmosphere. (a),(d),(g) NARR is shown with fluxes shown as 3-h averages ending at 0000 UTC 28 Aug; (b),(e),(h) WRF is shown with warm SST bottom boundary conditions, with fluxes shown as instantaneous; and (c),(f),(i) WRF is shown with cold SST bottom boundary conditions (with negative latent heat flux allowed), with fluxes also shown as instantaneous.

cold SST. This is verified by a radius of maximum wind (RMW) comparison between the warm and cold SST simulations and b-deck data from the Automated Tropical Cyclone Forecast [ATCF; Sampson and Schrader (2000)] system database (Table 2). The data files within ATCF are within three decks known as a, b, and f decks. The b-deck data for Irene, available every 6 h, shows good agreement with both warm and cold SST simulations, with 13 km or less difference in RMW between warm and cold SST for the first 24 h of simulation, and 21 km or less difference in RMW between model and "observed" b-deck radii for the first 18 h of simulation. At 1200 UTC 28 August, the cold SST simulation shows a much larger RMW, likely due to the strongest winds occurring in an outer band thunderstorm and indicating more rapid enlargement of storm size.

Vertical east–west (Figs. 9a–c) and north–south (Figs. 9d–f) cross sections of wind speeds through the eye of Irene at 0900 UTC 28 August, just before landfall, tell the same story—that NARR has issues reproducing the higher wind speeds not only at 10 m but through the entire atmosphere, and that there are only slight differences in wind speed structure between the warm and cold SST simulations. Both simulations show an asymmetric storm west–east with the core of the strongest winds over water, on the right side of the eye, extending all the way up to the tropopause at about 200 hPa (Figs. 9b and 9c), with the warm SST run showing much higher wind speeds

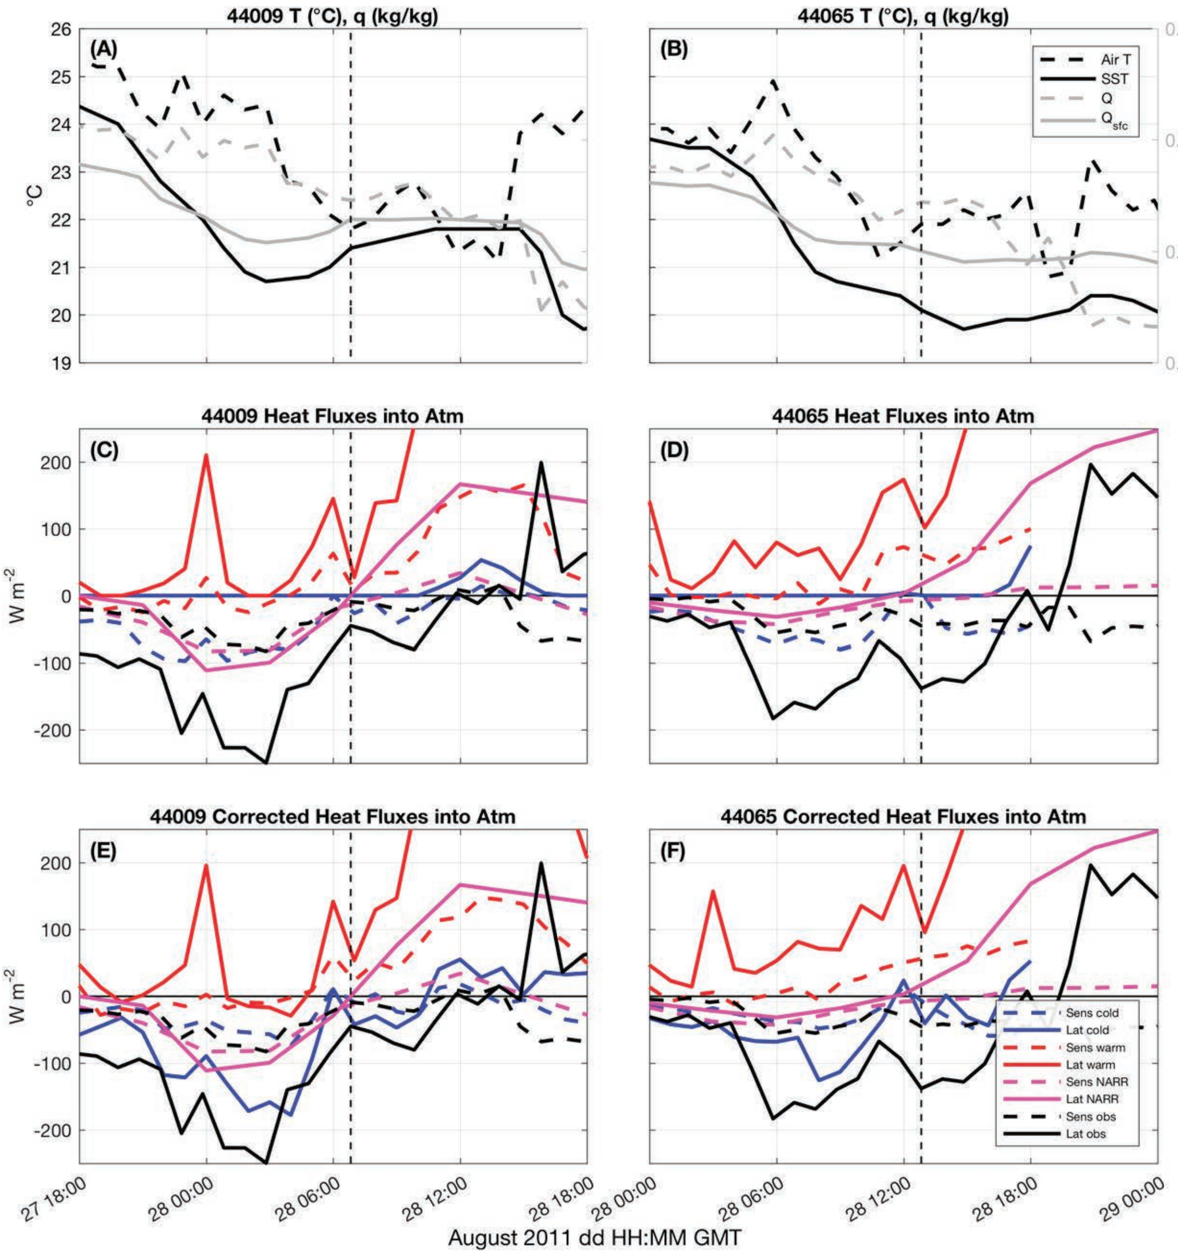

FIG. 11. Time series of air temperature (°C, black dashed), near-surface water temperature (°C, black solid), air specific humidity (kg kg^{-1}, gray dashed), and specific humidity at water surface (kg kg^{-1}, gray solid) at buoy (a) 44009 and (b) 44065, with vertical dashed line indicating timing of eye passage by that buoy (note the time axes are different for each buoy). (c) Sensible (dashed) and (d) latent (solid) heat fluxes (W m^{-2}) are shown for observed (black), NARR (magenta, 3-h flux averages), warm SST (red), and cold SST (blue). Fluxes are positive from ocean to atmosphere. (e),(f) The same fluxes are shown for observed and NARR as in (c),(d), but WRF fluxes are corrected to allow for negative latent heat flux over water.

from ~950 to 700 hPa. On the left side of the eye, the strongest winds extend only up to 700–800 hPa and the core is much narrower from west to east. The north–south cross sections show a more symmetric storm, as well as the outer edges of the jet stream at about 200 hPa and 45°N.

Because air–sea heat fluxes drive convection, TC circulation, and thus resulting TC intensity, a closer look at the sensible and latent heat fluxes, specifically to determine just how sensitive they are to a change in SST, is warranted. The fluxes are plotted spatially at 0000 UTC 28 August in Fig. 10, and temporally at two MAB buoys in Fig. 11. The largest modeled latent and sensible heat fluxes correlate well spatially with the strongest winds in NARR, warm SST, and cold SST runs (Fig. 10).

However, there are large differences in both latent and sensible heat fluxes between the warm and cold SST runs, most notably over the MAB where a reverse in the sign of both latent and sensible heat flux occurs. In some locations over the MAB, the warm SST run shows a few hundred watts per meters squared in latent heat flux directed from the ocean to the atmosphere (Fig. 10e), whereas the cold SST run shows several hundred watts per meters squared in the opposite direction (Fig. 10f). NARR also shows slightly negative latent heat flux over the MAB (NARR fluxes are 3-h averages). Similar patterns are evident in sensible heat flux, but at a much smaller magnitude. It is again important to note that a negative latent heat flux over water—directed from the atmosphere to the ocean—is disallowed in WRF (similarly, sensible heat fluxes $< -250\,\mathrm{W\,m^{-2}}$ are also disallowed over water). What is shown for the cold SST (warm SST) run in Fig. 10 is the cold SST (warm SST) simulation from sensitivity number 19 (18) (Table 1), with latent heat flux < 0 allowed over water. When negative latent heat flux is not allowed, all negative latent heat fluxes (e.g., the blue areas in Fig. 10f) become zero (not shown).

The negative latent heat fluxes were also ''observed'' at both buoys at which they were calculated—44009 and 44065. At both buoys, for almost the entire times shown, air temperature was greater than SST—in some cases over 4.5°C warmer—and air specific humidity was greater than specific humidity at water surface (Figs. 11a,b). The largest temperature and specific humidity differences occurred either during or right at the end of the SST cooling at each buoy, and coincided with the largest calculated observed negative sensible heat fluxes (–50 to $-100\,\mathrm{W\,m^{-2}}$) and negative latent heat fluxes (-200 to $-250\,\mathrm{W\,m^{-2}}$) at both buoys (Figs. 11c,d). These negative values are in stark contrast to the positive enthalpy fluxes (latent + sensible heat fluxes) of $O(1000)$ $\mathrm{W\,m^{-2}}$ found under normal and rapid TC intensification scenarios (Lin et al. 2009; Jaimes and Shay 2015). At this time, NARR latent heat fluxes approached $-120\,\mathrm{W\,m^{-2}}$ at 44009 and $-40\,\mathrm{W\,m^{-2}}$ at 44065. The cold SST simulation shows latent heat fluxes zeroed out this whole time period (Figs. 11c,d), and approached $-180\,\mathrm{W\,m^{-2}}$ at 44009 and $-130\,\mathrm{W\,m^{-2}}$ at 44065 when negative latent heat fluxes are allowed (Figs. 11e,f). Meanwhile, the warm SST simulation shows latent heat fluxes with opposite sign, approaching $470\,\mathrm{W\,m^{-2}}$ toward the end of the simulation at 44009 and $530\,\mathrm{W\,m^{-2}}$ at 44065. Further, heat flux sensitivity to air–sea flux parameterizations was low, especially when compared to its sensitivity to warm versus cold SST. This evaluation of air–sea heat fluxes confirms that the cold SST simulation not only begins to resolve the negative latent heat fluxes that have been indicated by observations, but also approaches negative values that significantly affect storm intensity.

TABLE 3. Track error (in km) as compared to NHC best-track data, for the warm and cold SST simulations.

	Track error (km)	
Time	Warm SST	Cold SST
0600 UTC 27 Aug	12	12
1200 UTC 27 Aug	23	23
1800 UTC 27 Aug	13	11
0000 UTC 28 Aug	16	10
0600 UTC 28 Aug	5	14
0935 UTC 28 Aug[a]	8	28

1300 UTC 28 Aug	26	48

[a] Landfall in NJ.

3) Validation of track, wind shear, and dry air intrusion

To test our hypothesis that upper ocean thermal structure and evolution in the MAB was the missing contribution to Irene's decay just before NJ landfall, the control run's treatment of track, wind shear, and dry air intrusion was evaluated.

Track was handled very well by the simulations, remaining within 30 km for the entire time series for the control run and until landfall for the cold SST sensitivity (Fig. 1, Table 3). As Irene tracked so close to shore, this was critical for teasing out any potential impact from land interactions. In addition, control run translation speed over the MAB ($\sim 10\,\mathrm{m\,s^{-1}}$) and cold SST sensitivity translation speed over the MAB ($\sim 10\,\mathrm{m\,s^{-1}}$) were consistent with NHC best-track translation speed for Irene over the MAB ($\sim 10\,\mathrm{m\,s^{-1}}$). For context, typical TC translation speed at 36°–40°N (approximate MAB latitude range) is 8–$10\,\mathrm{m\,s^{-1}}$ (Mei et al. 2012).

Wind shear values within and ahead of Irene during its MAB presence were similarly handled well by the simulations. At the time of entrance into the MAB, 200–850-hPa wind shear values in NARR, WRF warm SST, and WRF cold SST runs approached $60\,\mathrm{m\,s^{-1}}$ in the near vicinity ahead of Irene's eye (Figs. 12a,c,e). Radiosonde launches from KALB, KCHH, and KWAL at the same time showed 200–850-hPa wind shear values of about 38, 34, and $15\,\mathrm{m\,s^{-1}}$, respectively, which matched well with NARR (44, 29, and $22\,\mathrm{m\,s^{-1}}$) and both WRF simulations (41, 33, and $17\,\mathrm{m\,s^{-1}}$ for warm SST; 39, 32, and $19\,\mathrm{m\,s^{-1}}$ for cold SST); furthermore, simulated u and v wind profiles across the entire atmospheric column correlated well with observed profiles (Figs. 12g,i,k). Twelve hours later, wind shear values ahead of Irene in NARR and both WRF simulations again approached $60\,\mathrm{m\,s^{-1}}$, and observed wind shear at all three radiosonde sites

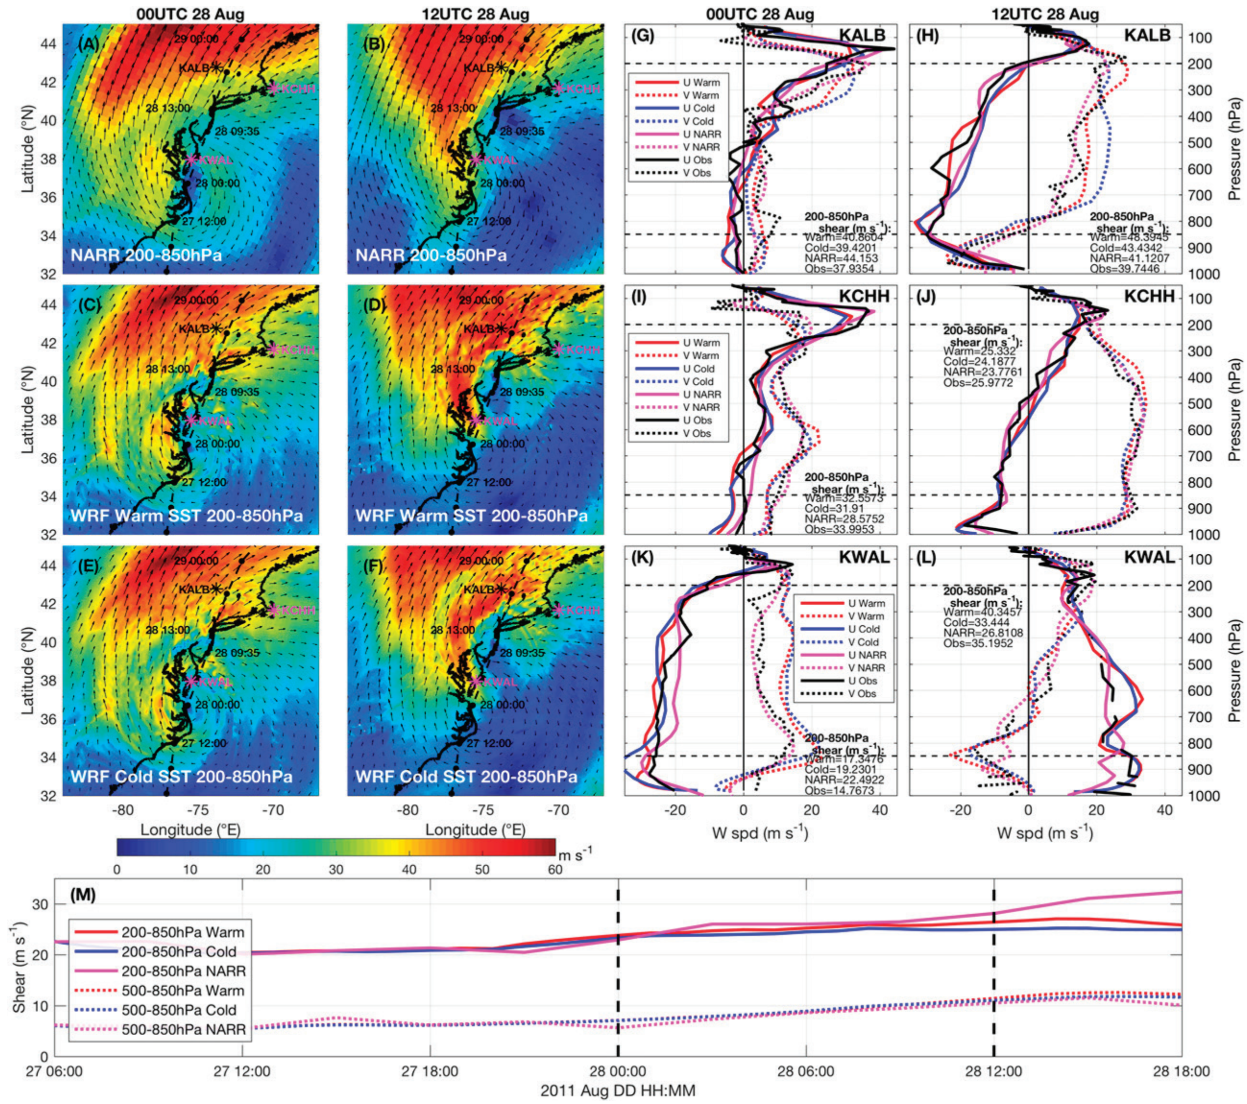

FIG. 12. Wind shear validation (a),(c),(e),(g),(i),(k) at 0000 UTC 28 Aug and (b),(d),(f),(h),(j),(l) at 1200 UTC 28 Aug. Spatial plots are the 200–850-hPa wind shear magnitude and vectors (m s^{-1}) with (a),(b) NARR; (c),(d) WRF warm SST; and (e),(f) WRF cold SST. KALB, KCHH, and KWAL indicated by labeled stars on maps and upper air radiosonde data at (g),(h) KALB; (i),(j) KCHH; and (k),(l) KWAL plotted, with solid lines for u winds (positive from west) and dashed lines for v winds (positive from south), and observed in black, NARR in magenta, WRF cold SST in blue, and WRF warm SST in red. The 200–850-hPa wind shear values (m s^{-1}) are labeled on graphs for observed, NARR, and WRF (cold and warm) simulations. (m) Time series of 200–850 hPa (solid) and 500–850 hPa (dotted) vertical shear (m s^{-1}) for WRF warm SST (red), WRF cold SST (blue), and NARR (magenta), with vertical dashed lines indicating times of (a)–(l).

correlated well with NARR and WRF (Figs. 12h,j,l). Finally, time series of 200–850- and 500–850-hPa wind shear values for NARR and WRF simulations were calculated by averaging wind shear values within an annulus 200–800 km from Irene's center (Rhome et al. 2006; Zambon et al. 2014b). The 200–850-hPa wind shear values increase from approximately 20 m s^{-1} at 1200 UTC 27 August to 25–30 m s^{-1} by the end of the simulation. These wind shear values were likely extremely detrimental to Irene's intensity. Our WRF simulations accurately reproduced these very high values and thus our model captured this important contribution to Irene's decay.

Finally, a snapshot of RH at 200 and 700 hPa from WRF at 1200 UTC 28 August shows an intrusion of dryer air into the southeast quadrant of Irene, agreeing well with a *GOES-13* water vapor image 12 min later (Figs. 13a–e). This *GOES-13* image indicates dry upper levels (~200 hPa) and moist lower levels (~700 hPa) in the southern half of the storm. In the northern half of the storm there are moist upper and lower levels. Our WRF simulations match well in both halves. WRF simulations

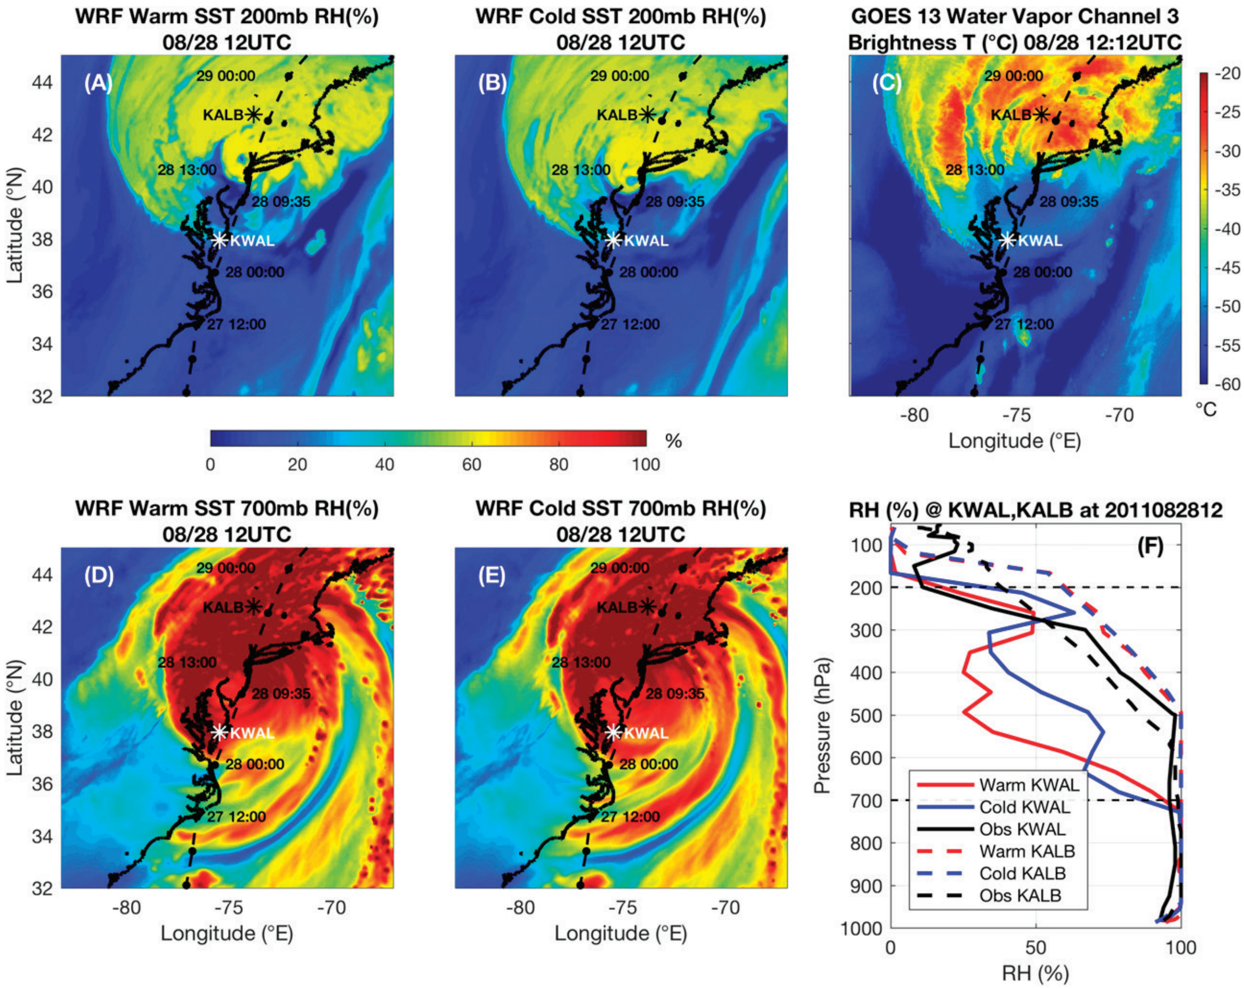

FIG. 13. Dry air intrusion validation (relative humidity, RH, %) at 1200 UTC 28 Aug with (a),(d) WRF warm SST; (b),(e) cold SST; and (c),(f) observations. (c) *GOES-13* water vapor channel-3 brightness temperature (°C) at 1212 UTC 28 Aug and (f) upper air radiosonde relative humidity (%) at KWAL (KALB in dashed) with observed in black, WRF warm SST in red, and WRF cold SST in blue. (a), (b) WRF RH (%) at 200 mb for upper atmosphere, and (d),(e) WRF RH (%) at 700 mb for mid- to lower atmosphere. KWAL (KALB) location is shown in white (black), and the NHC best track is shown in black in spatial plots.

are also consistent with observations from a KALB radiosonde (Fig. 13f, dashed lines), which was in the storm's northern half at this time and showed moist lower levels and relatively moist upper levels. Comparisons with a KWAL radiosonde (Fig. 13f, solid lines), which was in the storm's southern half at this time, showed WRF actually drying out the atmosphere more than observed between approximately 700 and 300 hPa. Overdrying the midlevels would result in additional decreases in storm intensity, so it is clear that dry air intrusion was also not a neglected contribution to Irene's decay.

4. Discussion

In summary, significant ahead-of-eye-center SST cooling (at least 6°C and up to 11°C, or 76%–98% of in-storm cooling) was observed over the MAB continental shelf during Hurricane Irene. Standard coupled ocean–atmosphere hurricane models did not resolve this cooling in their predictions, and operational satellite SST products did not capture the result of the cooling. In this paper, the sensitivity of Irene's intensity, size, and structure to the ahead-of-eye-center SST cooling was quantified. The intensity sensitivity to the ahead-of-eye-center cooling turned out to be the largest among tested model parameters, surpassing sensitivity to the parameterization of air–sea fluxes themselves. Storm size and structure sensitivity to the ahead-of-eye cooling was comparatively low.

Furthermore, accounting for the ahead-of-eye-center SST cooling in our modeling through the use of a fixed cold poststorm SST that captured the cooling mitigated the high bias in model predictions. Validation of modeled

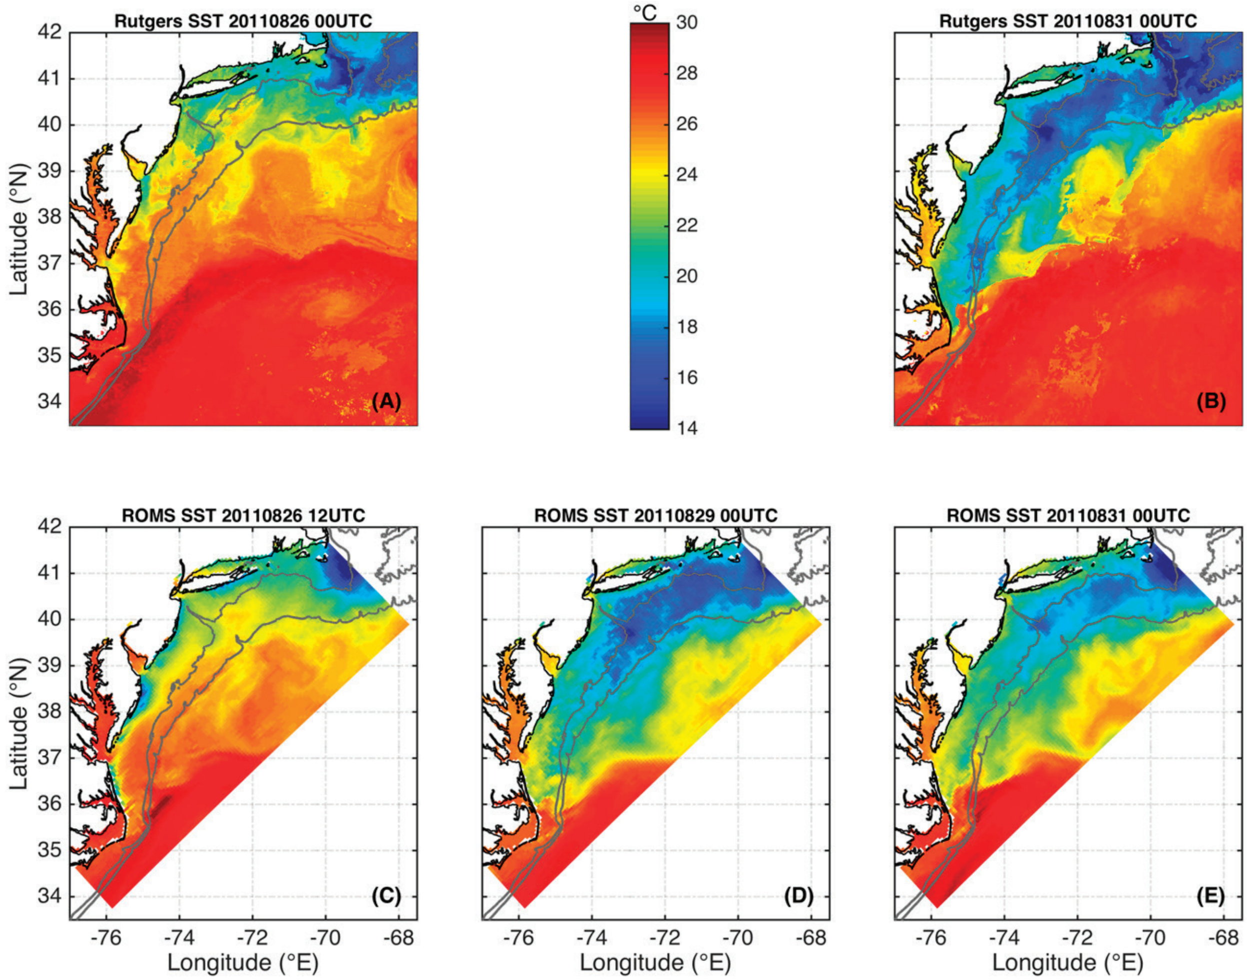

FIG. 14. SST from the new Rutgers SST composite in (a) from before Irene at 0000 UTC 26 Aug to (b) after Irene at 0000 UTC 31 Aug. The water temperature of top layer from a simulation using the ROMS ESPreSSO grid, (c) before Irene at 1200 UTC 26 Aug (simulation initialization), (d) just after Irene at 0000 UTC 29 Aug, and (e) well after Irene at 0000 UTC 31 Aug.

heat fluxes indicated that the cold SST simulation accurately reversed the sign of latent heat flux over the MAB as observed by two NDBC buoys. This would confirm the use of poststorm SST fixed through simulation so that Irene would propagate over the colder ''premixed'' waters, even though some slight cooling did indeed occur after eye passage. Finally, the simulations handled track, wind shear, and dry air intrusion well, indicating that upper ocean thermal evolution was the key missing contribution to Irene's decay just prior to NJ landfall.

Simplistic 1D ocean models are incapable of resolving the 3D coastal baroclinic processes responsible for the ahead-of-eye-center cooling observed in Irene, consistent with Zambon et al. (2014a) in their study of Hurricane Ivan (2004). Rather, a 3D high-resolution coastal ocean model, such as ROMS, nested within a synoptic- or global-scale ocean model like HYCOM and initialized with realistic coastal ocean stratification, could begin to spatially and temporally resolve this evidently important coastal baroclinic process (as described above in the ''results'' section), adding significant value to TC prediction in the coastal ocean—the last hours before landfall where impacts (storm surge, wind damage, and inland flooding) are greatest and are most closely linked with changes in storm intensity.

A ROMS simulation at 5-km horizontal resolution over the MAB not specifically designed for TCs can begin to resolve this ahead-of-eye-center cooling spatially (Fig. 14). This moderately accurate treatment of TC cooling, however, was arrived at through the combination of weak wind forcing from NAM (maximum winds $\sim 10\,\mathrm{m\,s^{-1}}$ too low) and a broad initial thermocline, thus providing a right answer for the wrong reasons. Some issues with SST cooling from ROMS remain, including insufficient cooling in the southern MAB and surface waters warming too quickly poststorm. Further improvements may be realized with:

1) Better initialization to resolve and maintain the sharp initial thermocline and abundant bottom cold water.
2) Better mixing physics/turbulence closure schemes to accurately widen and deepen the thermocline upon storm forcing.
3) More accurate wind forcing and air–sea flux coefficients.

These suggestions are consistent with the recommendations of Halliwell et al. (2011), who studied Hurricane Ivan (2004) in detail as it moved over the relatively deeper and less stratified waters of the Gulf of Mexico. Future research will be conducted to test these ocean model improvements.

Other future work is threefold. First, better ocean data (e.g., more coastal ocean profile time series from flexible platforms like underwater gliders), will be needed to better spatially validate ocean models and identify critical coastal baroclinic processes. Second, Glenn et al. (2016) identified 10 additional MAB hurricanes since 1985, as well as Super Typhoon Muifa (2011) over the Yellow Sea, that exhibited ahead-of-eye-center cooling in stratified coastal seas. In-depth investigation of these storms, the response of the coastal baroclinic ocean, and the feedbacks to storm intensities will be crucial. Finally, movement toward a fully coupled modeling system is critical. Studies like this help isolate specific processes that components of coupled models should simulate.

Acknowledgments. Support was provided by New Jersey Board of Public Utilities (2010RU-COOL, BP-070), the Environmental Protection Agency (EP-11-C-000085), New Jersey Department of Environmental Protection (WM13-019-2013), National Oceanic and Atmospheric Administration (NOAA) led Integrated Ocean Observing System through the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS, NA11NOS0120038), NOAA Cooperative Institute for the North Atlantic Region (NA13OAR4830233, Disaster Recovery Act), Teledyne Webb Research, and Rutgers University. We thank Hyun-Sook Kim and Zhan Zhang of the HWRF team at NCEP for providing the HWRF-POM and HWRF-HYCOM data. We also thank John Wilkin at Rutgers University for his suggestions regarding the ocean modeling and upper-air validation, the Rutgers Ocean Modeling research associates for their ROMS help, and the RU COOL group for their support and ideas. We thank Louis Bowers for his help with WRF, Hugh Roarty for his ocean observational guidance, and Rich Dunk for his helpful meteorological discussions and ideas. Finally, we thank David Titley, Jim Price, Joe Zambon, and the anonymous reviewers for their useful comments.

CHAPTER OUTLINE

s0010 ## 1. INTRODUCTION

p0010 Phytoplankton are integral to complex natural processes such as the carbon cycling, food web dynamics, coastal hypoxia events, and harmful algal blooms (HABs). Identification and quantification of phytoplankton are listed as high-priority measurements needed to address six of the seven societal goals identified in the Integrated Ocean Observing System (IOOS) Summit[1] and were listed as core variables for observatory systems.[2,3] Similarly, chromophoric dissolved organic matter (CDOM) is the primary constituent that is absorbing light in the ocean and often exceeds even the light absorbed by phytoplankton.[4] As a result, CDOM dominates ocean color, plays a critical role in photobiology and photochemistry, photoproduction of CO_2,[5] as well as controlling the absorption of light energy and subsequent impacts on heat flux[6] and other ocean−climate interactions. The IOOS Summit[1] included CDOM among its 26 high-priority variables required to address three of its seven societal goals. The Optical Phytoplankton Discriminator

Coastal Ocean Observing Systems. http://dx.doi.org/10.1016/B978-0-12-802022-7.00018-3

organic matter (FDOM) as a proxy for CDOM. Fluorescence-based CDOM instruments, however, measure only a small subset of DOM molecules that have the aromaticity and conjugation to fluoresce. The FDOM:CDOM relationship varies with the source of CDOM, its lability, and its light exposure history. Significantly, FDOM cannot provide spectral slope information.

p0040 Unlike FDOM determinations, spectrophotometric CDOM absorption measurements directly quantify the desired light absorption properties in both coastal and oceanic waters, provided adequate sensitivity and accuracy are obtained. Spectral slope data can be readily derived from full spectrum absorption. Conventional path lengths of both laboratory spectrophotometers and field absorption instrumentation are typically limited to 10 or 25 cm, respectively, which limits some open ocean applications. Corrections for salinity, temperature, and scattering[31] are also applied for the most exacting work. The most sensitive commercially available CDOM absorption instrument and the OPD utilize liquid-core waveguide (LCW) technology, in which the difference in refractive index between sample and waveguide wall results in a highly efficient internal reflection, permitting an illumination of the core to be transmitted through a coiled waveguide and resulting in path lengths of 200 cm or more. Operational issues common to all LCW instruments include fragility of silica capillary, bubble artifacts, condensation, and clogging of small lumen apertures. Additionally, because light transmission through the LCW is a function of the sample refractive index in addition to the sample absorption,[32] data collection requires careful accounting for temperature and salinity differences between references and samples. The commercial LCW instrument, though limited to manual benchtop operation, has advanced the sensitivity of CDOM analysis and resulting knowledge.[4,32,33] The OPD provides similar absorption measurement sensitivity with the additional feature of unattended, in situ, automated operation.

s0015 2. HISTORY OF THE OPD

p0045 In a set of laboratory experiments, Millie et al.[34] utilized in vivo absorbance spectra to discriminate different light acclimation states of *K. brevis* cultures grown under differing light levels. Results from those experiments on a single species provided evidence that there might be utility in the use of absorbance spectra to discriminate multiple taxonomic groups of phytoplankton. Subsequently, taxonomic groups were discriminated in theoretical mixes of absorbance spectra collected from multiple monospecific cultures.[35] A stepwise discriminant analyses was used to differentiate mean-normalized absorbance spectra for laboratory cultures of *K. brevis* from absorbance spectra of a diatom, a prasinophyte, and peridinin-containing dinoflagellates. Wavelengths delineated by the stepwise techniques were associated with the accessory carotenoids. Unfortunately, the comparative absorption by the carotenoids in the green, yellow, and orange wavelengths was much less than the absorption by chlorophyll in the blue and red wavelengths, limiting the sensitivity of that approach. Furthermore, the absorbance attributable to class-specific groupings of accessory

s0020 3. METHODOLOGY

p0060 Photopigments of plants and algae are light-harvesting molecules that function to channel light energy into the photochemical pathway for photosynthesis or to shunt excess light energy away from the photochemical pathway when there is a risk of damage from too much light energy.[45] There are approximately 45 known plant pigments found in marine microalgae, each with a slightly different molecular structure.[46] These differences in molecular structure yield differences in the shapes of light absorption spectra for each pigment. The absorption spectrum of an individual plant pigment can be modeled as the sum of a set of Gaussian curves centered at wavelengths of maximum absorption by the light-absorbing chemical structures. The absorption spectrum of any phytoplankton cell is the sum of the absorption spectra of all the pigments making up the cells pigment complement modified by factors such as cell size and the concentration of pigments within the cell (pigment-packaging effects).

p0065 The OPD method is a computational means of highlighting the absorption characteristics of plant photopigments, removing or minimizing the absorption and scattering characteristics of nonpigmented components of the bulk sample, and then fitting a set of known taxonomic class photopigment signatures to the highlighted photopigment absorption characteristics. To accomplish this, the bulk water particle absorbance spectrum is subjected to derivative analysis, and then that derivative spectrum is compared to the derivative spectrum of the known target taxa yielding a similarity index (SI).

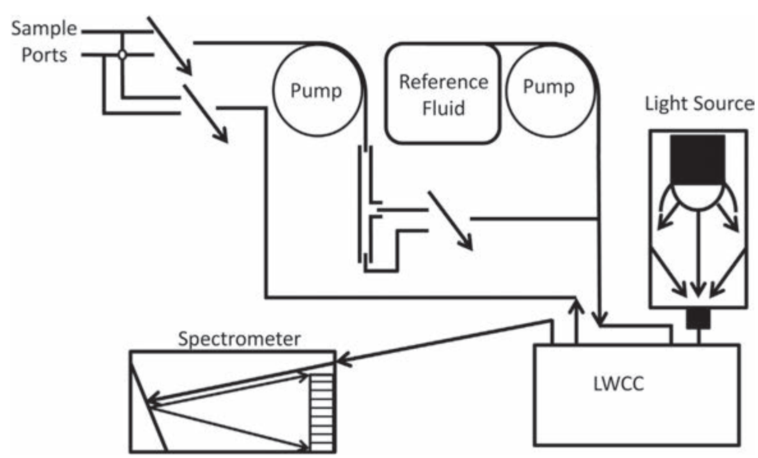
p0090 Absorption by CDOM is determined using the standard approach where the natural logarithm of the ratio of the light transmission through the CDOM containing water sample to the light transmission through "pure" water is scaled by the optical path length of the water-containing cell. CDOM absorption is an exponential function of wavelength and can be expressed as follows:

$$a_{CDOM}(\lambda) = a_{CDOM}(\lambda_S) * e^{-S*(\lambda-\lambda_s)} \quad (1)$$

where $a_{CDOM}(\lambda_S)$ is the absorption value at a "standard" wavelength (λ_S), typically 400 or 440 nm), and S is the exponential slope of the CDOM absorption spectrum at λ_S. By accepting the standard form of the CDOM absorption spectrum (Eqn (1)), it is possible to completely describe a CDOM absorption spectrum by reporting just $a_{CDOM}(\lambda_S)$ and S. To determine those two parameters for any CDOM absorption spectrum, first, the spectral absorption values are transformed by the natural log (ln), and then a least squares linear regression is fit to the transformed absorption values over the wavelength range from 380 to 500 nm. The best fit linear coefficients, intercept and slope, then represent $\log_e(a_{CDOM}(\lambda_S))$ and S, respectively. During every sample cycle, the CDOM absorption is calculated.

s0025 4. SYSTEMS LEVEL INTEGRATION

p0095 The OPD is a system of fluidic, optical, and computational systems that obtains a water sample, illuminates the sample with a calibrated light source, and measures the transmission spectrum through the water sample (Figure 3). There are two



f0020 **FIGURE 3**

Schematic of major OPD components including the fluidic pathways.

and a whole water transmission spectrum ($I(\lambda)_w$) is collected. For this sample, a dark spectrum is not collected because it follows immediately after the previous filtered (CDOM) sample. Calculation of SI and CDOM absorption spectra are completed, and results are stored and transmitted as specified by the user. If the OPD is ~~set~~ configured
~~up~~ to continuously cycle, only the portion of cycle described ~~that comes after~~ the proceeding
CDOM reference is repeated. The CDOM reference cycle is repeated on an adjustable schedule, but usually every 8 to 10 cycles to account for the development of fouling in the LWCC, changes in the light source spectrum, and drift in the spectrometer. Additionally, if there will be a delay before the next cycle, a small volume of CDOM reference water is pumped into the LWCC to displace fouling organisms and compounds and to inhibit growth.

p0110 Computational, electronic, fluidic, and optical systems are controlled by a low-power Persistor Instruments, Inc. CF2 microcontroller. This processor handles all data management, processing, and communications capabilities of the OPD. Communications with host systems, which can include external communications systems (LP units) or independent control and communications systems (HP units on AUVs), are handled by RS232 serial standard protocol.

p0115 The Optical Phytoplankton Detector provides a relatively low-cost way to monitor phytoplankton community structure and CDOM. On a systems level, an LP OPD capable of operating unattended for approximately one month has a purchase price of under \$30,000. Operating costs are on the order of \$1000 per deployment, including costs of operating marine vessels to deploy and recover units. A single trained operator is capable of maintaining approximately four instruments. An HP OPD for deployment on an AUV has a purchase cost on the order of \$40,000, in addition to the cost of the AUV, and it can run with minimal user intervention on the order of two weeks. In comparison, shipboard survey work costs on the order of \$10,000−20,000 per day for vessel operations and personnel, plus the cost of scientific staff on board, and sample processing costs once grab samples are returned to shore. For the purpose of regional HAB monitoring, the OPD is capable of identifying domains of interest for shipboard surveys without the cost associated with large-scale surveys.

s0030 5. APPLICATIONS

p0120 The OPD is a modular instrument, in that components can be adapted for different water types with varying optical transmission properties and phytoplankton concentrations. In offshore environments, namely oligotrophic waters, planktonic and CDOM concentrations can be extremely low, requiring an increase in instrument sensitivity. This can be achieved by increasing the sample volume and path length, for planktonic and CDOM detection, respectively, to result in a measurable change in absorbance. Similarly, in extremely turbid waters, absorbance by CDOM in the water can extinguish the characteristic transmission spectra of planktonic cells contained within the sample volume, necessitating a shortened waveguide.

instrument for continuous position information in time and space. Variants of the CDOM mapper have been designed that incorporate updated sensor components to prevent obsolesce, to measure conductivity and temperature for refractive index modeling and correction, and to prevent and remove bubbles in the sampling pathway. The most recent variant of the CDOM mapper has increased ease of operation to make it possible to integrate into the SeaKeeper Discovery Yachts Program, increasing available deployments to include both scientific research vessels and private vessels of opportunity.

s0035 6. VALIDATION AND RESULTS

p0135 Because of the remote, unattended nature of OPD deployments, it was often not feasible to directly verify the results telemetered back to the laboratory. Data from several projects that employed the OPD (Table History1) were used in the validation of the method. To accurately conduct a validation exercise, it was necessary to assure that the OPD and the comparison method utilized the same water sample very
closely in ~~close to the~~ same time. Phytoplankton communities, especially at bloom concentra-
very spatially tions, can be ~~spatially very~~ patchy. Photo-acclimation of photopigments can change pigment compliments and the resulting absorbance signature on minute time scales. Fortunately, there have been studies, both laboratory and field, that conducted simultaneous sampling and processing. Additionally, comparison methods are subject to their own inaccuracies, making it necessary to place caveats on validation results. For instance, the use of optical microscope enumeration of phytoplankton taxonomic classes has been the de facto standard method for many years. Although the optical microscope is a powerful tool when used by skilled taxonomists, it is very time consuming and problematic when identifying very small cells. Because *Karenia* sp. cells are large and very distinctly shaped, optical microscope enumeration provides very accurate data for comparison to the OPD estimations of *Karenia* sp. However, the diatom class, for instance, includes a wide range of species with varying sizes and shapes. Some are large and uniquely shaped, making practical the use of microscopic enumeration for numerous samples. Conversely, very small-sized diatom species with nondescript shapes (at optical microscope resolution) are difficult to enumerate accurately by optical microscopes in large numbers of samples. The upshot of these issues in optical microscope enumeration is that there were no complete taxonomic enumerations of community structure to use in validation of the OPD community structure estimates. There are molecular techniques for identification of taxonomic groups, but few simultaneously provide comprehensive coverage of all the possible groups. Chemotaxonomic classification of class-level taxonomy, utilizing high-performance liquid chromatography (HPLC), is a widely accepted approach to dealing with relatively large numbers of samples and for including the full complement of taxonomic classes in natural water samples.

s0040 7. FUTURE DEVELOPMENT/PLANS

p0165 The OPD has been developed for over a decade and has been implemented across a broad geographic range including North America, from the Eastern Pacific to the Western Atlantic, around the Gulf of Mexico, and in the Great Lakes. An OPD has made its way across the Mediterranean, around the Arctic, and there have been deployments in Mexico. With this experience, there are several developmental pathways that will enhance future development. Improvements fall into the domains of expanding species identification capabilities, enhancing CDOM measurement, and expanding the user base.

p0170 To identify plankton species and allocate species to a community structure using the OPD, characteristic fourth derivative spectra must be maintained on file. These spectra are obtained by running isolated plankton samples through the OPD. Typically, plankton are collected during bloom conditions, or they are isolated and grown in culture to detectable levels. A rigorous effort to generate absorption spectra from cultured samples must be conducted and verified by testing plankton from both culture and wild blooms. Additional validation of OPD results against known samples of mixed cultures and against ambient samples determined through more complete molecular and microscopic methods is desirable. The present library of species files would benefit from including phytoplankton from different geographic regions, and a database of libraries would enable researchers and operators of monitoring stations to access and share species files.

p0175 The OPD has demonstrated success in responding to naturally varying levels of CDOM in the natural sampling environment. For OPD to provide CDOM measurements as absorption coefficients (m^{-1}) for research purposes, remote sensing validation, and generating hybrid in situ remote sensing products, a thorough validation and calibration of CDOM measurement must be demonstrated. Simultaneous analyses of CDOM via OPD and benchtop spectroscopy would be performed on estuarine samples that cover a range of both CDOM and salinity values, as well as a matrix of constructed, fixed CDOM-varying salinity samples. The resulting dataset would allow an algorithm to correct measured absorbance with actual CDOM absorption coefficients by accounting for variations in refractive index between sample and reference salinity. The successful algorithm to compensate CDOM absorbance for changing salinity would motivate that integration of a conductivity cell within the OPD, similar to that designed as part of CDOM mapper, as well as the integration of this algorithm into the automated sampling sequence.

p0180 To integrate additional sensors, such as a conductivity cell and thermistor into the OPD, as well as to maintain compatibility with the upcoming generations of ocean sampling platforms, it will eventually be desirable to convert the OPD hardware from the Persistor CF2 processor to an ARM Linux architecture. This would enable a more flexible computing infrastructure and additional computing power to calculate plankton community structure and chlorophyll *a* biomass contributions in real time. It has already been determined that the Slocum Glider will make a similar transition from the Persistor series of processors to the more flexible Linux architecture.

p0185 In the Gulf of Mexico, the Gulf of Mexico Coastal Ocean Observation System (GCOOS) currently supports a number of OPD installations in the eastern Gulf. In addition, GCOOS is currently seeking to expand observing systems including, among other systems, an extended harmful algal bloom monitoring system, of which the OPD could be an integral component. The Sarasota Operations of the Coastal Ocean Observation Laboratories (SO-COOL) model of combining fixed and mobile HAB monitoring instruments with real-time data telemetry and distribution to end users can easily be extend to accommodate additional sampling sites. An effective model would be an instrument exchange program that would support sites around the Gulf, maintaining continuous OPD operations with minimal instrument/site downtime and minimal replication of technical expertise.

Mixing and phytoplankton dynamics in a submarine canyon in the West Antarctic Peninsula

Filipa Carvalho[1], Josh Kohut[1], Matthew J. Oliver[2], Robert M. Sherrell[1,3], and Oscar Schofield[1]

[1]Department of Marine and Coastal Sciences, Rutgers University, New Brunswick, New Jersey, USA, [2]College of Earth, Ocean and Environment, University of Delaware, Lewes, Delaware, USA, [3]Department of Earth and Planetary Sciences, Rutgers University, Piscataway, New Jersey, USA

Key Points:
- Underwater gliders observe phytoplankton dynamics in Antarctic coastal seas
- Mixed layer depth and water stability as key driver of seasonal phytoplankton blooms
- Contrary to what was initially hypothesized, mUCDW does not seem to play an important role in the phytoplankton spring bloom in the canyon

Abstract Bathymetric depressions (canyons) exist along the West Antarctic Peninsula shelf and have been linked with increased phytoplankton biomass and sustained penguin colonies. However, the physical mechanisms driving this enhanced biomass are not well understood. Using a Slocum glider data set with over 25,000 water column profiles, we evaluate the relationship between mixed layer depth (MLD, estimated using the depth of maximum buoyancy frequency) and phytoplankton vertical distribution. We use the glider deployments in the Palmer Deep region to examine seasonal and across canyon variability. Throughout the season, the ML becomes warmer and saltier, as a result of vertical mixing and advection. Shallow ML and increased stratification due to sea ice melt are linked to higher chlorophyll concentrations. Deeper mixed layers, resulting from increased wind forcing, show decreased chlorophyll, suggesting the importance of light in regulating phytoplankton productivity. Spatial variations were found in the canyon head region where local physical water column properties were associated with different biological responses, reinforcing the importance of local canyon circulation in regulating phytoplankton distribution in the region. While the mechanism initially hypothesized to produce the observed increases in phytoplankton over the canyons was the intrusion of warm, nutrient enriched modified Upper Circumpolar Deep Water (mUCDW), our analysis suggests that ML dynamics are key to increased primary production over submarine canyons in the WAP.

1. Introduction

The cross-shelf canyon systems in the West Antarctic Peninsula (WAP) are considered biological "hotspots" because they are associated with penguin chick rearing locations [*Erdmann et al.*, 2011; *Fraser and Trivelpiece*, 1996]. The association of penguin colonies with deep submarine canyons has led to the hypothesis that phytoplankton productivity is enhanced as a result of water column dynamics in the canyon heads [*Schofield et al.*, 2013]. The presence of the UCDW has been linked to increased phytoplankton productivity [*Kavanaugh et al.*, 2015; *Prézelin et al.*, 2000; *Prézelin et al.*, 2004] which supports a productive regional food web [*Schofield et al.*, 2010], yet the physical mechanisms driving phytoplankton blooms in these canyons are not well understood.

The canyons in the WAP are shelf-incising [*Harris and Whiteway*, 2011], and often connect the off-shelf region to the coast. Heat transport facilitated by cross-shelf canyons/troughs is enhanced by mixing particularly due to tides [*Allen and de Madron*, 2009]. Small-scale roughness in canyons can be responsible for much of the internal tidal energy [*Kunze et al.*, 2002], which tends to be enhanced in canyons. Additionally these regions have enhanced internal waves with periods shorter than that of tides, and has been associated with the vertical mixing over the slope and shelf waters [*Bruno et al.*, 2006]. Tides in these canyons also appear to be important for penguin foraging behavior [*Oliver et al.*, 2013] and krill swarms [*Bernard and Steinberg*, 2013].

These canyons allow UCDW to penetrate across the shelf, providing warmer [*Martinson and McKee*, 2012; *Martinson et al.*, 2008] and nutrient-enriched water to mix with coastal surface waters [*Arrigo et al.*, 2015; *Prézelin et al.*, 2000; *Prézelin et al.*, 2004]. The presence of these canyons has been connected to locally increased sea surface temperature (SST), reduced sea ice coverage, and increased diatom biomass [*Kavanaugh et al.*, 2015]. Using a model, *Allen et al.* [2001] showed that the formation of an eddy over the head of a canyon trapped passive particles such as phytoplankton and small zooplankton in that location.

Globally, light and nutrients are key drivers of a bloom, but their relative importance in primary production depends on the region and the role of local stratification. Light is a key factor regulating phytoplankton growth in polar regions, including the WAP. Several studies have linked shallower mixed layer depths (MLD), which increases the overall light available to phytoplankton [*Holm-Hansen and Mitchell*, 1991; *Mitchell and Holm-Hansen*, 1991; *Moline and Prezelin*, 1996; *Sakshaug et al*., 1991], with increased phytoplankton biomass, especially diatoms [*Fragoso and Smith*, 2012]. Increased irradiance and vertical stratification have also been positively correlated with increased diatom biomass [*Mitchell and Holm-Hansen*, 1991; *Nelson and Smith*, 1991], especially during early spring season [*Fragoso and Smith*, 2012]. Macronutrients are generally abundant throughout the WAP [*Ducklow et al*., 2012; *Serebrennikova and Fanning*, 2004] and although they show marked seasonality [*Clarke et al*., 2008], in most cases they do not seem to limit phytoplankton growth [*Holm-Hansen and Mitchell*, 1991]. Micronutrients such as iron do not seem to limit primary production in the coastal waters of the WAP where canyon heads are located either [*Annett et al*., 2015; *Helbling et al*., 1991; *Martin et al*., 1990], but available data are limited.

It is important to understand the link between some of the physical drivers, like stratification and MLD, and phytoplankton dynamics as the higher trophic levels are dependent on primary producers [*Schofield et al*., 2010]. In this work, we characterize the phytoplankton dynamics in submarine canyons in the WAP using Palmer Deep Canyon (PD) as a focused study area. Here we describe, both temporally and spatially, the phytoplankton spring bloom at PD, using a 6 year Slocum glider dataset. The high spatial and temporal resolution sampling provides a detailed analysis of the phytoplankton and physical dynamics at the head of a submarine canyon in the WAP. While the mechanism initially hypothesized to produce the observed increases in phytoplankton over the canyons was the intrusion of warm, nutrient-enriched mUCDW [*Prézelin et al*., 2000; *Prézelin et al*., 2004; *Schofield et al*., 2013], our analysis suggests that ML dynamics are key to increased primary production over submarine canyons in the WAP.

2. Materials and Methods

2.1. Slocum Gliders

Slocum electric gliders are a robust tool to map in high-resolution the upper water column properties in different environments [*Schofield et al*., 2007] including polar regions [*Kohut et al*., 2013; *Oliver et al*., 2013; *Schofield et al*., 2013]. These 1.5 m torpedo-shaped buoyancy-driven autonomous underwater vehicles provide high-resolution surveys of the physical and bio-optical properties of the water column [*Schofield et al*., 2007]. Data were collected using both shallow (100 m depth range) and deep (1000 m) gliders. However, only data above 100 m were considered for this analysis as we are focusing on processes within the euphotic zone. All gliders were equipped with a Seabird Conductivity-Temperature-Depth (CTD) sensor and WET Labs Inc. Environmental Characterization Optics (ECO) pucks, which measured chlorophyll-*a* fluorescence, and optical backscatter at 470, 532, 660, and 700 nm. Glider based conductivity, temperature, and depth measurements were compared with a calibrated ship CTD sensor on deployment and recovery to ensure data quality, as well as with a calibrated laboratory CTD prior to deployment. Glider profiles were binned into 1 m bins and assigned a midpoint latitude and longitude.

2.2. Sampling Overview

Our analysis includes all available concurrent glider physical and biological profiles in the WAP region (Figure 1) where bathymetric depressions have been linked to deep-water intrusion onto the shelf, with a focus on the dynamics at PD. Overall, the data include 26,455 profiles, 265 deployment days, and 3,937 km flown. For comparison purposes, the WAP-shelf analysis excluded all the points in PD region (purple rectangle in Figure 1).

The deployments on the shelf along the WAP were part of the NSF Palmer-Long-Term Ecological Research Project (PAL-LTER) [*Ducklow et al*., 2007] effort, with the goal of understanding changes (1) in the entire WAP ecosystem with 26 deployments conducted throughout the peninsula from Anvers Island to Charcot Island ($-64°$ to $-69°$ latitude) and (2) with a focus on the PD region where Palmer Station is located. In the PD region (Figure 1, right), data were collected during six field seasons (2010–2015) over the austral summer as part of the NSF PAL-LTER and one field season (2014–2015) as part of the NSF CONVERGE Project [*Kohut et al*., 2014]. Gliders were deployed from Palmer Station (Anvers Island) with the goal of characterizing PD, focusing on the head of the canyon.

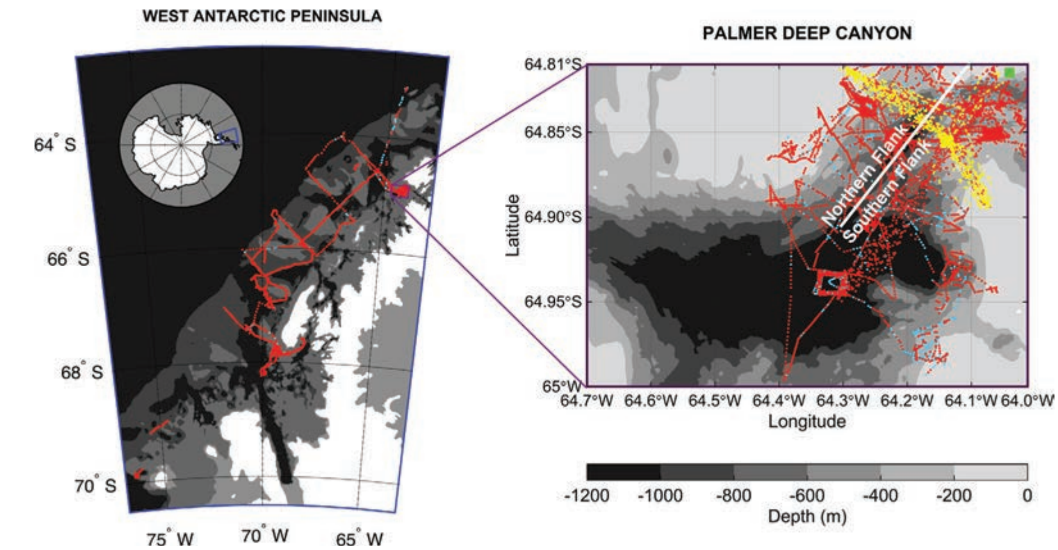

Figure 1. Bathymetry maps overlaid with location of the glider profiles (red – MLD Quality index (QI) > 0.5; blue dots, remaining profiles where MLD was not determined and therefore not included in the analysis, i.e., QI < 0.5) for the regions, (left) WAP and (right) PD. Cross-canyon transects highlighted in yellow from the 2015 mission (gliders ru05 and ud134). White line separates the head of the canyon into northern and southern flanks. Green square indicates location of Station E where dissolved iron data were collected.

PD (Figure 1, right), a cross-shelf canyon bathymetrically similar to others in the WAP, is associated with large penguin colonies [*Fraser and Trivelpiece*, 1996; *Schofield et al*., 2013]. PD extends approximately 22 km in length and 10 km across with a maximum depth of 1420 m. Over the head of the canyon, there is evidence of increased primary production [*Kavanaugh et al*., 2015] and localized penguin foraging [*Oliver et al*., 2013]. Our study will describe glider data collected over varying spatial scales from the WAP shelf, to PD, and, at the smallest scale, the head of PD.

2.3. Mixed Layer Depth Estimation

For each profile, MLD was determined by finding the depth of the maximum water column buoyancy frequency, max (N^2). A quality index (Equation 1) following *Lorbacher et al*. [2006] was used to quantify the uncertainty in the MLD estimate, and to filter out profiles where MLD was not resolved. Using

$$QI = 1 - \frac{rmsd(\rho_k - \overline{\rho})|_{(H_1, H_{MLD})}}{rmsd(\rho_k - \overline{\rho})|_{(H_1, 1.5\times H_{MLD})}} \tag{1}$$

where ρ_k is the density at a given depth (k) and rmsd () denotes the standard deviation of from the vertical mean $\overline{\rho}$ from H_1, the first layer near the surface, to the MLD or 1.5xMLD. This index evaluates the quality of the MLD computation, where MLD was determined with certainty (QI > 0.8), determined but with some uncertainty (0.5 < QI < 0.8) or not determined (QI < 0.5). This index does not take into account the strength of stratification, rather it indicates that there is a homogeneous layer present and the MLD calculated is close to the lower boundary of that vertically uniform surface layer. Higher QI are observed during summer and fall, where sharp gradients at the base of the seasonal mixed layer are present [*Lorbacher et al*., 2006].

MLD criteria were tested and matched against the chlorophyll fluorescence data to evaluate whether the MLD definition chosen was capturing the biological observations (Figure 2). ML-averaged temperature and salinity were calculated by averaging all 1-m binned data points from the surface to the base of the ML.

2.4. Optical Measurements

2.4.1. ML-Averaged and Integrated Chlorophyll

Chlorophyll-*a* (chl-*a*) fluorescence, as measured by the glider ECO pucks, is our indicator of phytoplankton biomass. Discrete in situ water samples were collected from eight depths (0, 5, 10, 20, 35, 50, and 60 m) from CTD casts during each glider deployment and recovery. Water samples were filtered onto 25 mm Whatman GF/F filters and extracted using 90% acetone. Chl-*a* concentration was then measured using a fluorometer and compared to its correspondent glider profiles. QA/QC methods were applied to the data to ensure data quality. Concurrent measurements of optical backscatter and chl-*a* fluorescence were used to

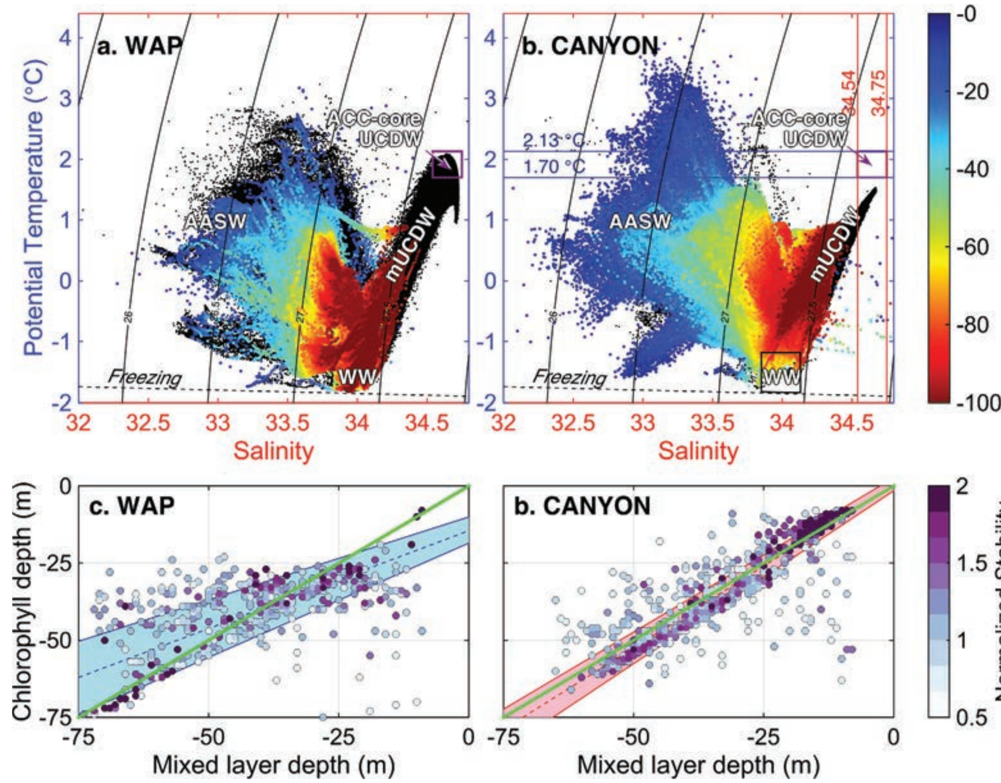

Figure 2. (top row) θ-S for the two areas shown in Figure 1: (a, c) WAP, and (b, d) Palmer Deep Canyon. All data collected below 100 m are plotted in black. Color indicates depth of the water column measurement (upper 100 m of the water column). Primary water masses sampled are indicated and labeled (WW = Winter Water; AASW = Antarctic (summer) Surface Water; mUCDW = modified Upper Circumpolar Deep Water; and the regional ACC-core UCDW. (bottom row) Scatter plots comparing depth of the mixed layer (MLD) with the depth of the lower boundary of the chlorophyll profile for all glider profiles with Quality Index (QI) over 0.5. Shaded region represents 95% confidence intervals (CI) for each region. Trend lines are shown for each area and each quality index. Line 1:1 shown in green. A quality index of 0.5 was also applied to chlorophyll (QI_{chl}) profiles and only profiles with $QI_{chl} > 0.5$ are shown above. Color of the dots represents normalized stability, i.e., the stability frequency at the depth of the ML divided by the median stability of that region.

correct for light-dependent effects. Given the high linear correlation found between backscatter and chlorophyll-*a* fluorescence (R^2 between 0.76 and 0.95 for all deployments), a correction was applied to the latter to account for nonphotochemical quenching [*Behrenfeld et al*., 2005]. Linear regressions were calculated by deployment using all the measurements taken between 20 and 40 m, below the light influenced chl-*a* values and above the possible sedimentary (deep) sources of backscatter. Slope and intercept were calculated and used to correct chlorophyll from the surface to the chlorophyll maximum in each profile. No chlorophyll maxima were found shallower than 15 m.

Integrated and averaged chlorophyll from our defined MLD to the surface were determined using the trapezoid method. Chl-*a* concentration was calculated for each 1 m bin and a cumulative value from the surface down to the MLD was calculated to determine the ML-integrated chlorophyll. The ML-averaged chlorophyll was determined by dividing the ML-integrated chlorophyll by the depth of the mixed layer.

2.4.2. Chlorophyll Depth

A model-2 regression was used to compare the MLD with the lower boundary of the surface chlorophyll fluorescence layer. Following a method adapted from the maximum angle principle [*Chu and Fan*, 2011], the depth of lower boundary of chlorophyll was estimated (referred to as chlorophyll depth in Figure 2). Here we apply the same principle using the maximum angle, as we are interested in calculating the depth at which the chlorophyll profile starts decreasing. Using a vector of n = 7 data points, the depth of the max ($\tan_\theta$) of the chlorophyll profile was determined and used as the chlorophyll depth.

2.5. Climatology

One of the main goals of this study is to characterize the physical setting and to map the seasonal phytoplankton dynamics at the head of the PD by taking advantage of the high spatial and temporal glider coverage. Using a 6 year data set of glider deployments (13,972 profiles after all filters applied), MLDs were calculated for each individual profile and daily MLD averages were calculated for temperature, salinity and chlorophyll by averaging all the values between the surface and the base of the MLD.

Wind and Photosynthetic Available Radiation (PAR) data were collected from an automated weather station (AWS) at Palmer Station, on Anvers Island. Daily averages were calculated using 2 min data.

2.6. Seawater Iron Methods

Surface water was collected at LTER Station E (6.5 km NE of the head of PD), at eight time points between 5 January and 9 March 2015. Samples were cleanly collected in duplicate from a Zodiac inflatable boat using all-polypropylene syringes and filtered directly into 60 mL LDPE bottles (Nalge®) using 25mm Acrodisc (Pall®) 0.45 μm pore size syringe filters, within minutes of sample collection. The resulting samples were stored at 4°C until arrival at Rutgers University, where they were acidified to pH∼2.0 with ultrapure HCl (Fisher Optima®, concentration in seawater 0.012 *M*). The mean of the duplicates is reported if they agree within 15% (difference about the mean), otherwise the lower of the two values is reported.

Seawater samples were prepared for analysis of dissolved Fe and other trace metals at Rutgers University using the commercially available version of an automated preconcentration and matrix elimination system (SeaFAST pico®, ESI, Omaha, NB) which operates on the same principle as reported in *Lagerström et al.* [2013], and employs the method of isotope dilution, but collects eluates offline rather than directly analyzing online.

The eluate solutions, 25-fold concentrates of the trace metals in the sample but with greatly reduced major ion concentrations, were analyzed in medium resolution on a Thermo Element-1 HR-ICP-MS. Determined process blanks for Fe typically averaged 0.040 n*M* and precision was 1–3% standard deviation about the mean. Accuracy was verified by repeated analysis of reference seawater materials (SAFe S and D2, GEOTRACES S, and D), which showed agreement within one standard deviation of the consensus values.

2.7. Cross-Canyon Analysis

To better understand the across canyon spatial variability in MLD and chlorophyll, a 1 month long glider mission was designed with a repeated transect (yellow, Figure 1) that crossed the head of the canyon perpendicularly to its deep channel axis (64°48.7′S and 64°17.9′W to 64°53.7′S and 64°4.2′W, corresponding to the northern and southernmost extreme of the transect, respectively). Gliders used for this temporal/spatial study were both shallow gliders (ru05 and ud134) rated to 100 m. The first glider (ud134) was deployed 6 January 2015 and performed six full transects before ru05 took over its mission of surveying the head of the canyon. The second glider was recovered, brought back to Palmer Station, and redeployed twice more during its mission to replace batteries and resume the cross-canyon mission. Final recovery took place on 8 February 2015. Gliders repeated transects across the head of the canyon 39 times throughout their missions, taking an average of 16 h to complete each cross section. The orientation of PD was used to divide (Figure 1, white line) the head of the canyon into two regions, the northern and the southern flanks.

3. Results

3.1. Physical Properties Around the Palmer Deep Canyon

Gliders were able to map many of the key water masses during the austral summer in the WAP shelf and PD region (top plots of Figure 2). The glider profiles over six field seasons identified the Antarctic Surface Water (AASW), Winter Water (WW), and modified Upper Circumpolar Deep Water (mUCDW). The core-UCDW seen immediately offshore of the WAP shelf ($1.7 \leq T \leq 2.13$; $34.54 \leq S \leq 34.7$, following *Martinson et al.* [2008]) was not present in the canyon; instead the canyon was characterized by a modified colder and fresher mUCDW water mass. This mUCDW extended to depths below 100 m. A second water mass present in PD was the WW (or T_{min}, minimum temperature), defined by $T \leq -1.2$°C and $33.85 \leq S \leq 34.13$. The WW represents the remnants of the mixed-layer water from the previous winter [*Martinson et al.*, 2008] and was found over a range of depths. Above the WW was the AASW (seen in the blue colors of Figure 2). In the canyon, AASW showed a wider range of temperature, salinity, and depth. In both the WAP and PD, this water mass was freshest of all the water masses present. The main differences between the PD and the WAP shelf (PD profiles were excluded from the latter) were the absence of core-UCDW and fresh surface waters at PD. WW was found at greater depths in the WAP compared to the canyon.

We evaluated the relationship between the MLD and chlorophyll depth with a model-2 linear regression (Figures 2c and 2d). In the canyon, the MLD-chlorophyll relationship was close to a 1:1 line with 95% confidence levels with the tightest regression associated with the profiles with the highest stability. Generally the PD had shallower MLD than the WAP. Although more profiles in the WAP fell away from the 1:1 line, there were no significant differences (with a 95% CI) from that line for MLDs below 23 m.

3.2. Coupled Dynamics at Palmer Deep Canyon

3.2.1. Seasonal Climatology of MLD and Chlorophyll

A seasonal climatological analysis of the MLD properties (Figure 3) was conducted by averaging the data between the surface and the corresponding ML for temperature, salinity, and chlorophyll-*a* fluorescence. Generally, MLD shoaled in December, reaching its shallowest depth ($\overline{MLD} = -11 \pm 0.76$ m) in the beginning of January. MLD remained fairly constant (above 20 m) throughout most of January, then started to deepen at the end of this month. The ML in January was generally fresher and colder and as it deepened it became warmer and saltier. Wind speed was fairly constant and low until late January. From then, there was increasing wind speed until the end of the growing season. The summer MLD reached its maximum depth ($\overline{MLD} = -52 \pm 0.66$ m) during the first week of February and then started shoaling again in early March. Both the temperature (Figure 3a) and salinity (Figure 3c) showed a very clear temporal signal. Secondary shoaling of the ML in mid-February was accompanied by a freshening and slight cooling of the ML. The ML-averaged chlorophyll (Figure 3b) was highest when MLD was shallowest, i.e., throughout January. Going into February, when MLD was deepest, chlorophyll concentrations were low. ML-averaged chlorophyll showed a direct relationship with MLD ($y = 0.136x + 7.03$; $r^2 = 0.42$; $p < 0.0002$), with higher chl-*a* when MLD is shallow and lower chl-*a* when deeper. An increase in chlorophyll was observed when MLD shoaled again later in the season. Surface dissolved iron (Fe) concentrations (Figure 3d) at a station 6.5 km from the

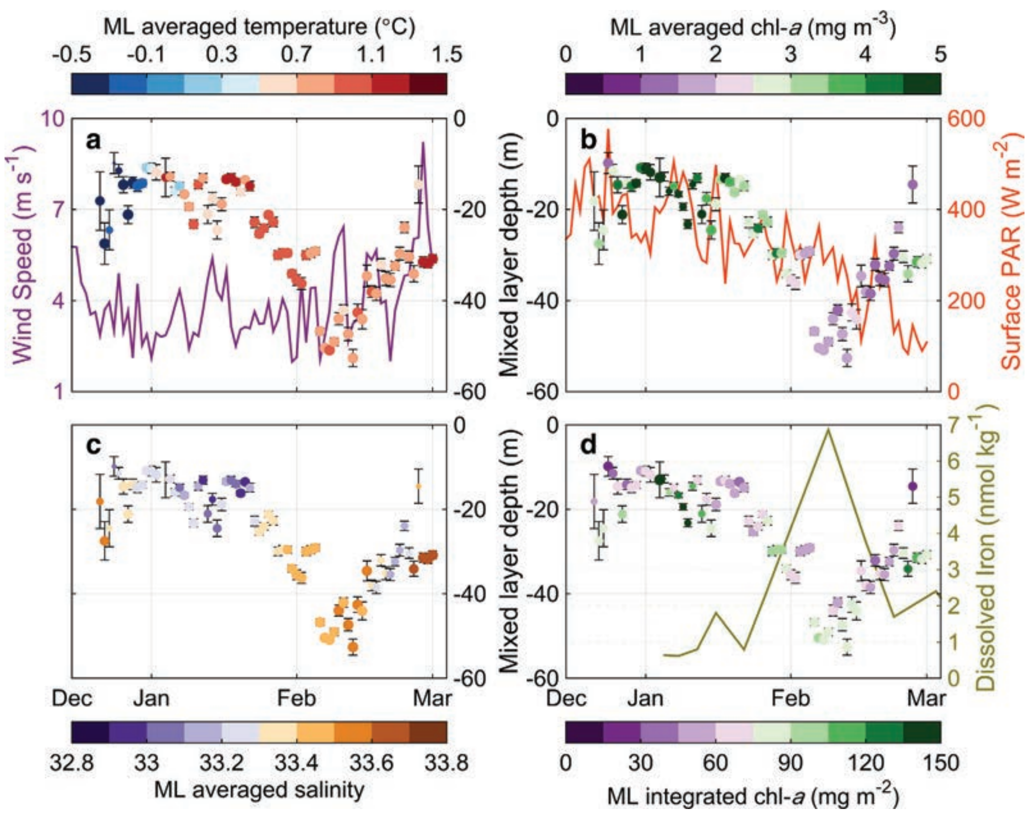

Figure 3. Mixed Layer Depth (MLD) in the Palmer Deep region showing evolution on MLD throughout the spring/summer season. Color denotes ML-averaged: (a) temperature, (b) chlorophyll, (c) salinity, and (d) ML-integrated chlorophyll. Marker size represents the standard error of the variable in color (larger marker represents lower standard error, and vice-versa). Standard error of depth MLD is shown in the vertical bars. Averages were calculated using 13,972 individual glider profiles collected during 2010–2015 deployments. Daily averages of wind and surface PAR are shown in Figures 3a and 3b, respectively. Surface iron measurements at Station E are shown in Figure 3d from 2014–2015 season.

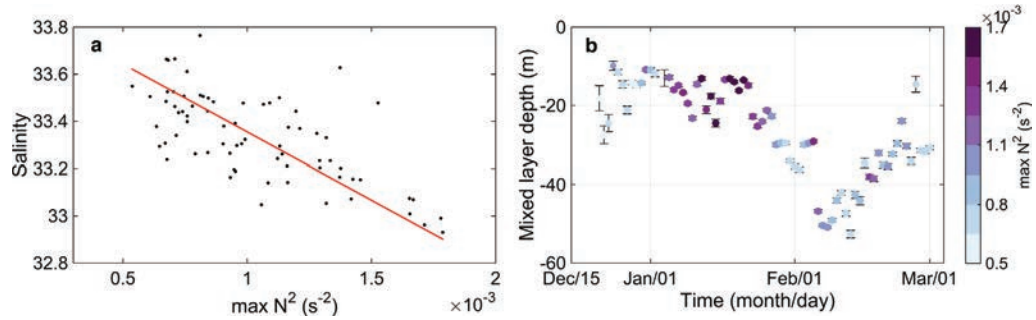

Figure 4. Water stability in the Palmer Deep region using daily averages: (a) salinity and maximum of stability frequency (max N^2); (b) seasonal climatology of MLD with max(N^2). Averages were calculated using 13,972 individual glider profiles collected during 2010–2015 deployments.

canyon head, exhibited an inverse relationship with chlorophyll, reaching maximum values when MLD was deepest. Throughout the season, Fe concentrations at this station never fell below 0.6 nmol kg^{-1}.

The strength of water column stratification at the depth of the ML (max N^2) was seen to vary through the season (Figure 4). In January, when chlorophyll concentrations were high, the water column was more stable (Figure 4b) and over the season the water column stability decreased. Stability was inversely correlated with salinity ($R^2 = -0.77$, $p < 0.0001$), with higher stability associated with shallower MLD and lower salinities (Figure 4a) suggesting the importance of sea ice melt and potentially glacial melt in phytoplankton primary productivity.

3.2.2. Cross-Canyon Variability

Four glider deployments, conducted over 1 month, collected high-resolution data across the head of the canyon in PD with the goal of understanding the dynamics of the water masses in the canyon over the summer season. The mission characterized the spatial variability between the northern and southern regions of PD (Figure 1). A temporal and spatial analysis of the θ-S plot is shown in Figure 5. The AASW, represented by the shallowest depths (blue), was cold and fresh in the beginning of January. As the month progressed, surface water became warmer and saltier. Winter water ($T < -1.2$°C), was present in the beginning of January and was found in deeper waters as time progressed. Deeper water (reds) was warmer and saltier in the beginning of January. The AASW was warmer at the beginning of February (Figure 5, last column).

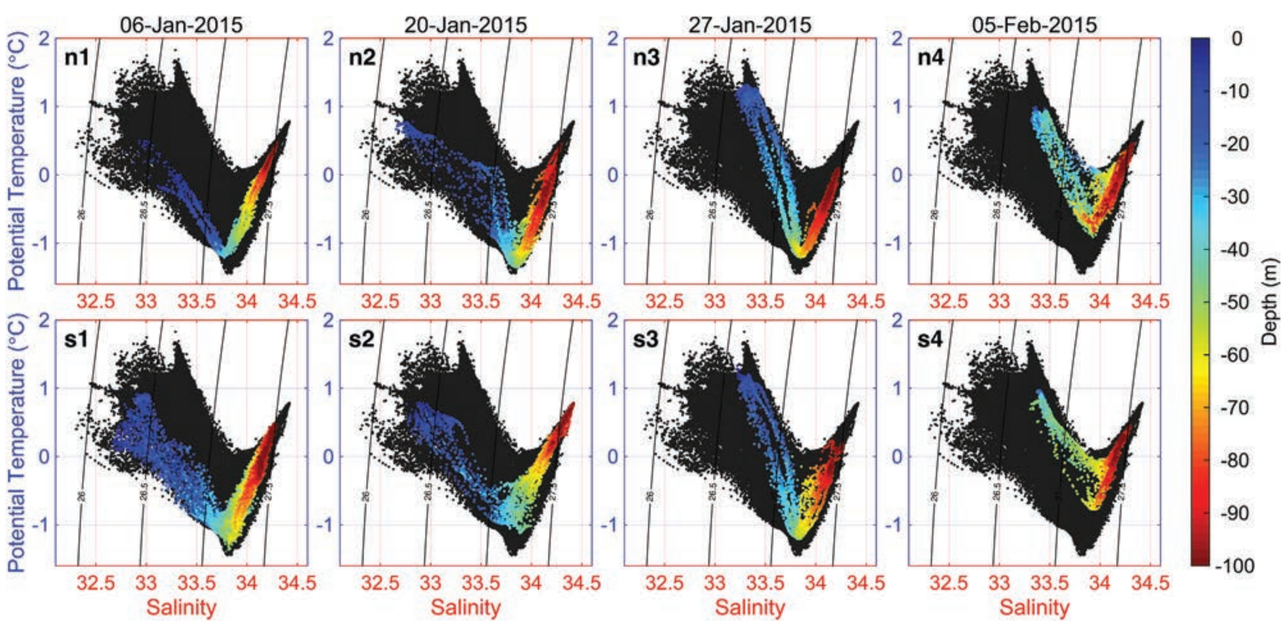

Figure 5. θ-S scatter plots from ru05/ud134 gliders, comparing the water masses of Northern (N, top) and Southern (S, bottom) flanks of the head of the Palmer Deep canyon through time (plots left to right). Black dots represent all glider measurements (both areas) for the entire deployment. Color denotes depth of the water column measurement.

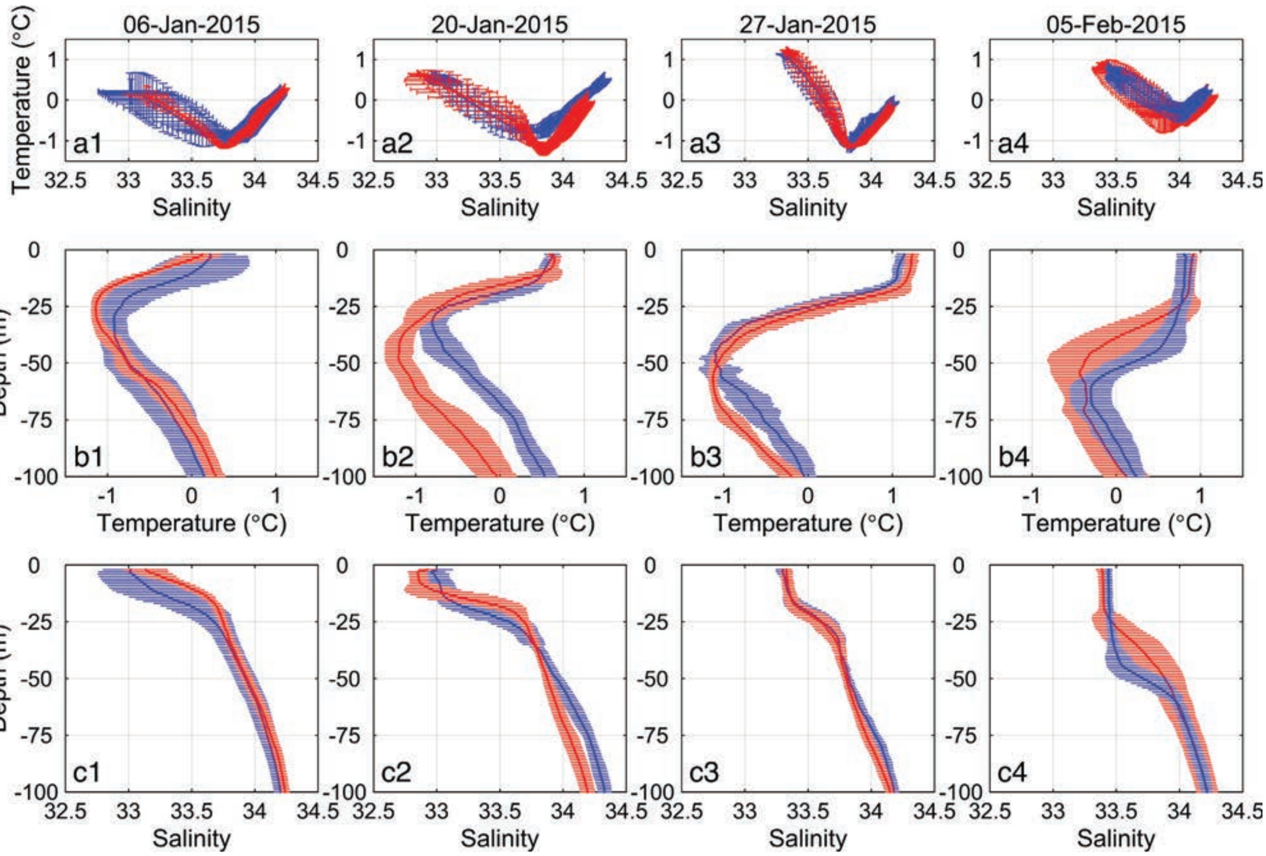

Figure 6. Decomposition of the θ-S diagrams from Figure 5, for Northern (red) and Southern (blue) flanks of the head of the Palmer Deep canyon: (a1–a4) average θ-S diagram with average (center points) and standard deviation (horizontal bars for salinity; vertical bars for temperature), (b1–b4) average temperature profile, (c1–c4) average salinity profile, with standard deviation (shaded area), per depth for each time point.

Given the importance of ML structure in driving the chlorophyll, the θ-S plots in Figure 5 were decomposed into average depth profiles (Figure 6). The average temperature (b plots, middle row) and salinity (c plots, bottom row) depth profiles for each time point, were calculated and then compared between the two regions (blue and red) at the head of the PD canyon. The top row in Figure 6 is for the average distribution and respective standard deviation for the temperature and salinity for each depth and different time periods over the month. The southern region (blue, Figure 6a1) showed overall a wider range in temperature and salinity in the beginning of January. This increased variance was especially marked in AASW, which was characterized by lower salinities. This trend reversed over the month with the northern region of the canyon (red) showing a wider variance in surface water properties (both temperature and salinity). Observed differences were more influenced by temperature (Figures 6b1−6b4) than by salinity (Figures 6c1−6c4). Although surface temperatures were similar between regions, below the MLD, the northern region (red) had consistently lower temperatures (Figures 6b1−6b4) compared to the southern region. Differences of over 0.5°C, sometimes almost up to 1°C, were found at depth on 20 January (Figure 6b2). Both areas showed similar salinity profiles in January. The only salinity differences found were in February and were mostly due to deeper MLDs in the southern region.

The ML-averaged and integrated chlorophyll were calculated for each profile and plotted against its corresponding MLD (Figure 7). Here we define the end of the bloom (21/22 January) by evaluating the evolution of individual profiles of chlorophyll and the change of the trends between MLD and chl-*a* through time. This date separated two time periods, one during bloom conditions (blue, from 5 to 21 January) and the second during postbloom conditions (red, from 22 January to 9 February). Bloom conditions were characterized by a clear progression from a moderately shallow (30 m) and highly productive MLD (dark blue) to an even shallower (8 m) and less productive ML (light blue). Both ML-integrated (Figure 7a) and averaged chlorophyll (Figure 7b) showed similar trends. While ML-averaged chlorophyll decreased with the deepening of

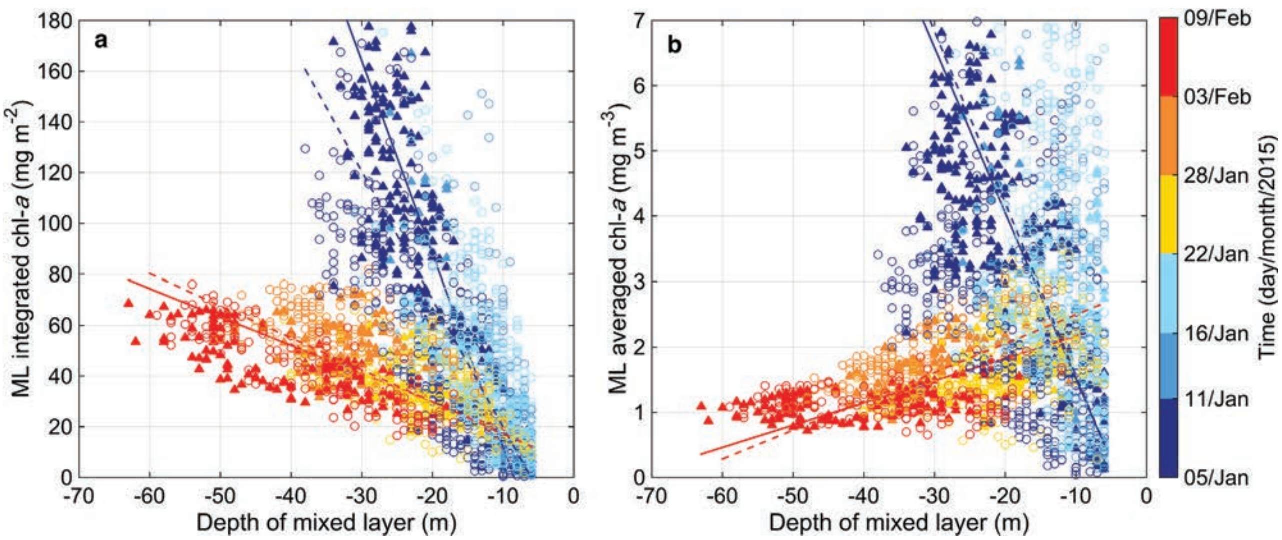

Figure 7. Relationship between the depth of the mixed layer (defined by the maximum water column buoyancy frequency, N^2) and: (a) ML-integrated or (b) ML-averaged chlorophyll concentrations. Comparison between the northern (filled marker, solid line) and southern (open marker, dashed line) flanks. The colors indicate time. Lines represent the trends seen between 6 January to 21 January (blue) and 22 January to 9 February (red).

the ML and consequent ending of the bloom, ML-integrated chlorophyll increased during this postbloom condition (Figures 7 and 9e). When comparing the two regions (northern-solid line; southern-dashed line), few differences were found.

Sustained cross-canyon sampling in 2015 allowed for an analysis for the spatial differences within the canyon. The time-averaged transect (6–28 January 2015) for temperature and salinity is shown in Figures 8a and 8b. While the warm surface layer appears uniform in both regions, a thicker and colder layer (light blue), with a tongue of colder ($T < -1°C$; dark blue) water at mid depths of 45-70 m was evident in the northern region. The southern region showed warmer and saltier water at depths below the colder layer. A fresher layer was evident in the surface few meters in the northern region. The bottom plot of Figure 8 shows a time-averaged mixed layer depth (blue dotted line) and upper 100 m integrated chlorophyll (solid green line) for each 1 km along the transect line. Northern region was characterized by shallower MLD

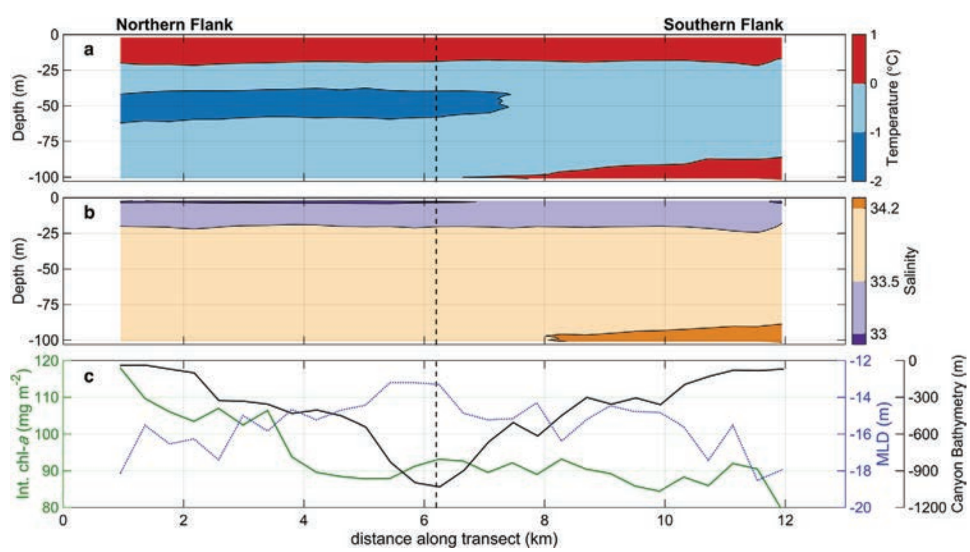

Figure 8. Time-averaged transect (6 January to 28 January 2015). Northern and Southern regions are separated by the dashed vertical line at km 6.2 in the along-track distance. Variables plotted are time-averaged transect of: (a) temperature, where warm layer at the surface represents AASW, dark blue denotes WW, bottom layer in red indicates possibly mUCDW intrusion; (b) salinity and (c) mixed layer depth (MLD; blue-dotted line) with integrated chlorophyll (upper 100 m; green solid line) and canyon bathymetry (black solid line).

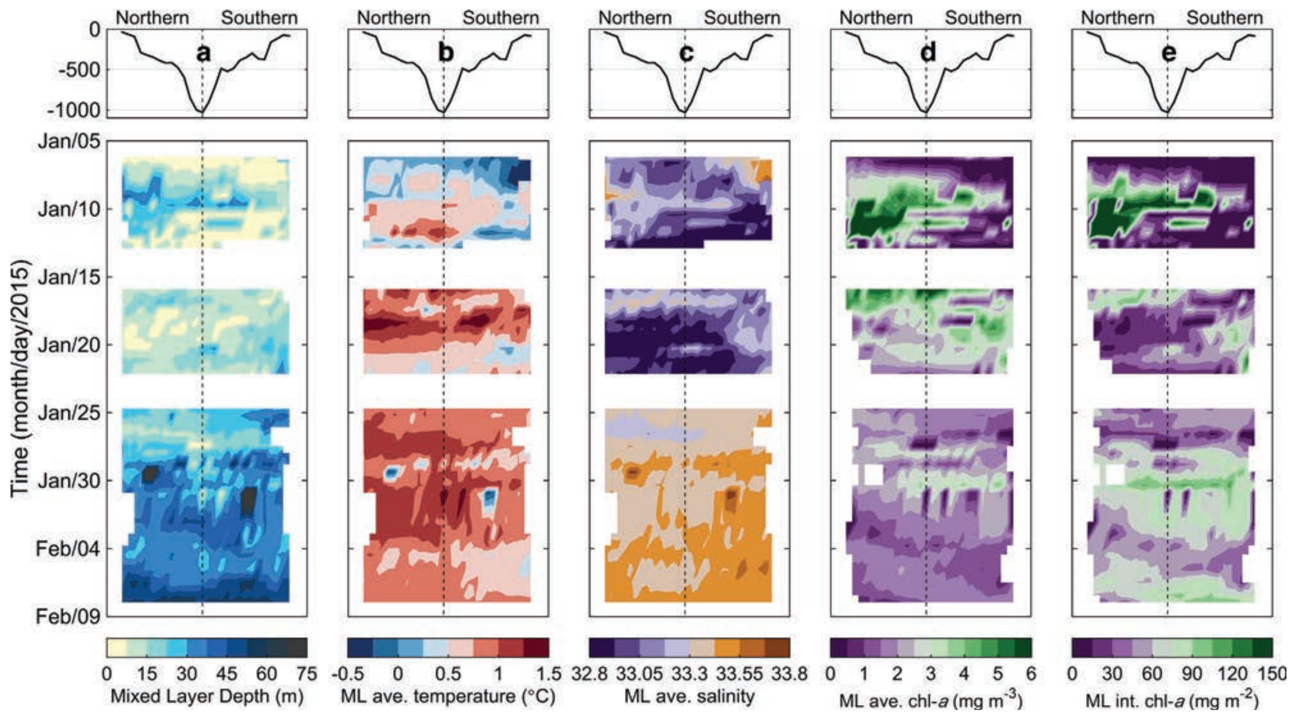

Figure 9. (top) Bathymetry of the cross-canyon transect performed by ru05 (yellow, Figure 1). (bottom) Hovmöller diagram of the temporal evolution of each transect by ru05 regarding: (a) mixed layer depth, (b–d) ML-averaged (b) temperature, (c) salinity, (d) chlorophyll, and (e) ML-integrated chlorophyll. Dashed line separates northern and southern flanks of the head of the Palmer Deep canyon.

and increased integrated chlorophyll in the upper 100 m of the water column while the southern region showed overall deeper MLD and slightly lower integrated chlorophyll concentrations.

A repeated glider section across the head of the canyon captured the temporal and spatial variability of the phytoplankton (Figure 9). Each glider cross section was interpolated through space and time with a resolution of 500 m and 16 h, respectively. Temporal gaps in Figure 9 correspond to glider recovery and redeployment after battery exchange. The top plot shows bathymetry of the two regions (northern and southern) being fairly symmetrical, going from deeper (~1000 m) depths at the center to shallower depths (~100 m) when moving away from the deep trough.

Again, the temporal signal is the most evident across all five plots. Early in January, the MLD was shallow, colder, and fresher. This period was also characterized by increased chlorophyll (both ML-integrated and averaged chlorophyll). As January progressed, the MLD (Figure 9a) deepened, accompanied by warming (Figure 9b) and increased salinity (Figure 9c) in the upper ML with a decrease in the chlorophyll concentration (Figures 9d and 9e). An increase in ML-integrated chlorophyll (Figure 9e) late in the mission is also present in the climatology (Figure 3).

The magnitude of the spatial variability was less than the temporal variability observed over the entire summer season, yet differences were observed, particularly in the physical properties of the water. The MLD was overall shallower in the northern region. This is especially true for the second and fourth deployments. Warmer temperatures and lower salinities also characterized this region. This pattern was also clear when looking at the homogeneous surface ML later in the season (Figures 6b4 and 6c4).

4. Discussion

The WAP ecosystem is characterized by high interannual phytoplankton variability [*Smith et al*., 2008], with chlorophyll-*a* showing a wide range in both time and space [*Moline et al*., 1997; *Montes-Hugo et al*., 2008; *Smith et al*., 1998]. Chlorophyll concentrations are highest near shore with a decreasing gradient moving offshore [*Vernet et al*., 2008]. The canyons are known hotspots for penguin foraging [*Kahl et al*., 2010; *Oliver et al*., 2012; *Schofield et al*., 2013] with increased chlorophyll compared to coastal regions with shallow bathymetry [*Kavanaugh et al*., 2015]. While previous studies have focused on the primary productivity over the entire WAP [*Moline and Prezelin*, 1996; *Montes-Hugo et al*., 2010; *Prézelin et al*., 2004], the high-resolution sampling capabilities introduced with gliders, allowed us to conduct a detailed analysis of the canyon primary production focusing on the physical forcing of the increased production observed over submarine canyons.

4.1. The Seasonal Cycle at Palmer Deep Canyon

4.1.1. Primary Water Masses

A fundamental question regarding phytoplankton dynamics in the region [*Schofield et al*., 2013] involves the supply of heat and nutrients from the warm, deep water (UCDW) found at depth off the shelf. Canyons provide a conduit for this water to move across the shelf [*Martinson et al*., 2008]. No direct pathways have been found of ACC-core UCDW onto the Palmer Deep Canyon, so no ACC-core UCDW is present in the canyon, but by looking at T_{max} at depth, we find a modified-UCDW (relatively colder and fresher than pure UCDW) at depth. Because the bulk of the mUCDW is found at deeper depths and the gliders are usually only sampling the upper 100 m of the water column, we are only partially capturing this intrusion onto the canyon. This intrusion however is not observed to reach the euphotic zone until after the growing season. Therefore it is unlikely that it plays an important role in supplying nutrients to primary producers over the canyon during the growing season.

The WW, identified by T_{min} in the profile, was found above mUCDW. This water mass is the remnant surface water from the preceding winter season and is typically found at 50–60 m. WW has a very clear seasonal pattern (Figure 5), showing a well-defined and strong presence early in the season, followed by erosion by mixing with warmer water from above and below as the season progresses. The increase in solar radiation and winds, typical of the late summer season in the region, deepens the MLD, further mixing AASW with the WW below. As the latter, saltier water mass is slowly eroded, together with the decrease in freshwater input later in the season due to the reduction in sea ice meltwater, a marked increase in the overall salinity of surface water is observed.

4.1.2. Phytoplankton Seasonal Dynamics

In the WAP, chlorophyll-*a* variability has been correlated with local physical forcing such as wind, water column stability, and sea ice [*Saba et al*., 2014]. The relationship between sea ice dynamics and biological productivity is complex. While decreasing sea ice cover can remove the shading effect of ice resulting in higher productivity, as seen in the southern region of the WAP [*Montes-Hugo et al*., 2009; *Saba et al*., 2014], at the same time, the decrease in fresh water input from melting sea ice will result in lower stratification and likely deeper MLDs, which should lead to decreased primary production resulting from decreasing average light levels [*Vernet et al*., 2008].

The high variability in the timing of the sea ice retreat [*Stammerjohn et al*., 2008] matches the high variability seen in the MLD (*y*-axis, Figure 3) in late December. Shallower MLDs in the early growing season show both increased stability (Figure 4) and decreased salinity (Figure 3d). They have been associated with low wind speeds over weekly timescales [*Moline*, 1998; *Moline and Prezelin*, 1996], freshwater input from glacial and sea ice melt [*Meredith et al*., 2008], and surface warming from incoming solar energy. The input of fresh water from glacial and sea ice melting shoals the MLD, increases the stability of the water column [*Garibotti et al*., 2003] and restricts deep mixing. This creates a stable upper water column in which phytoplankton cells are allowed to remain in a favorable light regime [*Garibotti et al*., 2003; *Vernet et al*., 2008]. In addition, the canyon's proximity to land shelters the canyon head from storms and strong winds seen offshore [*Hofmann et al*., 1996], helping to maintain the observed shallow and stable MLD. Modeling work by *Mitchell and Holm-Hansen* [1991] concluded that intense phytoplankton blooms develop when MLD is shallower than 25 m, there is no limitation by nutrients and specific loss rate is $\sim$0.3–0.35 d^{-1}, with grazing and respiration comprising over 2/3 of this loss. Although we do not have direct measurements of nutrients or loss rates at the same time as the glider profiles, our MLD and chlorophyll data match this model, with high concentrations of chlorophyll observed in MLD of 25–30 m or shallower and declining when the MLD is deeper. Note that there was a decrease in ML-averaged chlorophyll when MLD shoals to values close to 10 m (Figure 7), suggesting some photoinhibition processes due to high light or light limitation by self-shading [*Moline et al*., 1996].

The mechanisms driving the chlorophyll decrease later in the growing season remain an open question. Data show that decreases in ML-averaged chl-*a* are accompanied by a deepening of the ML (Figures 3 and 7). Decrease in freshwater input together with increased vertical mixing from wind forcing causes MLD to deepen and water stability to decrease. Another contributor to this decreased water column stability is the warming of WW by vertical mixing with intruding mUCDW from below. The deepening of the ML can decrease the ML-averaged chl-*a* concentrations by diluting a high concentration of phytoplankton over a larger depth interval; this idea is also supported by the increase in ML-integrated chl-*a* as MLD deepens (red line; Figure 7a), indicating there are phytoplankton below the MLD. While the deepening of the ML alone could drive down the ML-averaged chl-*a* concentrations as it also decreases the mean light levels required for phytoplankton photosynthesis [*Mitchell and Holm-Hansen*, 1991], other factors, such as nutrient limitation and grazing, can also play a role in this decrease. Although gliders do not provide in situ measurements of the nutrient concentrations in the water column, an inspection of historical nutrient data from the LTER Station E (6.5 km NE of the sampled area) shows that no macronutrient limitation is observed throughout the season [*Ducklow et al*., 2012]. The scarce micronutrient (trace metal) studies in the region make it difficult to evaluate the micronutrient limitation question, especially regarding iron deficiency after a bloom. Iron is known to be a limiting factor controlling primary productivity in the Southern Ocean, mainly due to the lack of efficient supply mechanisms [*Boyd et al*., 2012]. However, recent studies have shown that regions in close proximity to the coast in Antarctica, such as canyon heads, are not iron limited, and that in certain parts of the WAP there is enough iron to allow the potential utilization of all macronutrients available [*Annett et al*., 2015]. Surface dissolved Fe:PO_4 ratios measured at Station E were always above 1.1 mmol mol^{-1}, much higher than cellular Fe:P$\sim$0.2 mmol mol^{-1} measured in Fe-limited Southern Ocean waters [*Twining and Baines*, 2013]. In addition, dissolved Fe was always $>$0.5 nmol/kg (Figure 3), higher than dissolved Fe concentrations $\sim$0.1 nmol kg^{-1} typical of Fe-limited waters [*Sedwick et al*., 2008], further supporting our inference that Fe is not limiting phytoplankton production at the head of Palmer Canyon. Increases in surface dissolved Fe concentrations at Station E (Figure 3) are concurrent with the deepening of the ML, indicating a potential source of iron to the surface waters. The presence of WW, acting as a physical barrier between the AASW and mUCDW implies that this Fe source is likely related to vertical mixing from shallow sediments or lateral advection of surface inputs such as glacial meltwater. Losses by grazing are likely a contributing cause of chl-*a* decline as canyons are known to aggregate zooplankton prey for the apex predators [*Bernard and Steinberg*, 2013], however, we do not have concurrent zooplankton data to address this question.

The timing of a secondary shoaling of the MLD in late February/early March is matched with a freshening of the ML and a small increase in water column stability. The rising air temperatures in the summer months drive the increased fresh, glacial meltwater input onto the surface coastal waters. Concurrent with this, a secondary peak in chl-*a* is observed, consistent with previous work by *Moline and Prezelin* [1996], and a reduction of dissolved Fe to intermediate values, presumably a result of decreased supply from below and increased Fe removal in association with the chl-a increase, balancing the increased supply of Fe from glacial meltwater.

4.2. Palmer Deep Cross-Canyon Spatial Analysis

While most phytoplankton studies in the WAP canyons have focused on the temporal (seasonal and interannual) variability [*Kavanaugh et al*., 2015; *Moline and Prezelin*, 1996], little is known about what is driving the high small-scale spatial variability observed in the foraging behavior of penguins [*Oliver et al*., 2013]. Spatial differences in phytoplankton are also likely to occur as a cyclonic eddy feature is expected to dominate the upper water column circulation over the canyon and to aggregate small nonmigratory species at the head of canyons, particularly at the downstream side of the canyon [*Allen et al*., 2001].

Preliminary analysis of CODAR High-Frequency Radar (HFR) data at PD [*Kohut et al*., 2014], which provides surface maps of ocean currents, shows on average for the months of January and February, a strong Northeastward (onshore) current toward the Bismarck Straight that crosses the southern region of this study, with average speeds an order of magnitude faster than the flow that crosses the northern region. On the other hand, although a less prominent feature, a weaker Southeastward (offshore) coastal current crosses the northern flank of the transect. Initial analysis of the mean current standard deviation shows higher variability in the flow that crosses the southern region [*Todoroff et al*., 2015]. This highly energetic and variable flow can explain the increased variability in the water properties in that region as seen in Figures 5 and 6. This variability decreases with the temporal evolution of the water masses, with surface water becoming warmer and saltier and with WW being warmed both from above and below. Main spatial differences in water properties can be found at depth, with the northern region showing overall colder temperatures, as evident by the presence of WW until later in the season. The southern flank shows intrusions of warm, salty, deep water likely from the onshore current forcing mUCDW onto the shelf that then mixes upward, weakening the signal of WW from below (Figure 8). The northern flank shows a strong presence of winter water and a fresh water lens that comes from glacial and sea ice melt brought by the coastal current. The differences in magnitude and the variability of the currents between the two regions are likely to contribute to the stability of the MLD dynamics on local scales. With less energetic currents, the water in the northern region is likely to show higher residence times, ideal for local primary production to occur. On the other hand, southern region mean currents show higher variability and magnitude that can potentially impede local production to fully thrive as the timescales of the mean currents are shorter than the doubling time of Antarctic phytoplankton.

Another factor known to control primary production is the availability of iron [*Twining and Baines*, 2013]. Although there are several potential sources of iron to surface waters (glacial melt, sea-ice melt, seawater interaction with shallow sediments, atmospheric input and deep water upwelling), glacial meltwater has been identified as one of the most important [*Dierssen et al*., 2002; *Hawkings et al*., 2014], by its volume flux and because of the continuous yet variable supply during the growing season [*Meredith et al*., 2008]. The close proximity of canyon head systems on the WAP to the coast where glaciers are prominent features, may also contribute favorably to the increased production seen in the canyon as the increased glacial meltwater input (and pushed by the coastal current) contributes to increased water column stability and is a potential source of iron to the system [*Alderkamp et al*., 2015; *Annett et al*., 2015; *Arrigo et al*., 2015]. While mUCDW upwelling enriched with iron from sediments has been proposed as a potential source of iron to coastal WAP regions [*Annett et al*., 2015], at Ryder Bay (340 km south of Palmer Deep) it was found to account for very little of the iron input due to the highly stratified waters during the growth season. It is however identified as an important source of iron over annual or longer time-scales. The same seems true for the overall nutrient budget. Glider observations during the austral spring and summer show no evidence of this mUCDW upwelling reaching surface waters during the growth season as there is a clear layer of WW physically separating surface waters from the deep waters below while the bloom is present. However, this water mass is slowly warming throughout the season due to vertical mixing from above and below, contributing to the decreased water column stability. While there is no evidence of the surface waters at PD being limited by macro or micronutrients at any point, a drawdown in the nutrient pool is apparent while the bloom is thriving [*Ducklow et al*., 2012]. After the growth season, as the stratification weakens, mUCDW intrusions from below will replenish the surface water with both micro and macronutrients required for the following year's spring phytoplankton bloom.

5. Conclusions

Understanding the spatial and temporal variability of phytoplankton is important, especially to assess the dynamics of higher trophic levels as they are dependent on primary producers for food source. The high-resolution capabilities of gliders allow sampling and coverage at appropriate scales to evaluate phytoplankton dynamics. Using the 6 year glider observations over PD, we were able to describe the fine temporal and spatial variability of the phytoplankton seasonal cycle and relate it to its main physical drivers, namely MLD and water stability. Although interannual variability was observed in the data, the shoaling of the MLD in late spring matching increased chlorophyll concentration was a pattern observed in all years sampled (2010–2015), as more light becomes available to the phytoplankton community. Following this period, a summer (February) deepening of the MLD was accompanied by decreased chlorophyll concentration.

Observations showed that MLD dynamics and chlorophyll variability were tightly coupled in both time and space. Spatial variability was evaluated by glider transects across the head of the canyon. While MLD dynamics was similar in the northern and southern canyon regions, the physical setting observed in different regions of the canyon, such as water column stratification and water masses present, explain some of the observed chlorophyll variability. Preliminary analysis of surface currents provides an insight on what could be driving some of the observed differences in water column structure that are key for phytoplankton development. The northern region with increased chlorophyll showed a more coastal influence, with increased freshwater input, slower currents, and increased stratification, while the southern region with lower chlorophyll showed more influence from offshore with faster currents and more intrusions of mUCDW from below. However, further sampling and analysis is necessary to evaluate whether water column physics is driving the spatial differences in chlorophyll concentrations alone or if iron supply plays a role in the system at any point in the growth season.

***Abstract*— On the continental shelf of the west Antarctic Peninsula (WAP), waters below the permanent pycnocline are strongly influenced by intrusions of water masses shed from the Antarctic Circumpolar Current. These intrusions carry relatively warm water toward the coast and to glacier grounding lines, but intrusion locations, mechanisms, and pathways by which this water moves on the shelf are still poorly understood. Dozens of deployments of autonomous underwater vehicles (gliders) in the vicinity of Palmer Deep, a biologically productive canyon on the WAP, have collected temperature and salinity data at extremely high spatial resolution. These data can be used to calculate geostrophic currents in the across-glider-track direction, and this would provide an extensive dataset to study circulation on the WAP shelf, but the relative importance of the geostrophic component to the total current field must first be determined.**

Here, we present a comparison between one ADCP transect and several repeat glider transects along the same line. Velocities measured by the ADCP are difficult to compare to geostrophic velocities because the shallowest ADCP bin is 46 m below the surface, while geostrophic velocities are referenced to dead-reckoned velocities with a significant contribution from surface currents. Despite limitations, depth-averaged geostrophic currents show promise in being a useful proxy for total depth-average currents on the WAP. The depth-averaged currents from glider deployments show significant day-to-day variability in both magnitude and direction, but the glider transect timed most closely to the ADCP transect showed a similar pattern. Vertical shear is predominantly directed onshore, and measurements of shear below the permanent pycnocline are small compared to those at the surface.

***Keywords*— geostrophic velocity, thermal wind, glider, vertical shear. Antarctic**

I. Introduction

Palmer Deep is a canyon on the continental shelf of the west Antarctic Peninsula (WAP) considered to be a hot spot of biological activity. The high productivity of the region has been attributed to the presence of a deep nutrient-rich water mass called Upper Circumpolar Deep Water (UCDW) [1] which originates offshore within the Antarctic Circumpolar Current. A modified form of UCDW (mCDW) is always present deep within the canyon, but the pathways by which it travels from the shelfbreak are poorly understood.

Understanding the pathways by which UCDW travels across the shelf and becomes mCDW is important to our understanding of how circulation affects biological activity. These pathways are linked to residence time on the shelf, mixing with other water masses, and the formation areas of convergence and divergence at the surface where phytoplankton bloom. Intrusions of UCDW are also important in delivering heat to the WAP [2]. This region of the world is one of the fastest warming on Earth and the rising temperatures are thought to be driven more by the ocean than the atmosphere [3]-[5]. Upper Circumpolar Deep Water is the source of heat to the WAP. It is known to enter the shelf via canyons at depths between about 200 and 500 m, but the frequency and magnitude of these intrusions are mostly unknown.

Although circulation is thought to be an important driver of productivity on the WAP, and it plays a critical role in regulating the heat budget, its patterns are still not well mapped. Data collection is limited by harsh weather conditions and the extent of sea ice during winter. During the summer months (October – March), the United States Antarctic Program conducts research cruises along the peninsula. Water velocity measurements are often taken on these cruises by a hull-mounted Acoustic Doppler Current Profiler (ADCP), and these data have been used to explain the general circulation patterns on the WAP [6], but the detailed mechanisms by which UCDW reaches Palmer Deep and circulates within it remain undescribed.

Geostrophic current calculations have long been used to understand circulation patterns where velocity data are limited. They rely on the geostrophic balance between a pressure gradient and the Coriolis force. Differences in the density profile between two locations in the ocean lead to a pressure difference which forces water to move between the two locations. The effect of the Coriolis force introduces a rotation to the motion such that, when a current is in geostrophic balance, it flows perpendicular to the pressure gradient. Any two density profiles, therefore, can be used to calculate the geostrophic velocity between them, as long as one reference velocity somewhere on the profile is known (otherwise, only relative velocity is calculated).

Since 2010, the Rutgers University Center for Coastal Observation Leadership (RUCOOL) has conducted dozens of glider deployments within and near Palmer Deep. The gliders were deployed from Palmer Station, a research outpost situated at the head of Palmer Deep (Fig. 1), and

978-1-5090-1537-5/16/$31.00 ©2016 IEEE

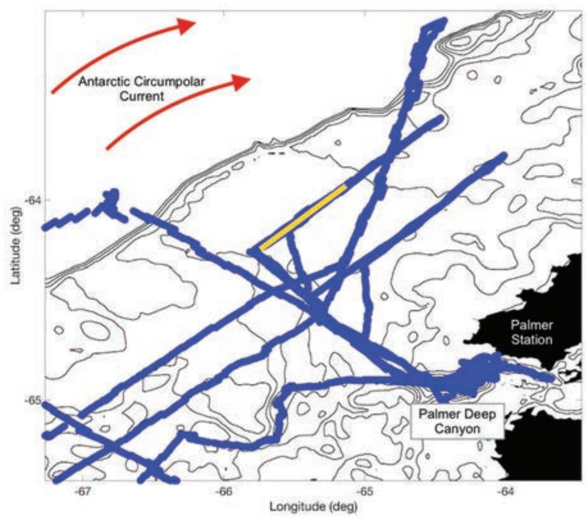

Fig 1. Map of Palmer Deep vicinity with RUCOOL glider deployments in blue. The ADCP transect is shown in yellow, overlapping eight repeat transects of one glider deployment.

were equipped with a variety of sensors depending on the purpose of each individual mission. The gliders do not directly measure current speeds, but every glider measured density. Additionally, the gliders calculated a depth-averaged current between every surfacing based on dead-reckoning. This information, combined with the density profiles can be used to calculate geostrophic velocities everywhere the gliders flew.

The spatial extent and resolution of this dataset provides an exciting opportunity to map circulation patterns within and near Palmer Deep. But first, in order to assess the utility of these measurements, a comparison between glider-calculated geostrophic currents and known currents must be

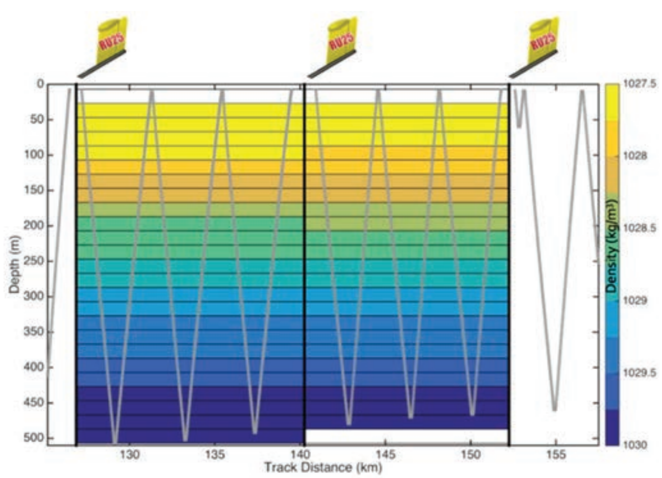

Fig. 2. Example of two neighboring averaged profiles used to calculate geostrophic velocities. Each time the glider surfaces (indicated by tail icons), it calculates a depth-integrated dead-reckoned current velocity between the present and previous surfacing location. All profiles between surfacings are averaged into 10-meter depth bins and the average profiles are used to calculate northward and eastward velocities.

performed. Geostrophic currents describe only the baroclinic component of velocity, so the simultaneous measurement of true velocity is important for understanding the relative contributions of the baroclinic and barotropic components in this region. Here we compare several repeat transects of a glider to the same transect measured by shipboard ADCP. The ADCP data is considered the true velocity field, including both the barotropic and baroclinic velocities. The differences between the two types of measurements reveal some circumstances under which geostrophic currents can describe the circulation near Palmer Deep.

II. METHODS

A Teledyne Webb glider was used in this study to measure temperature and salinity profiles on the WAP continental shelf. Gliders are buoyancy-driven autonomous underwater vehicles that sample the water column from the surface of the ocean to the bottom in a see-saw pattern as they travel between operator-specified waypoints (Fig. 2). They move slowly (~1 km/hr) and, as a result, sample the ocean with very high spatial resolution. The glider used here was deployed from Palmer Station in late December 2014 and flew to the mouth of a canyon that extends from the shelf break to Palmer Deep (Fig. 1). It made eight repeat transects across the mouth of this canyon on its northeastern side (Fig. 1). The glider traveled parallel to, and approximately 45 km away from, the shelf break. This location was chosen because it was through to be a possible intrusion point for UCDW onto the shelf. Studies of a different canyon on the WAP shelf have shown that warm water tends to intrude along its northeastern wall [7]. These eight passes were made between January 2, and January 18, 2015.

The glider was equipped with a conductivity, temperature, and depth sensor. These variables were measured four times per second and were used to calculate density. Each time a glider surfaces it gets a GPS fix. Using the difference in its position between surfacings and its own measurement of heading and speed, the glider calculates the depth-averaged velocity between its previous and present position.

Density profiles were averaged between glider surfacings and into 10-meter depth bins, and vertical shear was calculated between every pair of averaged profiles according to the geostrophic relationship:

$$\frac{\partial v}{\partial z} = \frac{g}{f\rho_0}\frac{\partial \rho}{\partial x}, \tag{1}$$

where x is distance in the along-track direction, and v is the geostrophic velocity in the across-track direction. The integrated form of the equation:

$$v = \int_z^0 \frac{g}{f\rho_0}\frac{\partial \rho}{\partial x}dz + \text{constant} \tag{2}$$

$$= \text{depth-averagred velocity}$$

reflects the across-track component of velocity, resulting from the density structure. Here, ρ is the density of a given depth bin, ρ_0 is a reference density, set as the average of all measured densities, g is the acceleration to due gravity, f is the Coriolis parameter, and z is depth. The integrated shear profiles are scaled using a constant offset so that the total depth-integrated shear matches the across-track component of the depth-averaged current experienced by the glider.

The research vessel *Laurence M. Gould* made a transect along the glider path on January 9, 2015. The vessel was equipped with a hull-mounted ADCP operating at 38 kHz. This frequency allowed for measurements of velocity between 46 m and 1462 m water depth with depth bins of 24 m. Corrections for heading and speed of sound were applied by Dr. Teresa Chereskin at the Scripps Institute of Oceanography. These data were interpolated into 10 m depth bins and averaged hourly resulting in a total of four water velocity profiles calculated along the transect. The processed and interpolated data was acquired from the Joint Archive for Shipboard ADCP.

To facilitate comparison between all transects, velocity data from the eight glider sections and one ship section were interpolated onto a grid with a vertical spacing of 10 m and a horizontal spacing of approximately 5 km.

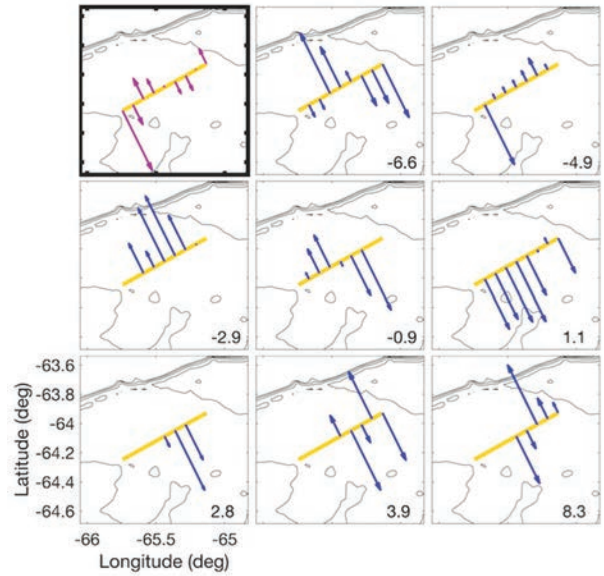

Fig. 3 The depth-averaged across-track component of velocity measured by the Gould ADCP is shown in the upper left plot. The other eight plots show the depth-averaged across-track geostrophic velocities calculated by the glider. The number of days between the ship transect and the glider transect is given in the lower right corner of each plot. Starting from the middle of the top row and moving left to right, the first four glider transects occurred before the ship transect and the last four occurred after it.

III. Results

Velocity profiles measured by the shipboard ADCP were rotated into along- and across-track coordinates, where the track was defined as the line passing through the first and last ADCP profiles. Working in the coordinate system defined by the track is important to be able to directly compare the ADCP velocities to those measured by the glider. Since the glider was not equipped with its own ADCP, geostrophic velocities were calculated instead. Using the geostrophic relationship, across-track currents are calculated from along-track pressure differences, but nothing is known of the magnitude of geostrophic velocity in the along-track direction. Depth-averaged across-track currents measured by the ADCP and the glider are shown in Fig. 3. Glider transects were made over the course of sixteen days, and there is significant variability in the geostrophic

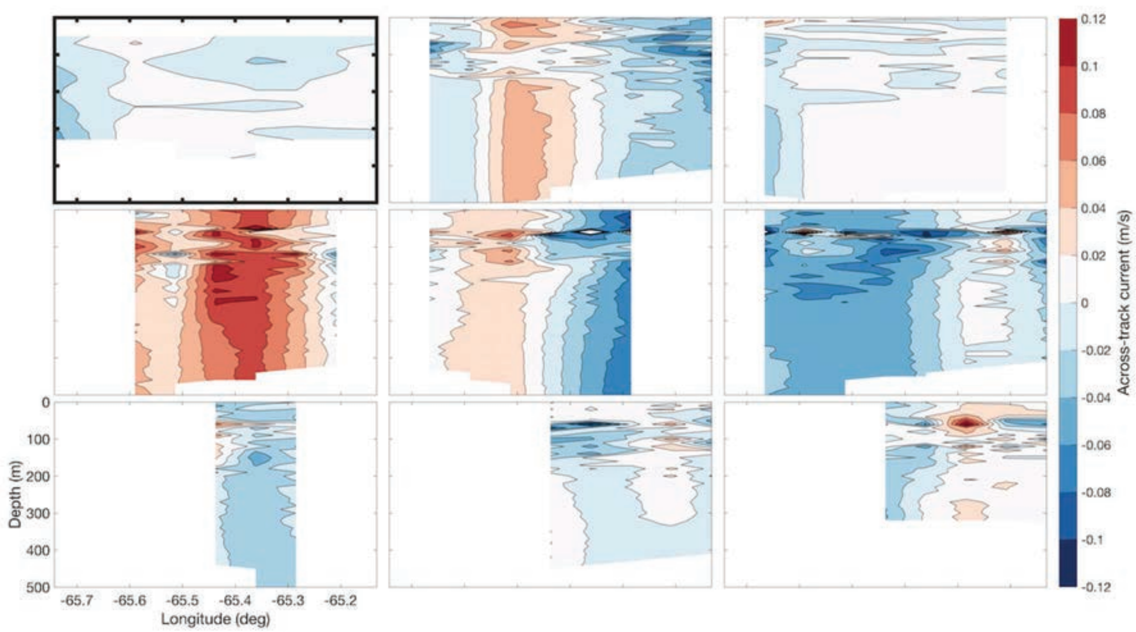

Fig. 4. Across-track component of velocity measured by the Gould ADCP is show in the upper left plot. The other eight plots show the across-track geostrophic velocities calculated from density measurements on the eight repeat glider transects that covered the same path.

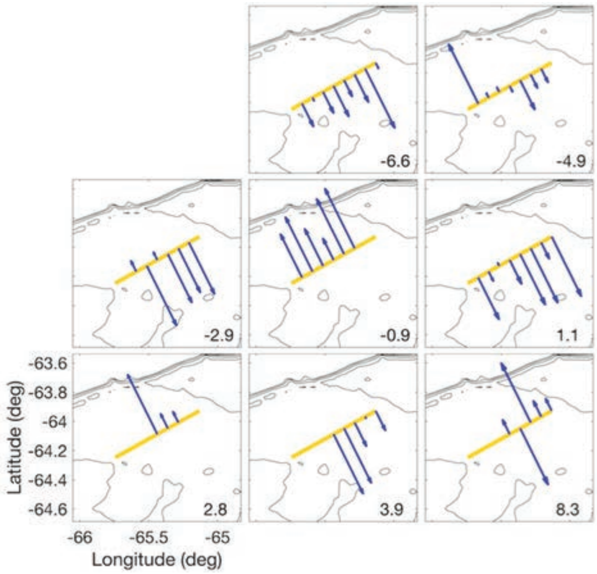

Fig. 5. The depth averaged vertical shear measured by the glider on its eight repeat transects. Each pass is shown in the same position as in Fig. 3.

currents measured over this time (Fig. 3).

The overall direction of geostrophic flow measured by the glider is slightly in the southeast direction (onshore). Fifty-four percent of the total across-track depth-averaged flow measured by the glider was onshore while 46% was offshore. Most of the flow across the ADCP track was also directed onshore, but this was mainly due to a strong onshore flow along the southwest edge of the canyon. The northeastern side of the track showed a surface-intensified onshore flow and a subsurface offshore flow that was smaller in magnitude (Fig. 4).

Unfortunately none of the glider transects happened at exactly the same time as the ADCP transect which is serving as the ground truth for velocity measurements. Simultaneous measurements are difficult to achieve because 1) the glider moves much slower than the ship and 2) the glider is kept away from ships whenever possible to avoid the possibility of collision. The fourth pass of the glider was closest in time to the ADCP transect: the glider completed the transect slightly less than one day earlier than the ship. The depth-averaged geostrophic currents on this pass look most similar to depth-averaged velocity from the ADCP track (Fig. 3, center panel). Flow was onshore on the northeast side of the canyon and offshore on the southwest side of the canyon.

The magnitude of the geostrophic currents in this and most other glider passes was greater than the magnitude of currents measured by the shipboard ADCP, but this is likely due to the fact that ADCP velocity measurements began at 46 m depth while currents are generally strongest at the surface. The depth-averaged current is used to shift the shear profile so that its mean value is equal to the depth-averaged value. With stronger currents at the surface, a depth-averaged current that includes the upper 46 m is likely to be greater than one that does not. A velocity measurement taken deeper in the water column would be a more appropriate reference point for comparisons to depth-averaged ADCP velocities between 46 m and the bottom, but the glider dead-reckoned current was the only reference available here.

Vertical shear profiles reflect the baroclinic component of velocity throughout the water column. They are relative velocities, unshifted by a reference velocity. Depth-averaged shear profiles are shown in Fig. 5, mapped the same way as in Fig. 3. In contrast to the geostrophic currents, shear is predominantly directed onshore, suggesting that the baroclinic component of velocity through the canyon is generally onshore and total currents are influenced by other

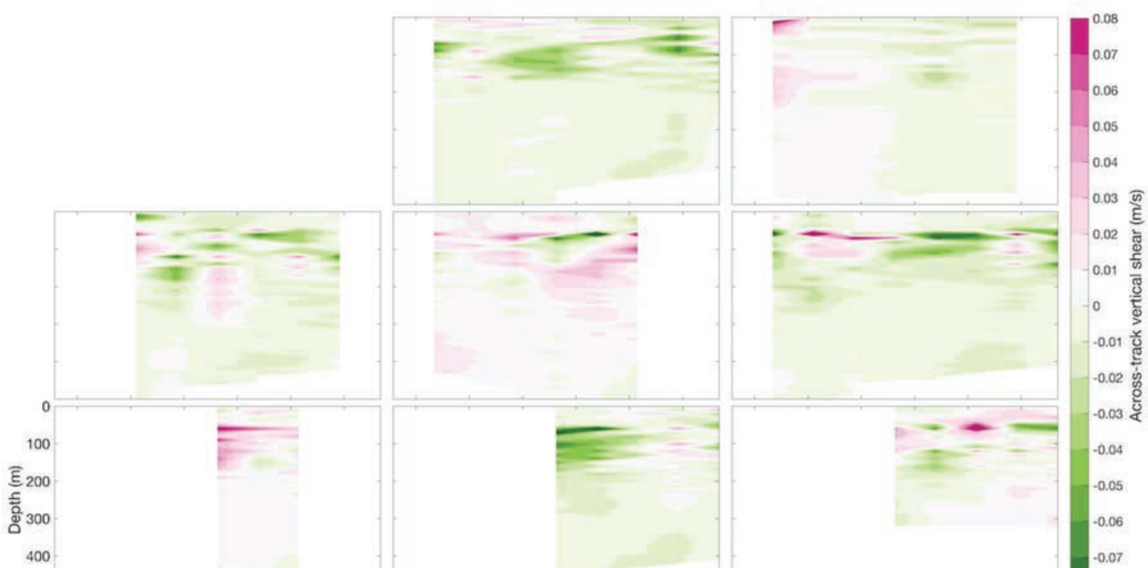

Fig. 6. Vertical shear due to along-track density gradients. Each of the eight glider transects are shown in the same subplots as in Fig. 3 and 4. The first pass is shown in the middle plot on the top row and the last is shown in the bottom right plot.

factors (ex. tides, weather) on daily timescales.

Shear tends to be surface intensified suggesting that the greatest lateral density differences are at the surface and deeper waters are more homogenous (Fig. 6). Surface intensity extends to a depth of about 200 m, which is the approximate depth of the permanent pycnocline in this region. The vertical shear pattern seen in the fourth glider pass (the pass closest in time to the ADCP transect) is similar to the pattern seen in the ADCP data with a localized surface intensification on the northeast side of the canyon. This suggests that a significant portion of the total velocity may be explained by the baroclinic component.

IV. Conclusions

Geostrophic currents measured by gliders show promise as being a useful proxy for total currents in this region of the ocean, but more direct comparisons with total velocities measured by ADCP would be helpful in determining their relative importance Since the completion of this deployment the RUCOOL group has completed a few glider deployments within Palmer Deep with glider-mounted ADCPs. Continued research on the relative importance of baroclinic and barotropic components of velocity in this region will be conducted using these new datasets.

The ability to map the velocities on the WAP is critical for understanding the regional circulation patterns. The transport of UCDW to Palmer Deep is known to be important, but its pathways are unclear. Paired with temperature measurements made by the gliders, geostrophic velocities could be used to better understand these transport pathways.

Acknowledgement

ADCP data was processed by Dr. Teresa K. Chereskin at the Scripps Institute of Oceanography and made available at the Joint Archive for Shipboard ADCP: http://ilikai.soest.hawaii.edu/sadcp. Thanks to the RUCOOL glider technicians for their support during the glider deployment and thanks to the field team and staff at Palmer Station for successful deployment and recovery of the glider.

Interannual variability and trends in the Middle Atlantic Bight cold pool

Abstract— **The Middle Atlantic Bight (MAB) exhibits one of the largest seasonal cycles of temperature in the global ocean. During the summer, the water column is strongly stratified with warm surface waters separated from much colder bottom waters by a strong, shallow thermocline. The bottom water that remains cold in the summer months is referred to as the 'cold pool'. The cold pool is formed as the stratification sets up in late spring and it remains until fall mixing breaks down the seasonal thermocline with each passing storm; it usually breaks down in September or October. The cold pool is an important feature of the MAB as it influences the surrounding waters, the intensity of storms, and fish assemblages over the MAB. We use various data sources to explore interannual variability and long-term climatic trends in summer stratification and cold pool source water. Annual trawls conducted by the National Oceanic and Atmospheric Administration National Marine Fisheries Services (NOAA NMFS) provide temperature and salinity measurements consistently from 1980 to the present. Slocum gliders have been regularly deployed along New Jersey shelf since 2003 and collect data for various organizations such as Rutgers University and the Environmental Protection Agency. NOAA's National Data Buoy Center provides several buoys in the region that have been collecting data since the early 1980's. A better understanding of the cold pool can lead to a better understanding of ocean and storm interactions in the MAB and of potential climate change impacts on the region.**

Keywords— Ocean observing systems, Autonomous underwater vehicles

I. Introduction

The Middle Atlantic Bight (MAB) is the region off of the Northeastern coast of the United States that extends ~1000 km from Cape Hatteras, North Carolina to Cape Cod, Massachusetts. The MAB is characterized by a shallow sloping continental shelf that is at its narrowest (50 km) off of North Carolina and its widest (~200 km) east of New Jersey and west of Long Island, New York. The New York Metropolitan area adjacent to the MAB has a population of over 19 million people and accounts for close to 10% of the US GDP. This region is important for fishing, shipping, and recreational use, and is also highly vulnerable to coastal storms, including frequent nor'easters in winter and fall as well as tropical cyclones in summer months (Glenn et al., 2016). Due to its large population and highly concentrated population at the coastline it is highly vulnerable to changing climates and sea level rise. The coastal ocean of the MAB is unique as it has one of the largest intra-annual temperature ranges. In winter the water column is subject to salinity dominated stratification but in the spring, the surface water is warmed by solar heating. This warming causes the creation of a strong thermocline, trapping cold water along the bottom of the shelf (Castelao, Glenn, & Schofield, 2010; Houghton, Schlitz, Beardsley, Butman, & Chamberlin, 1982). This thermal stratification persists through summer and into the fall when storm induced vertical mixing breaks down the thermocline. Surface cooling in the fall has been shown to not be the dominant process in the breakdown of the thermocline (Castelao et al., 2008; Lentz, 2003).

The cold water that gets trapped by the thermal stratification is referred to as the 'cold pool'. The cold pool is defined as any water inside the 10° Celsius isotherm over the shelf, and is typically located between the 40 and 200 meter isobaths. During the summer, the cold pool migrates south along the coast but remains over the shelf. The stratification and formation of the cold pool starts in the Gulf of Maine and then moves south with a speed of approximately 5 cm/sec and the flow rate is .15 Sv (Flagg, Wallace, & Kolber, 1997). The cold pool stretches along the length of the MAB and has been shown to be relatively uniform with respect to temperature. The time frame the cold pool exists is not rigid because it is dependent on atmospheric influences (Lentz, 2003). The formation and breakdown of the cold pool is heavily influenced by local and remote sources. As source waters, like the Labrador Sea, are affected by climate change, the cold pool reflects these changes.

The dominant factor in the break down of the thermocline, and the subsequent dissolution of the cold pool, is strong wind events. In summer, when tropical cyclones follow a northward track along the MAB, studies have found that intense leading-edge winds can drive shear-induced mixing of the water column, which has implications in atmospheric models. As a storm moves north through the MAB, the water ahead of the storm is cooled because of the induced mixing (Glenn et al., 2016). Thus the storm's intensity is reduced, as there is no longer warm water to give the storm strength. This 'ahead of eye cooling' phenomenon was missing from atmospheric

978-1-5090-1537-5/16/$31.00 ©2016 IEEE

models, which led to an under-prediction of Hurricane Irene's intensity just prior to landfall. The characteristics and tendencies of the cold pool are still widely unknown and unrepresented in simulations, which remains a critical challenge for hurricane intensity forecasters in the region.

The Mid-Atlantic Bight is an economically important region because of fishing. Certain species of fish such as winter flounder, *Pseudopleuronectes americanus*, depend on the cold pool during the summers. As surface temperatures in New Jersey estuaries rise during the summer, winter flounder migrate to the ocean with the goal of finding colder water (Able, Grothues, Morson, & Coleman, 2014). The cold pool provides these flounder with cooler water and when the seasons change and the thermocline fades, the flounder migrate back in shore. Yellow tail flounder, *Limanda ferruginea*, is another fished species in the MAB that is dependent the coldest, deepest water of the MAB to thrive. Another ecologically important species is the glacier lantern fish, *Benthosema glaciale*, which thrives in the benthic region over the shelf in most of the north Atlantic (Grothues & Cowen, 1999).

A number of recent studies have identified warming trends in the surface waters of the MAB showing increasing temperatures of 0.0026 $^{\circ}C\ yr^{-1}$ from 1977 to 2013 with an increase to 0.11 $^{\circ}C\ yr^{-1}$ in more recent years (Forsyth, Andres, & Gawarkiewicz, 2015). Additionally, Mountain et al., 2003 showed MAB shelf waters were 1°C warmer in the 1990s than 1977 to 1987. Despite the importance of resolving and understanding the dynamics and long-term trends of the cold pool, due to the high cost of ship-based monitoring there are limited observations over climate scales. In this study we aggregate over 38 years of National Marine Fisheries datasets and 10 years of high spatial and temporal resolution autonomous underwater glider data on the New Jersey continental shelf, south of the Hudson Shelf Valley.

II. Methods

For this analysis we define a study area based on depth and distance from the Hudson Shelf Valley as well as an area where gliders and ship-based surveys had significant overlap. The study area is defined as the polygon shown in Figure 1. The red shapes represent the location of static NDBC buoys and although they are not in the defined study area, because of their proximity, they still provide an estimate of the surface conditions in the study area. Future work will involve analyzing historic Advanced Very High Resolution Radiometer satellite data over the study area.

Teledyne-Webb Research Slocum gliders have been deployed on the MAB since as early as 2003. Gliders are autonomous underwater vehicles that move through the water

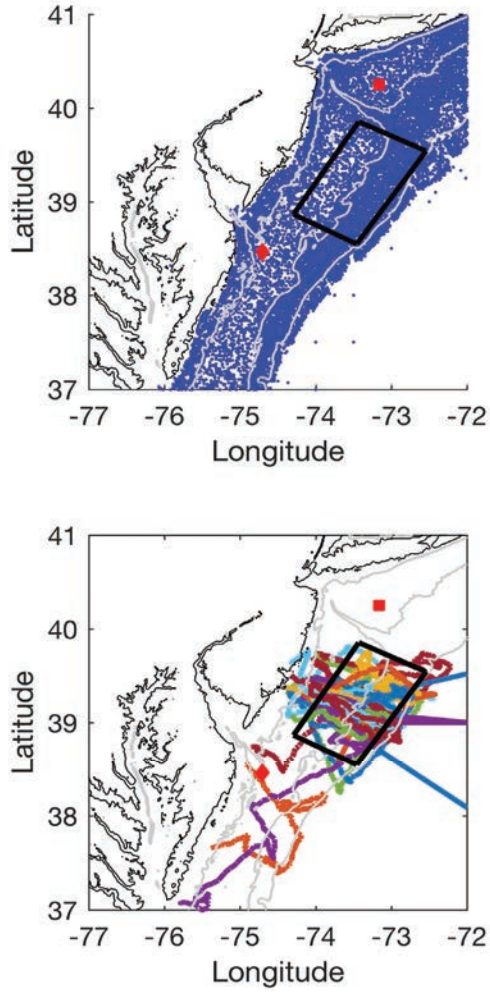

Figure 1 **Map showing the study area represented by the black polygon. The red shapes symbolize the two National Data Buoy Center buoys. a) Data from the National Marine Fisheries Society is shown in blue. b) Each color represents a different Slocum glider deployment that was used in this study.**

column by small changes in buoyancy. The glider is programmed to move the position of a pump, taking in or expelling seawater, to make the glider more or less dense than the water when it needs to dive or climb respectively. As the glider dives and climbs, it collects hydrographic data continuously and after surfacing transmits that data to shore, resulting in high temporal and vertical resolution data over broad spatial areas. Data collected from 49 glider deployments were used in this study (Figure 1b).

The data analysis for this study was supported by a Teledyne Webb Research undergraduate research fellowship.

Island, and 44009, off of the coast of Delaware, were used in this study.

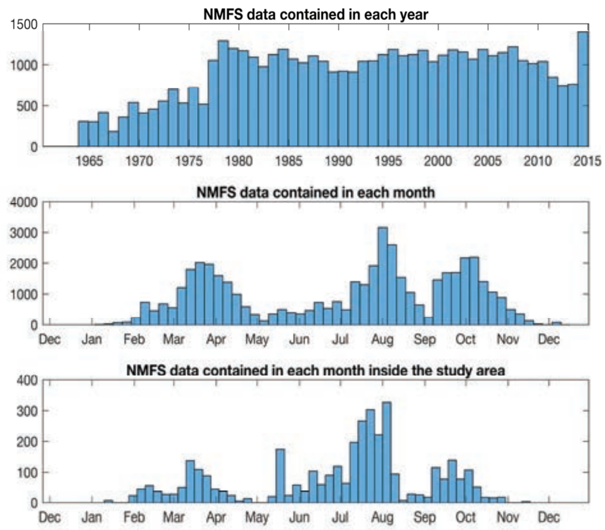

Figure 2 **Histograms showing the quantity of data collected by the NMFS surveys (a through c from the top down). a) Illustrates the number of data points collected in each month across all years. b) Illustrates the number of data points collected in each month across all years. c) Illustrates the number of data points collected inside the study area, each month, across all years.**

The National Oceanic and Atmospheric Administration's (NOAA) National Marine Fisheries Service (NMFS) has conducted seasonal trawls in the MAB as part of fish stock assessments since 1965. Before 1987, temperature was the only hydrographic data collected and it was measured using reversing thermometers. In this same time frame, there were 90 pre-selected stations that data was collected at during each survey. Not every station would be utilized every year but no data was collected anywhere but these stations. After 1987, a stratified random station design was implemented and now NMFS starts every trawl in a specified region and records the exact position (Mountain, 2003). Salinity data was not collected consistently until 1996. Before each trawl began, a CTD was dropped and surface and bottom data were recorded, where the bottom is defined as 5m above the sea floor. The area sampled is consistent from year to year but the time that each specific region is sampled is not always the same because of complications such as weather and malfunctioning equipment. These surveys provided a nearly continuous time series of temperature and salinity in the MAB over the last 50 years but this study only used data collected during or later than 1974. Figure 2 shows the annual and seasonal distribution of profiles of this dataset and the portion that falls within the study region.

NOAA's National Data Buoy Center buoy's are static buoys that continuous collect surface climatological data. This data was used to confirm the data collected by the NMFS surveys and to fill in the times when the NMFS surveys were not collecting data. Buoys 44025, off of the coast of Long Island, and 44009, off of the coast of Delaware, were used in this study.

III. Results

The minimum temperature in the study region at any time was defined as the temperature of the cold pool (Houghton et al., 1982). Weekly minimum temperatures were taken from both NMFS and glider data sets individually from every year of each data set. The data was limited using three standard deviations from the mean of each early and late data separately. This provides a time series of the cold pool throughout one year.

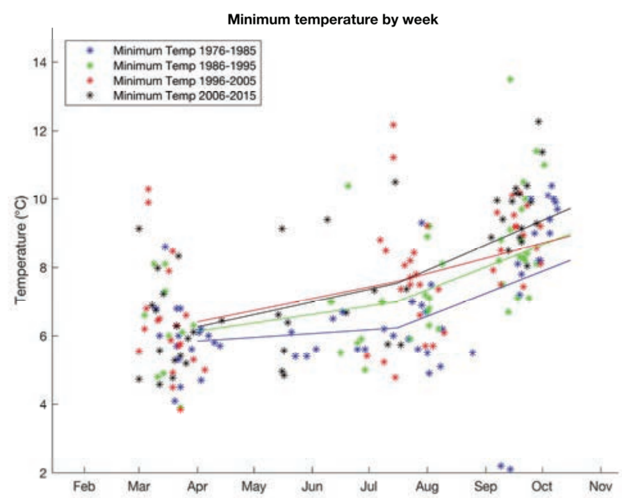

Figure 3 **The minimum temperatures displayed were found by taking the weekly minimum temperature inside the study region from both the NMFS and the glider data sets. These minimums were then limited to only include points within three standard deviations of the mean. The lines represent the decadal seasonal means, found by taking the average minimum in the time ranges of 1 March – 31 May, 1 June – 31 August, and 1 September – 31 November. The colors correspond to the colors of the data points, for example the blue line corresponds to the 1976-1985 decade.**

Figure 3 shows all of the bottom temperature readings separated into four decades starting with 1976 and ending in 2015. The absolute minimum temperatures recorded in each of the four decades were 2.1°C, 3.9°C, 3.84°C, and 4.58°C and were recorded 14 September, 23 March, 23 March, and 12 March respectively. The times associated with the latter three decades' minimum temperatures were as expected because the thermocline develops in the spring and the cold pool has no source of cooling after its formation (Houghton et al., 1982). In the earliest decade, the drop in temperature in September is under further investigation, as it may be an outlier. The large grouping of data points at and above the 10°C isotherm starting in September is a sign of the cold pool undergoing fall transition due to mixing with the upper layers of the water column. The points before September that fall above the 10°C isotherm were most likely a product of a mixing events, but not due to the full fall transition.

Table 1 **The table shows the data represented in Figure 3 by the colored lines. The means were calculated from the weekly minimums of both NMFS and glider data. The minimums were found for every year and the means were found decadally.**

Mean of the minimum bottom temperatures (°C)				
	1976-1985	1986-1995	1996-2005	2006-2015
1 March – 31 May	5.84	6.13	6.41	6.26
1 June – 31 August	6.23	7.00	7.59	7.54
1 September – 30 November	8.21	8.98	8.92	9.72

The minimum temperatures were averaged by season; 1 March-31 May, 1 June-31 August, 1 September-30 November. This average was calculated four times across the forty years of data. This data is displayed in Table 1. All time periods show increase in minimum temperature throughout one year. A warming across the four individual time periods is also shown. The absolute minimum average, 5.84°C, appears in the spring of the earliest time frame. The absolute maximum mean, 9.72°C, appears in the fall of the most recent time frame.

Figure 4 shows the difference between the annual mean bottom temperature and the mean of the bottom temperature throughout all years of the data set. The time frame of each year was limited to 1 March – 31 December to ensure that the cold pool is present within the time frame and to exclude the cold water in January and February from analysis. The largest differences from the mean bottom temperature occurred in 1977, -4.45°C, and in 2009, +4.45°C. The largest differences from the mean bottom salinity occurred in 1996, -1.10 PSU, and in 2015, 1.19 PSU. The mean difference for bottom temperature and bottom salinity were 1.27°C and 0.39 PSU respectively.

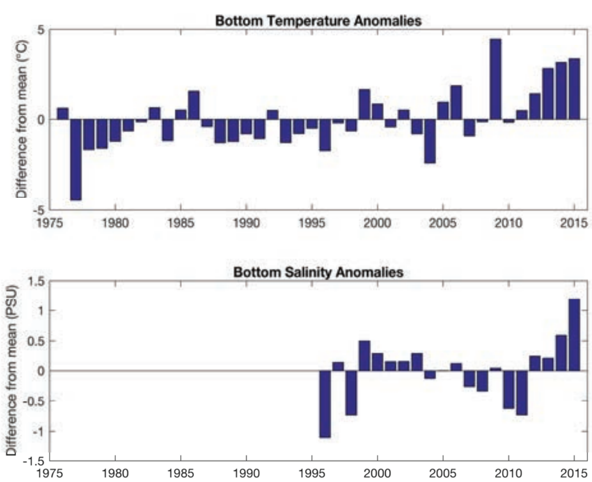

Figure 5 **The mean was calculated for all years of both the NMFS and glider data sets and then the yearly means were calculated. For the glider data, the bottom was defined as the maximum depth reached in each individual profile and was limited to only include profiles that reached depths greater than 35m.**

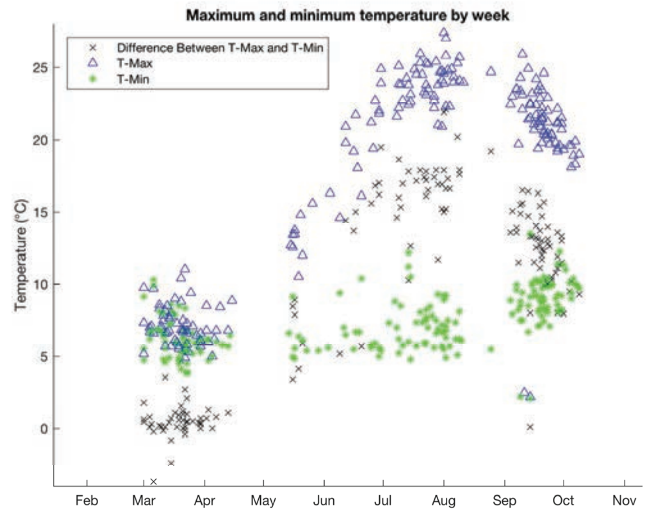

Figure 4 **The maximum temperature was found using an identical method to the method previously described for the minimum temperature, where the weekly maximums from each data set were found for each year of the data set. Both the maximum and the minimum were limited to only display data within three standard deviations of their respective means. The difference was calculated by subtracting the minimum from the maximum only for weeks when there was data recorded for each the maximum and the**

The minimum temperatures from every week over the forty year data set were subtracted from the maximum temperatures from every week over the same time. This provides maximum difference in temperature between the surface and the bottom serves as a proxy for thermal stratification. The largest positive difference between surface and bottom occurred on 2 August. The surface temperature was 22.1°C warmer than the bottom temperature. It is clear that the difference between the two water masses fluctuates throughout the year as the cold pool forms and is separated from the surface. The absolute smallest values of both maximum and minimum temperature are 2.2°C and 2.1°C respectively. This was most likely due to some error in the sensor used to take the readings. NMFS and glider data were compiled and then limited to contain three standard deviations above and below the mean.

IV. Discussion

Two warming trends can be seen in the analysis of the minimum bottom temperature. The first is the seasonal warming of T-min. Across each decade displayed in both Figure 3 and Table 1, there is a warming trend from spring to fall but the largest difference between fall and is seen in the most recent decade with an increase of ~3.5°C. This is reasonable considering the warm anomalies occurring in recent years shown in Figure 4. A previous study has shown a ~1°C across every month, starting in February (Houghton et al., 1982). Their study area encompassed a wider span of the MAB and they only focused on one year of data.

The second warming trend shown is the warming of each season across the forty year span. Each season's mean has increased from the beginning to the end of the data set by

~1°C. This is supported, again, by the anomaly data presented in Figure 4. Bottom temperature has been warming overall but the warming that has occurred with respect to each season varies. The fall has shown the largest change in mean temperature across the full length of the data set. The fall showed the most variability because the bottom temperature in the fall is dependent on what the surface temperature was in the summer. Fall is when the mixing begins to occur; the surface temperature has a strong influence on bottom temperature. Another factor in the variability of fall bottom temperature is the time at which the stratification is broken down. If there are strong mixing events early in the fall then the bottom starts to warm earlier causing the minimum temperature to rise early in the year.

Over the last forty years, a warming trend of the bottom water can be seen in Figure 4. The anomalies show a warming trend as the anomalies start below the mean and move more toward the mean and then above the mean as the data approaches the present. There is a higher density of data in the later years, starting in 2005, due to the glider data set that has helped illustrate this trend.

A similar analysis of bottom temperature was conducted by Mountain et al., 2003. Their study showed a smaller anomalous range from the mean. This study and theirs agree that the anomalies tend to be positive in the latter half of the time frame than in the earlier. The time frames of the two studies overlap but the anomalies do not agree. This is most likely due this study's wider time frame. Mountain's study area was not limited to anything but the MAB and looked at the full time frame of the year, not just from March to December like this study. The mean of this time frame includes the warmer recent years. This would also explain why this study has a larger range of anomalies. Although the two studies do not agree directly, the trend seen is similar.

The salinity anomalies shown in Figure 4 were found using the salinity associated with the bottom temperature reading recorded in each data set. No significant trend is evident in the data. However, the addition of the glider data in 2005 shows no impact on any potential trend in the data, further strengthening the argument that the amount of the glider data did not skew the means.

The difference between surface and bottom temperatures was used as an indicator of thermal stratification. The maximum and minimum temperatures recorded were used to represent surface and bottom temperatures respectively. A trend can be seen in the maximum temperature of warming in spring until the fall when it starts to cool again. This is because of seasonal changes in time exposed to the heating from the sun and storm activity. From Late August onwards, storms cause mixing of the water column in the region with strong winds (Lentz, 2003). The minimum temperature shows little variability in comparison to the maximum temperature. This caused the difference between the two to follow the trend of the maximum. This trend shows that thermal stratification is not present in March and April but is strong in the summer as the minimum temperature warms slightly and the maximum temperature rises quickly. The difference starts to decrease during the end of August as the frequency of mixing events increases.

Both the maximum and minimum temperature reach their minimum values in the same annual time period. This is when there is no or little thermal stratification, in winter and spring. This study has expanded the work of Lentz in 2003 by including forty years of data as opposed to his time series of two years. Utilizing the larger data set gives a more comprehensive picture of what can be expected to happen. Lentz showed that in the time frame they analyzed, there were major mixing events that led to a significant drop in the difference between surface and bottom temperature.

V. Conclusion

The major stages of the life of the cold pool are reflected in the changes of the minimum temperature in a region over the course of a year. It is important to understand when the cold pool is formed and when it breaks down. After it has formed, certain species of fish depend on its cold water to live in. The break down of the cold pool is important to understand because of the impact it has on storm predictions.

In terms of interannual trends, the bottom temperature's increase of ~1°C across all seasons is significant because of the ecological implications it holds. If the bottom temperature becomes too warm, the stratification that holds the cold pool on the bottom will no longer form or it may be weaker. This could lead to more vertical mixing in the water column during the summer, which may lead to stronger storms. This is ongoing research and in the future a more precise signal of the formation and destruction of the stratification will be pursued. If these signals are found, the exact state of the cold pool could be known at anytime which would aid in storm predictions.

The bottom temperature in the Middle Atlantic Bight has been shown to be rising over the last forty years. By analyzing the anomalies over a long time frame, an expected range of variability from the mean has been established for the bottom temperature in the region. As the bottom temperature warms, the impact the cold pool has on the ecosystem will diminish. Populations of fishes that depend on the cold pool for it's cold water may begin to diminish or they may just leave the region in search of colder water. The cold pool is also crucial in the disspiation of storms in the region. However, as it gets warmer, it will be less effective at this. As we continue this research, we will also study the effects of El Niño Southern Osciallation and North Atlantic Oscillation on the surface and bottom temperatures of the region.

By analyzing the maximum and minimum temperatures, as representative values for surface and bottom temperatures, on an intra-annual scale a standard of what the stratification should look like in the region is shown. It shows a time frame of when the stratification should develop and break down over the course of one year. By using a large data set, a standard of when the development and breakdown should happen is shown. To further develop this in the future, buoy data will be incorporated to determine a time frame where mixing events usually occur and that will be analyzed alongside the surface and bottom temperatures. This is with the hope of aligning drops in the difference between the surface and bottom with the time frame where mixing events usually occur.

ACKNOWLEDGMENTS

Glider data used in this study is available through the MARACOOS assets page http://maracoos.org/data and http://marine.rutgers.edu/cool/auvs/index.php?did=369. Buoy data used is available at http://www.ndbc.noaa.gov/ . NMFS data used is available at http://www.nefsc.noaa.gov/epd/ocean/MainPage/ioos.html. ***Abstract*—With recent developments in battery technology and ocean energy harvesting systems, biological fouling, or biofouling, a process referring to the gradual accumulation of organisms on underwater surfaces, has gained a foothold as the primary adversary in long-duration autonomous underwater vehicle (AUV) flights of the Challenger glider mission. Limiting biofouling on long-duration AUVs is essential to the success of the flight. Inverse relationships and correlations were drawn between biofouling, vertical velocity of the AUV, and in turn, steering capability. As organisms settle and grow on the AUV, the hydrodynamics of the vessel changed, resulting in larger volume and more drag, adding buoyancy discrepancies as well. The increased drag results in a lower vertical velocity, and therefore less water flow over the rudder, or fin, directly causing the reduction in steering capability. Additionally, the organisms were not evenly distributed about the AUV, causing an imbalance in the drag. The fin then needed to maintain an offset to counteract this imbalance, resulting in less overall range in fin movement, further reducing the ability to steer. Analysis of the data from four separate legs of ocean basin crossings has shown that as the AUV begins to foul, it needs to maintain a vertical velocity of greater than 12 cm/s to maintain viable steering. Overall the fin will move more as it attempts to compensate for biofouling, which will use additional power throughout the duration of the flight, bringing power budgets back into the equation.**

Although the biofouling issues facing long-duration AUVs are subject to the same settling processes as boats and ships, porting commercially available antifoulant technologies from larger, faster vessels to the AUVs has proven challenging. Non-like metals combined with biofilms can result in increased galvanic corrosion, so copper coating compounds on steel components and aluminum AUV hull are not ideal, particularly with limited space and weight for sacrificial anodes. Ablative paints, by design, can wear away, causing possible ballast issues while failing to prevent fouling. Biocides, for obvious reasons, have not been in the list of candidates for consideration in the ongoing battle against biological growth. We introduced some behavioral modifications in the flight characteristics of the AUV that provided some assistance. For example, we avoided the majority of the warmer and illuminated euphotic zone, where primary production occurred, or zones above a certain temperature range that could hamper organism growth, even if it was not possible to prevent settling. This paper will explore the differences in biofouling, flight environment, preventative measures, and lessons learned on the four legs of ocean basin crossings completed by two separate Slocum electric gliders, part of the Rutgers AUV fleet.

Keywords—gliders, long duration AUV, biofouling, flight characteristics

I. Introduction

Developed in the early days of the National Oceanographic Partnership Program, Slocum gliders have become a common, robust tool in oceanographic research [1]. Users from glider centers in the United States, Brazil, South Africa, Australia, the United Kingdom, Spain, and more now deploy these gliders in ocean basins worldwide, collecting both physical and biological parameters with an ever-expanding available sensor suite. Since the first test flight off the New Jersey coast in 1999, these autonomous underwater vehicles (AUVs) have gone through several iterations, upgrades, and "hardening" to ensure their durability at sea. Rutgers University has partnered with Teledyne Webb Research since the inception, and has often been a testbed - and the catalyst - for new designs. In 2007, Rutgers technicians began experimenting with lengthening the gliders to accommodate additional batteries, as well as exploring other battery technologies that offer more available power. This resulted in a larger onboard "fuel tank", opening the door for long duration underwater flights and potential sustained monitoring operations. Rutgers has since attempted five long duration flights; of which the last four consecutive have completed successfully. These flights comprise several firsts, including the first AUV to cross an ocean basin under its own power, and more recently, the first AUV to circumnavigate an ocean basin – all the while collecting and returning valuable physical data that can be ingested by global ocean models. These accomplishments have not come without their challenges, but they have provided Rutgers glider pilots with data and experience to both prepare gliders prior to deployment and fine-tune flight mechanics to sustain long-endurance missions.

II. Background

In 2008, Slocum glider RU17, with many of its parts fabricated from excess materials in the Rutgers machine shop, was launched off the New Jersey coast in an effort to cross the North Atlantic Ocean basin. After 160 days at sea, the glider sank, approximately 200 miles west of the Azores, presumably caused primarily by a large animal interaction. Although a wealth of valuable information was lost, many lessons were also learned along the way. While large animal encounters cannot be foreseen or necessarily avoided, potentially

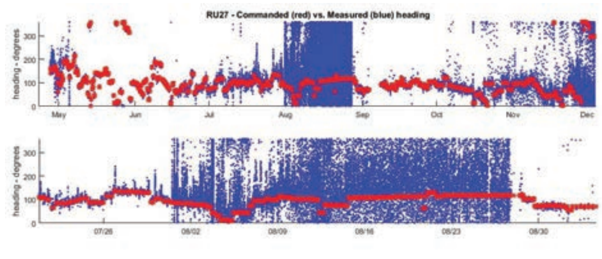

Fig. 1. Glider commanded (red) vs. measured (blue) heading. Bottom plot: August 2009 zoom.

problematic issues such as galvanic corrosion resulting from immersing non-like metals in seawater can be addressed in the lab prior to launch. Later that year, with the help of the manufacturer, a hardened version of the Slocum glider was assembled, taking note of issues observed during the previous deployment. Dubbed RU27, in April of 2009 this 200 m glider was once again launched off the New Jersey coast and headed across the Atlantic. After four months of flight in the summertime waters of the North Atlantic, RU27 could no longer maintain a heading in the intended direction of travel, even utilizing the full 25 degree extent of the rudder's range of travel. Fig. 1 shows RU27's commanded heading in red vs. measured heading in blue, highlighting the period between August and September where the glider had little to no control of its heading in the lower panel. Prior to August, there was little variation between the measured and commanded heading, but small spikes in the measured heading were becoming more noticeable as time passed. A 94% correlation in heading during the month of July dropped to less than 23% throughout August. RU27 was practically inoperable for, at this point, reasons unknown, and glider flight engineering data was doing little to aid the diagnosis.

III. Biofouling

Changes to the glider's buoyancy drive and pitch angle were made in an attempt to increase vertical velocity, but no amount of adjustment of flight parameters could bring RU27 back to operational status from afar, so a visit to the glider became imperative. Toward the end of August 2009, a small group was assembled to intercept RU27 at sea. Intentions were to provide a diagnosis and, if possible, repair the glider and allow it to continue on its mission. What met the intervention team was a rather unexpected adversary: Biofouling. Defined as the gradual accumulation of organisms on underwater surfaces, a plethora of research exists on the topic. The settling process has been well-cataloged - the initial adhesion of bacterial biofilms, followed by the settling of microorganisms (diatoms, fungi, and protozoans), and finally the settling of macroorganisms such as barnacles, polychaetes, and coelenterates [2,3,4,5]. Biofouling rates are highly dependent upon the environment; and can vary drastically between locales. Typically, areas with higher temperatures will experience a higher degree of biofouling, as temperature can determine breeding periods and growth rates [6].

Funded in part by The G. Unger Vetlesen Foundation, NOAA IOOS, University of Sao Paulo, University of Cape Town, and Rutgers, The State University of New Jersey

Fig. 2. Biofouling on University of South Florida glider after 28 days at sea

For example, Rutgers technicians experience is that a standard glider deployment off the coast of New Jersey of approximately one month duration will see little to no biofouling. Biofilms are typical of the fouling on these deployments, but barnacle growth and other macroorganism fouling is rare. Conversely, a deployment by the University of South Florida in the Gulf of Mexico will often see degradation of optical sensors within 10 days and a complete coating of fouling on the glider by the end of a one month mission [7]. (Fig. 2) Although this glider had fouled enough to compromise the quality of the data collected, it had not fouled enough to severely affect flight performance. Quite the contrary, RU27 had experienced macrofouling to such an extent that it was no longer able to function properly. Upon arrival at the glider's location approximately 200 nm west of the Azores, the intervention team noticed a fairly significant colony of Pollicipes pollicipes, or Goose Neck Barnacles, attached to various portions of the hulls of the glider. (Fig. 3) These barnacles are a common marine organism found in the mid latitudes that often attach themselves to flotsam or other debris adrift in the water column. Studies have shown that not only can these macroorganisms choose their settlement substrate on the basis of topography and/or water flow, they are also able to crawl toward their preferred location [8,9]. On RU27, these processes resulted in several distinct areas of significant growth, primarily around the joints of the glider, where the discontinuities in the smooth hull create microturbulent structures, allowing for settlement of macroorganism larvae [10]. As filter feeders, P. pollicipes have a number of cirri, which protrude from the oral cavity with the intention of collecting food. However, when a number of these organisms latch on to the hull of the Slocum Gliders, they have proven to be detrimental to missions – and especially the long duration missions - as the surface area of these foreign protrusions produces a large amount of drag. Occurrences such as these have the potential to reduce the velocity of a glider to <10% as seen with RU27. (Fig. 4)

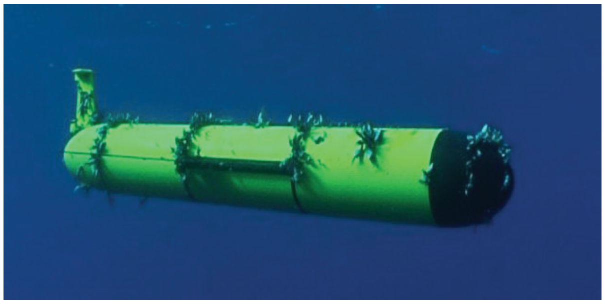

Fig. 3. P. pollicipes attached to glider RU27, primarily near joint areas (1st Atlantic glider crossing, 2009)

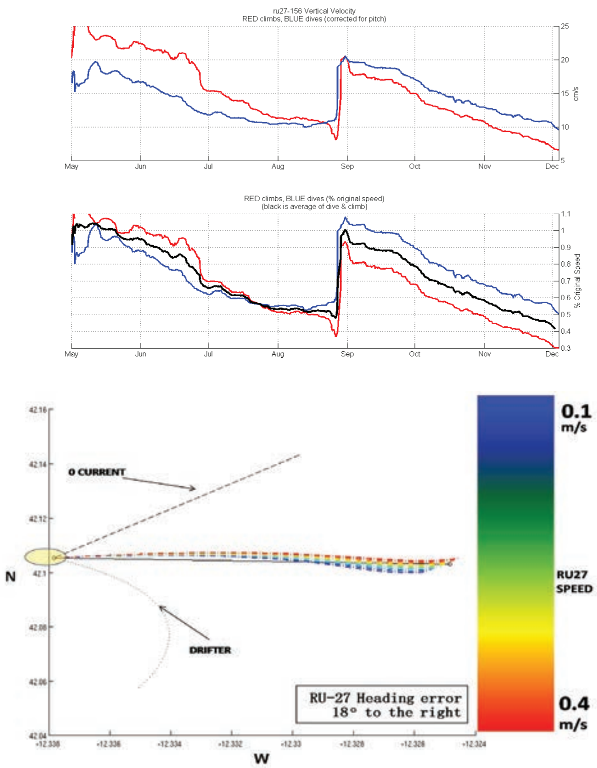

Fig. 4. RU27 vertical velocity (red – dives blue - climbs). Noticeable decay observed. The heading error was of 18º (1st Atlantic glider crossing, 2009)

Once the vertical velocity of a Slocum glider is reduced, hydrodynamic flow past the rudder is lessened, causing an associated reduction in steering ability. Although actual values can vary dependent upon glider size and configuration, these long duration flights have shown that any vertical velocity less than approximately 12 cm/s and increased drag from biofouling can result in the complete loss of ability to steer.

As depicted in Fig. 4, it does not take an excessive amount of growth to reach this threshold. Perhaps most surprising is that growth amassed despite antifouling measures taken into account prior to launch. The hull sections were covered in ClearSignal, a rubberized coating designed to be used on acoustic streamers used in surveys in the oil and gas industry [11]. An antifoulant paint provided by Epaint, EP-SN-1, was applied to the nosecone, fore stem, wings, wing rails, aft cap, tail stem, CTD (conductivity, temperature, depth sensor), and the aluminum rings between hull sections. More on antifoulant techniques will be discussed later in this paper. During the at-sea rendezvous, although it was never pulled from the water, RU27 was cleaned of all visible biofouling, and tests were conducted to ensure flight performance had been restored. With drag decreased, RU27's flight characteristics returned to normal, and the glider proceeded to make its way to Baiona, Spain. Upon recovery, it was discovered that the glider was once again fouled with P. pollicipes, albeit to a slightly lesser extent.

Colleagues from University of Las Palmas de Gran Canaria conducted a post-flight analysis of the vertical velocity decline showing that the rate of change of vertical velocity coincided with the changes in the average temperature of the water column in which RU27 was flying. Three separate episodes of velocity decline were considered, where Vmax is the initial velocity at t0, Vt is the velocity and time t (days), and k is the rate of change in days-1:

$$Vt = Vmax^{*}e^{-k(t-t0)}$$

In water with an average temperature just 1°C higher, the rate of velocity decay was an order of magnitude higher. (Fig. 5) The initial velocity decline (episode 1) encompassed 92 days – May, June, and July - and several flight parameter adjustments (increased pump throw, pitch changes, etc.). Prior to the start of episode 2, all mechanical changes to increase glider speed had been exhausted, and the next decline took a mere 12 days to reach 10% of an already reduced maximum velocity. Episode 3 encompasses the flight time after the glider had been cleaned at sea until recovery, a total of 98 days. The rate of velocity decay shows that the glider had a total of 160 days until it reached the 10% velocity threshold; a 2 month cushion, but the fouling had already begun to affect flight dynamics. This direct correlation between average water column temperature and rate of vertical velocity decay is an important consideration in long duration mission planning.

Analysis of rostrum width of P. pollicipes applied to the von Bertalanffy growth model has also provided a method to back out possible events during the glider's flight that may have contributed to barnacle attachment and speed lost. Several examples have correlated well with glider system aborts or extended analyses of flight data, where the glider had spent a considerable amount of time at the surface. Surfacing events greater than 1 hour in duration can aid in the protein polymerization, or the setting of the barnacle's "glue" [12,13,14].

IV. RU29 – CASE STUDY

RU27's success crossing the Atlantic Ocean while collecting data for global ocean models opened the door for sustained at-sea data gathering operations, and the continuance of the Challenger mission, initially proposed by Dr. Richard Spinrad, to recreate the H.M.S. Challenger's global mission w/ AUVs. To do so would require careful planning, taking note of lessons learned from RU27, as the next leg of the Challenger mission was slated for an even more remote location. The

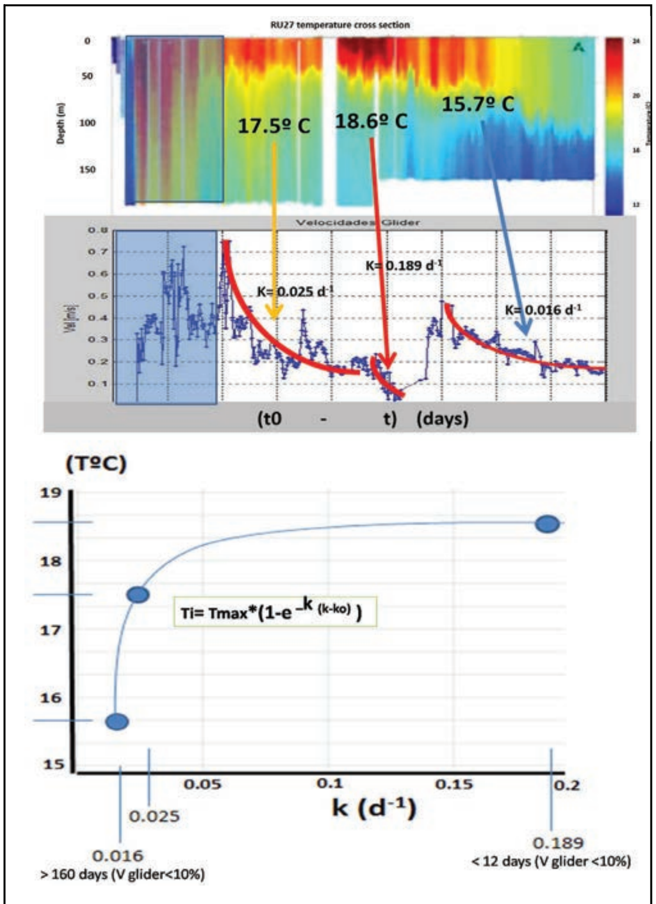

Fig. 5. Velocity decay (k in days-1) and average water column temperature correlation. (1st Atlantic glider crossing, 2009)

glider was scheduled to be launched in South Africa in January of 2013, passing near Ascension Island, and continuing on to Brazil as leg 1, with leg 2 being the return trip from Brazil to South Africa. Following is an analysis of what became 3 legs of the mission as related to background provided by RU27's maiden crossing.

A. Glider improvements – design and antifoulant techniques

RU27 was a first generation (G1) glider. The glider had anodized aluminum hulls, a flowthrough CTD, and a shallow buoyancy-drive pump rated to maximum depth of 200 m. This meant that RU27's entire flight was spent in the relatively higher productivity zones of the open ocean where light can penetrate. In addition, RU27's extended length was a product of replacing the science bay with a standard aft or fore hull. This increased the size of the glider without increasing the size of the buoyancy drive or the fin, resulting in a glider that is inherently slower than a standard sized glider. Battery packs also had to be purchased individually and soldered together to create a one-of-a-kind custom pack. For power savings, the onboard science computer was removed, and the CTD was wired back to the mainboard, similar to past Slocum glider designs, prior to the addition of a standalone science bay computer. Antifoulant protections included painting exposed parts with antifoulant paint provided by Epaint and coating the hulls with ClearSignal antifouling coating. Additional anodes were added to prevent the additional corrosion likely to be seen due to duration and the ability of marine biofilms to create additional ionic transport, thereby enhancing corrosion [15].

In contrast, RU29 is a second generation (G2) glider with several notable improvements. The extended energy bay, now a commercially available product, is simply an add-on section that allows standard battery pack fitment. Its buoyancy drive is an oil-filled bladder, ultimately resulting in both an additional 60 cc's of buoyancy drive and deeper rating, up to a maximum depth of 1000 m. It includes a standard science bay with a pumped CTD instead of flowthrough, which allows for flight characteristic (primarily pitch) changes without compromising data integrity and thermal lag calculations. Software improvements have given rise to a "low power mode", effectively allowing the glider to turn off between sampling intervals. Further updates included this feature for the standalone science computer as well, which was used to save power on leg 3, from Brazil to South Africa. Antifoulant measures again included an Epaint product on the CTD, wings, tail cone, and aft cap. Trilux 33 was used on the fore section, nosecone, and wing rails for leg 2. Paint choice was based more on color than compound at that stage. Extra zinc anodes were again added to combat biofouling-enhanced corrosion. The hull sections were coated only with the standard paint, but an additional step was taken to prevent larval settlement amidst the joints. A polyurethane "seam tape" was used to smooth out the joints and reduce the resulting microturbulent features.

B. Leg 1 – Cape Town, South Africa to Ascension Island, U.K.

Leg 1 saw the deployment of RU29 off the coast of Cape Town, South Africa, in January of 2013. The glider was deployed nearshore, in the cooler, nutrient-rich upwelled waters off the coast. Inside of the first week, RU29 had made its way toward Cape Canyon and off the shelf into the deeper waters of the South Atlantic. Eddies off the coast can push the warm surface waters down several hundred meters (Fig. 6), but the average temperature of the water column in which RU29 was able to fly (top 1000 m) was 9.75°C versus the 18°C average waters that RU27 traversed; nearly half as warm. Not wanting to pass up on lessons learned from RU27, the team at Rutgers soon decided to change RU29's top inflection depth from the surface to a depth of 125 m in an attempt to stay below the 15°C mark, and out of the euphotic zone. Average temperature of the water column from 125 m to 1000 m over the course of the deployment was 8.17°C, even with the deepening of the thermocline as the glider made its way closer to the equator. This vertical creep by the thermocline did, however, cause the top inflection depth of 125 m to be slightly over the 15°C threshold; a number chosen

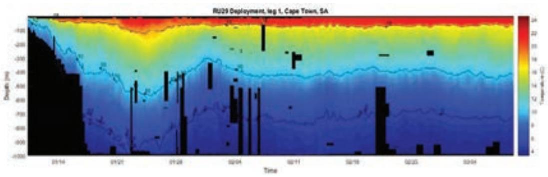

*Fig. 6. **Eddies of the Cape Town coast bring warm surface waters to depth*** (RU-29 1st South Atlantic Circumnavigation, Challenger mission (January 2013-March 2016)

to keep barnacle growth at a minimum, keeping the vertical velocity decay rate (k) less than .016/day, translating to approximately 3.5% of glider speed lost per month. Approximately halfway through the deployment RU29 fell victim to a software glitch, causing the glider to reset underwater, triggering a software bug that caused it to become stuck in a loop flying in the surface waters for the next 10 days without attempting to call in. Surprisingly, a similar software glitch allowed control to be regained, but the detrimental effects of RU29's hiatus had already begun to exhibit in the data. Running at full power in shallow water had burnt nearly 1.5 months of power in low power mode, and P. lepas, a South Atlantic species of the Goose Neck Barnacle, had colonized the glider, reducing its vertical velocity nearly 50% in less than 2 weeks, highlighting the perils of time spent at the surface. (Fig. 7) This reduction in velocity manifested itself again in the glider's inability to maintain a heading, even utilizing the full buoyancy drive and full extent of the fin's range of motion. In the true spirit of an international collaborative effort, help was enlisted from South Africa and U.K. to transport a satellite phone to an individual that was willing to sail out to the glider and clean it off – in similar fashion to RU27's initial crossing. This at-sea intervention restored the glider's vertical velocity to pre-hiatus levels, a faster rate of decay was noticed throughout the remainder of the mission. (Fig. 8) Rate of decay is presumed to be higher toward the end of the mission as the glider entered warmer surface waters near the equator, favorable to both growth and breeding rates of barnacles. Leg 1 ended with a recovery by Ascension Island residents just as the glider's battery expired. This recovery is noteworthy as it brings to light another method of biofouling; albeit more episodic as opposed to the typical chronic fouling over time. The glider had drifted overnight in relatively warm surface waters near the equator. Flying Fish, several species of which are common in the area, tend to lay their filamentous eggs on flotsam, as the eggs are negatively buoyant [16]. RU29 was fouled in mats of these filamentous eggs upon recovery. (Fig. 8) While likely not so thick and dense as to scuttle the glider, possible buoyancy discrepancies and certainly additional drag are issues to consider. The common theme throughout biofouling experiences becomes the primary lesson – keep the glider off the surface.

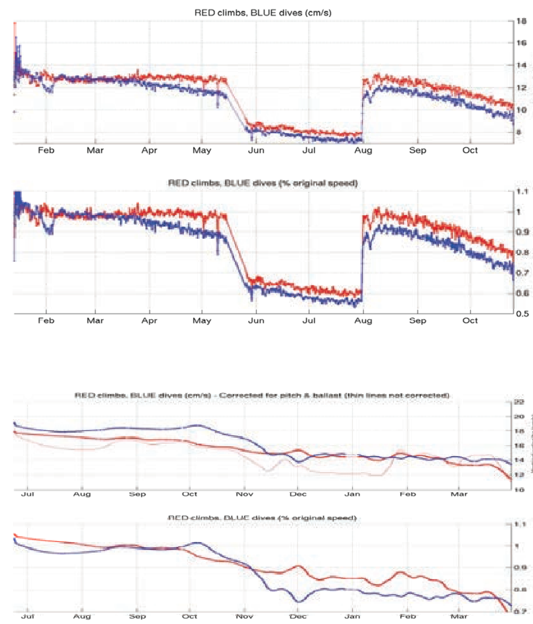

Fig. 7. (Top) RU29 vertical velocity corrected for pitch and ballast. Drastic reduction after hiatus; restored to nearly full vertical velocity after at-sea cleaning. Significantly faster rate of decay evident after cleaning, potentially due to warmer surface waters near equator. (Bottom) RU29 vertical velocity from leg 3; a more typical curve without any significant fouling events. RU-29 Challenger glider mission (January 2013-March 2016)

C. Leg 2 – Ascension Island to Ubatuba, Brazil

Leg 2 of RU29's ocean basin circumnavigation was initially unplanned, as Ascension Island was only an emergency bail-out point that became a necessity. A small team from Rutgers eventually made their way to the island with only enough field equipment to repair and redeploy the glider. Aside from replacing a damaged fin, it was no more than a routine servicing – rebattery, repaint, new anodes, and prepare for redeployment. RU29 was going in near the equator, in already warm waters, and flying throughout the southern hemisphere's summer, so biofouling concerns were forefront. Post-deployment, RU29 showed an average water column temperature of 10°C between 125-1000 m from Ascension Island to Brazil, with a significant deepening of the thermocline approximately midway through; the 18°C mark reaching as deep as 200 m between February and March. (Fig. 9) Heeding lessons learned during the two previous deployments, RU29 was deployed in deep water off the coast of Ascension Island, and was able to nearly immediately dive to full depth. With the "stay off the surface" protocol in mind, one further change was added to the glider's behavior – more yo's. Defined as a dive and a climb, adding a yo between surfacings will keep the glider underwater for several more hours. At this stage, the glider was only surfacing 1-2 times

Fig. 8. Mats of negatively buoyant flying fish eggs covering the glider (RU-29 1st South Atlantic Circumnavigation, Challenger mission (January 2013-March 2016)

daily (every 12-14 hours). A comparatively uneventful and short 6 months after deployment, RU29 was recovered off Ubatuba, Brazil – but not before collecting a wealth of data on a persistent eddy off the coast of the aptly named Cabo Frio.

D. Leg 3 – Ubatuba, Brazil to Cape Town, South Africa

Leg 3 of RU29's mission was initially slated to begin in July of 2014, but twice the glider leaked at depth only a few days after deployment. Once a miniscule scratch in the carbon fiber hull was finally located, the hull was replaced and the glider was ready for its return trip to South Africa. The glider was deployed in June of 2015, in an ocean basin averaging over 13°C, with warm surface waters comprising the top 200 m of the water column, and nearly 7000 km to traverse. (Fig. 10). Tristan de Cunha, a small island in the South Atlantic, was the only possible bailout point. Reachable only by vessel, it is not an ideal endpoint. But with experience gained, confidence levels were high. Precautions were taken during RU29's dry-dock time, and several pieces, including the bellows in the buoyancy pump, were replaced. An oddity with the persistor caused concern, and was promptly replaced. RU29 was redeployed off the shelf, where it could immediately reach full depth, in an attempt to avoid biological growth. Becoming typical of the midpoint of long duration flights, a valve on the buoyancy pump began to slip, causing oil to leak back until the pump reached an "out of deadband" phase, and turned on to pump the oil back out. This "slippage" of oil and the resulting double pumping while flying to 1000 m brought the energy usage up to a level that was not sustainable to make it across the ocean basin. The solution was to limit flight depth to 500 m, the point at which slippage would occur, but the glider would inflect prior to restarting the pump. This once again raised concerns of biofouling as the glider no longer had the ability to remain in the colder temperatures of the deep ocean. Antifoulant protection was nearly identical to previous flights; Epaint on various exposed parts of the glider, seam tape around the joints, with one additional measure taken. A number of seagoing technicians use Desitin or similar zinc oxide creams on moored instrumentation arrays with varying degrees of effectiveness, so the decision was made to add that around seams that could not be taped or painted effectively, such as where the aft cap meets the rear hull, and where the fore section tapers down to meet the nosecone. Upon recovery off

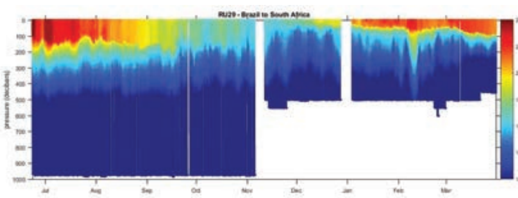

Fig. 10. RU29's temperature profile from Brazil to South Africa (Jun 2015-Mar 2016), clearly exhibiting the time spent limiting flight depth to 500 m depth (RU-29 1st South Atlantic Circumnavigation, Challenger mission (January 2013-March 2016)

the coast of South Africa, overall biofouling was minimal, confirming the effectiveness partially of antifoulant methods used prior to deployment, but primarily due to glider behavioral modifications. Adjusting flight parameters accordingly is a key component to the success of long duration flights.

Barnacles recovered along with the glider that were able to survive transport, handling, and sorting were once again analyzed by Antonio Ramos and other colleagues at University of Las Palmas de Gran Canaria. The barnacles were grouped into 3 primary size groups as measured by the width across the rostrum. Based on their sizes and estimated growth rates, their attachment date could be estimated. Results are summarized in table 1.

Table 1. Estimated barnacle settling date

Barnacle Size	Barnacle Count	Estimated Settling Date
0 to 0.75 cm	13	12/20/2015-1/15/2016
0.75 to 1.0 cm	12	10/31/2015-11/25/2015
1.0 to 1.75 cm	5	8/15/2015 (majority)

On a previous mission by another glider, Silbo, which flew almost 2000 km from the Azores Islands to the Canary Islands, a preliminary analysis of barnacle size and attachment dates was attempted. This lead to several observations that potentially long surfacing times could lead to increased barnacle settling. A typical surfacing interval (where the glider sits 1/4 above water and 3/4 in the top .5 meter) lasts 5-20 minutes. 10 minutes is typical for trans-oceanic missions. The dates in Table 1 above correlated to 2 specific events and a third sequence of events. For the smallest and largest barnacles, the singular event was an unintended reset of the computer system. This results in the vehicle performing short, shallow default missions until the glider can be retasked. In these examples, several hours passed prior to being able to retask the glider to dive deeper and stay underwater longer. The medium-sized barnacles correlated to an approximately 1 month long collection of surfacings after having switched to shallow missions due to buoyancy pump problems. These long surfacings and shallow dives were in effort to troubleshoot buoyancy engine issues and involved longer transfers of engineering data.

V. Conclusions

Advances is battery technology and other power systems have shifted biofouling to the forefront of issues facing long duration flights. Corrosion-enhancing biofilms and flight performance-hampering macrofouling can all contribute to the detriment of the project, and perhaps even the untimely demise of the vehicle. Thus antifoulant measures need to be taken both prior to launch and throughout the duration of the flight.

A. Antifoulants

Preparations for any glider flight longer than 1-2 months typically include a combination of antifoulant paints, a polyurethane seam tape, and some type of zinc oxide cream. There are 2 primary points of consideration for selection of an antifoulant paint – ablation and composition. While the vast majority of antifoulant paints on the market are ablative, this is not a desirable attribute for long duration AUVs. Typical speeds are much too slow for the ablation to prevent biofouling, and the loss of weight from this process could potentially contribute to ballasting complications. Paint composition must also be considered, as copper compounds have been the standard formula for many years. While effective against biofouling, in this particular two-metal system, aluminum becomes the anode. Galvanic corrosion could sacrifice the integrity of aluminum components, potentially causing a leak and the eventual loss of the vehicle. This reasoning led to the selection of Epaint's compounds and Interlux's Trilux 33, as both are purportedly aluminum safe antifoulant compounds. Most external components of the glider receive at least one coat of paint, including the nosecone, tail cone, wings, etc. Overall effectiveness appears marginal, and there is no protection for parts in proximity to these paints.

Polyurethane seam tape is used to cover the areas where the glider is joined together, with small holes poked around the perimeter to aid in allowing air to escape. This tape seals off the areas that cause microturbulent features that can allow barnacle larvae to settle and also prevents them from being able to crawl and settle in the joints. Thus far, this seam tape appears to be quite effective, as there has not been significant growth near areas where the tape was used. Experience with zinc oxide creams is limited to only one (albeit the longest) leg of the circumnavigation of the South Atlantic basin. This was applied to seams that were difficult to tape such as where the nosecone meets the fore section and where the tail cone meets the aft cap. Little to no growth was seen in areas where the zinc oxide cream was used.

In the case of an aborted mission, the glider should be cleaned and scrubbed thoroughly prior to being redeployed in an effort to remove any larvae that may have already settled. Barnacle attachment needs to be avoided and prevented for as long as possible.

Throughout the duration of the flight, behavioral modifications and flight parameter adjustments tend to be most critical and are perhaps the most effective tool for preventing biofouling. Whether event-based like a flying fish spawn or the more standard accumulation of biomass over time, keeping the vehicle out of the surface layer is a key component to mission success. Data returns are decimated to include only what is necessary for science and vehicle status monitoring in an effort to keep the time spent at the surface to a minimum. If the glider is adrift for greater than one hour, protein polymerization occurs and barnacles will likely remain attached for the duration of the flight. Avoiding long surfacings is paramount. CTD data is typically gathered on the following dive to ensure a full water column profile, but surface inflection depth is then adjusted to 125 m for several ensuing cycles. Keeping the glider out of the euphotic zone changes the photoperiod of barnacles that may already be attached, increases the average barometric pressure experienced, and reduces their feeding capabilities in the cooler water at depth. 125 m was chosen initially as the inflection depth as it coincided with the 15°C mark where barnacle growth rates remain slow enough as to provide a manageable decline in glider speed. These behavioral adjustments provide the best chance of success, and should be instituted as default parameters to avoid surfacings in the event of a system reset.

Continuing research in biomimicry (e.g. sharkskin paints) and liquefied surfaces could have significant future implications in the fight against biofouling, but as of this paper these products are not commercially available.

I. Introduction

Environmental factors, such as nutrient availability and irradiance, play the key role in phytoplankton physiology. Phytoplankton growth and marine primary production depend on physiological performance of phytoplankton that in turn respond to varying environmental conditions. The use of variable fluorescence kinetics has increasingly become a vital method in oceanographic studies; however, its use within the community is limited by the complexity of physiological data interpretation and the cost of available instruments. Physiological responses also span across different scales that are hard to record with the discrete manual sampling methods available.

The Quantum Yield of Photosynthesis (ϕ) is defined as the ratio of oxygen evolved in photosynthesis (or carbon assimilated) to the number of photons absorbed in the process [1]. Evaluating the Quantum Yield of Photosynthesis *in vivo* provides an alternate approach to C^{14} uptake, for example, for investigating how photosynthetic processes are affected by environmental factors, as it is highly sensitive to environmental stresses. The variable fluorescence [2] is the most sensitive signal detected from the ocean, which provides considerable insight into the photophysiology of phytoplankton, in particular the structure and function of Photosystem II (PSII). In the field, the maximum yield of photochemistry in PSII (Fv/Fm) has been widely used as a diagnostic tool to rapidly assess the health of phytoplankton and infer potential stresses or primary production controls [3].

Traditional sampling strategies such as the pump-and-probe, Fast Repetition Rate Fluorometers (FRRF) and more recently the Fluorescence Induction and Relaxation (FIRe) sensor [4] have been employed to characterize and understand the factors controlling phytoplankton physiology and primary production in the ocean. While continuous automated acquisition of physiological parameters is commonly used for surface waters using different fluorometers, repeated depth measurements over diel cycles are less often reported. When available, depth profiles have been built from discrete samples collected in bottles and ran on the benchtop instrument. Besides being a destructive sampling method, it is also constrained by the fact that the water collection and instrument run need to be done manually. Another benefit of measuring variable fluorescence *in situ* lies in the fact that the assessment of the photo-physiological properties of phytoplankton happens in the actual light fields in which these organisms are growing [5]. An important point since these physiological properties are highly sensitive to the ambient light fields.

Phytoplankton developed photoadaptation mechanisms to overcome light-induced stresses [6] i.e. to optimize light absorption under low light conditions or reducing total photon absorption under supra-optimal irradiances. These mechanisms, reflecting changes in the functional absorption cross-section of PSII (σ_{PSII}), are short-term light adaptation mechanisms such as Non-Photochemical Quenching (state transition, energy dependent and photoinhibition) and long term modifications in the light harvesting complex of phytoplankton (i.e. photoacclimation) [1]. The integration of an instrument, such as the FIRe sensor, that is capable of evaluating depth-dependent phytoplankton physiology in situ and in high resolution is an important step to fully understand phytoplankton dynamics and marine primary production.

II. Materials and Methods

A. Slocum gliders

Slocum electric gliders are a robust tool to map, with high spatial and temporal resolution, the upper water column properties in different environments [7], including polar regions. These 1.5 m torpedo-shaped buoyancy driven autonomous underwater vehicles provide high-resolution surveys of the physical and bio-optical properties of the water column [7].

Glider used for these deployments (ru24) was equipped with a Seabird Conductivity-Temperature-Depth (CTD) sensor. Glider based conductivity, temperature and depth measurements were compared with a calibrated ship CTD sensor on deployment and recovery to ensure data quality, as well as with a calibrated laboratory CTD prior to deployment.

978-1-5090-1537-5/16/$31.00 ©2016 IEEE

Glider profiles were binned into 1-meter bins and assigned a mid-point latitude and longitude. For each profile, Mixed Layer Depth (MLD) was determined by finding the depth of the maximum water column buoyancy frequency, max (N^2). An upward facing Photosynthetic Active Radiation (PAR) sensor was also integrated in the glider to record PAR in the range of 400-700 nm.

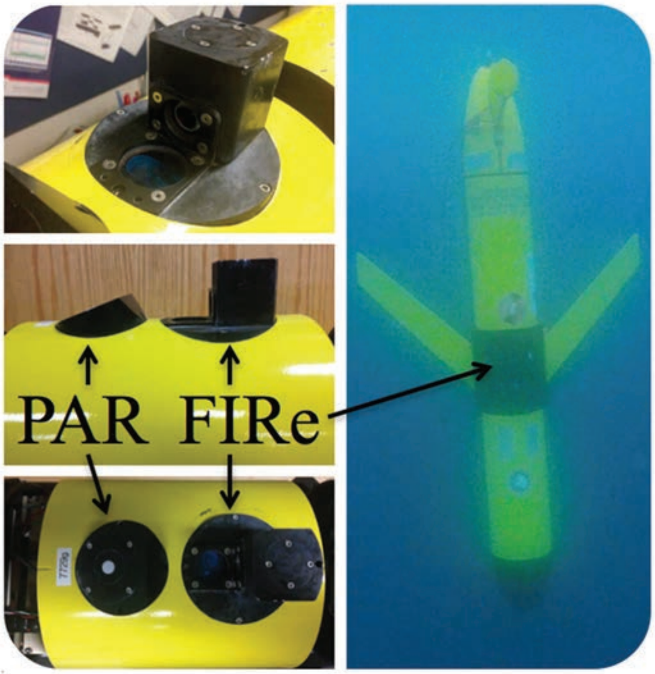

Figure 1: Fluorescence Induction and Relaxation (FIRe) and PAR sensors integrated into a Slocum glider.

B. FIRe sensor

In order to evaluate physiological responses of phytoplankton to physical forcing, ru24 was equipped with a FIRe sensor [8], the first sensor of its kind to be integrated in a glider. This allowed a high-resolution continuous mapping of the phytoplankton physiological responses to variable light regimes in the water column.

The FIRe sensor [4] provides a comprehensive suite of photosynthetic characteristics of the organisms, such as the minimum (F_o) and maximum (F_m) fluorescence yields corresponding to open and closed reaction centers of PSII, respectively, variable fluorescence component (F_v) and the functional absorption cross section of PSII (σ_{PSII}). This is accomplished by employing a sequence of excitation flashes of light with controlled intensity, duration and interval between flashes. The maximum quantum yield (efficiency) of photochemistry in PSII, denoted by ϕ_{PSII}, is given by the ratio F_v/F_m, i.e. $[F_m\text{-}F_o]/F_m$. Dark-adapted F_v/F_m has been widely used as an algal "health" parameter, which is responsive to the short-term (hours) light and nutrient history of the cells [9]. By definition, the actual quantum yield of photochemistry in PSII at a given PAR level is denoted Fv'/F_m'. A cap was used to cover the FIRe sample chamber so the signal was measured in the dark (the prime (') symbol after the variable denotes any light acclimated sample measured in darkness [10]). At low irradiance (under 100 $\mu E/m^2/s$, which comprises over 98% of the data points), Fv'/Fm' approaches Fv/Fm, and so for simplicity, Fv'/Fm' will be referred to as photosynthetic efficiency for the remaining of the manuscript.

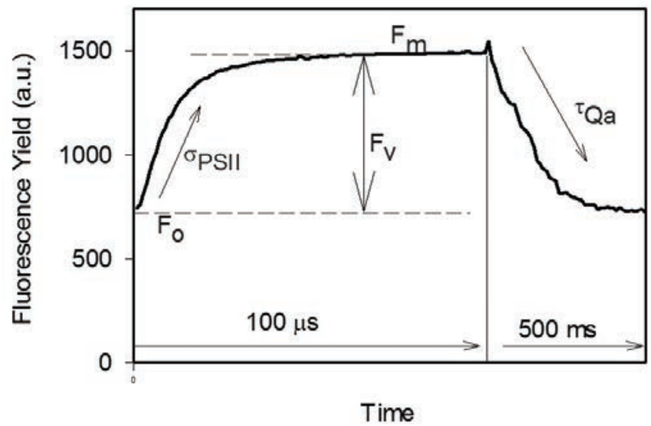

Figure 2: FIRe parameters from the Single Turnover Flash (STF) protocol. Minimum (Fo) and maximum (Fm) fluorescence yields corresponding to open and closed reaction centers of PSII, respectively, variable fluorescence component (Fv, where Fv=Fm-Fo), the quantum yield of photochemistry in PSII (Fv/Fm) and the functional absorption cross-section of PSII (σ_{PSII}).

C. FIRe glider data post-deployment processing

Several steps comprise the FIRe glider post-deployment processing. After the glider is recovered, raw data are downloaded from the onboard FIRe memory. Binary raw data is run through the Satlantic software and converted to ascii format. Data was then corrected for gain of the detector before applying any other corrections:

a) Blanks

"Blank" is the background signal recorded from the sample without phytoplankton in it. The blank signal includes a small amount of fluorescence from dissolved organic matter (DOM) and phytoplankton degradation products dissolved in water. As in any fluorometer, blanks must be removed from fluorescence signals (only Fm and Fo, as other FIRe parameters are blank-independent) to get accurate, blank-corrected values of chlorophyll fluorescence. Although blanks in the FIRe sensors are usually relatively small and may be neglected in many cases, the blank correction procedure will be critical in waters with high amount of DOM and/or small amount of phytoplankton (e.g. oligotrophic regions or deep layers below the euphotic zone).

As it is not possible to collect blanks while the glider is deployed, discrete *in situ* water samples were collected from the surface and at a depth well below the deep chlorophyll maximum (DCM), several times before and after the glider deployments. Surface and deep water samples were filtered and measured using the FIRe glider. Average surface and deep values were calculated and subtracted from the FIRe glider fluorescence signals during the deployment from the surface up to the DCM and below the DCM, respectively.

b) Functional absorption cross-section of PSII (σ_{PSII})

In order to convert the measured σ_{PSII} (in relative units) into absolute units (Å^2 quantum^{-1}), a correction coefficient was determined by cross-calibrating the FIRe glider against a "standard" calibrated benchtop FIRe instrument. A correction factor of 1650 was determined for the FIRe sensor RU24.

c) Converting FIRe Fm to chlorophyll-a concentrations

Discrete water samples at 8 different depths within the euphotic zone were collected during each glider deployment and recovery to further convert the measured Fm (maximum fluorescence intensities, in relative units) into absolute chlorophyll concentration (μg L^{-1}), a variable measured by other sensors, facilitating further comparisons with other studies. Chlorophyll-*a* (chl-*a*) is a proxy of phytoplankton biomass. Water samples were filtered onto 25 mm Whatman GF/F filters and extracted using 90% acetone.

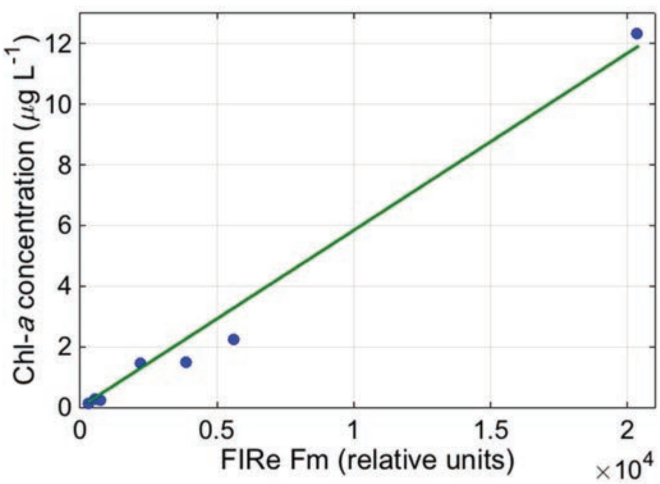

Figure 3: Scatter plot and respective linear trend from discrete water samples measured by the FIRe sensor (FIRe Fm) and chlorophyll-*a* concentrations obtained by the fluorometric method.

As a linear correlation is expected between FIRe Fm and chl-*a* concentration, the same sample was also run through the FIRe glider and its Fm measurement recorded. FIRe Fm throughout the deployment was then converted into chl-*a* concentration (Equation 1) using the high linear correlation (r^2=0.98) found between the 2 variables:

$$Chl = Fm \times 5.84 \times 10^{-4} \quad (1)$$

where *Chl* is the derived chlorophyll concentration and *Fm* is the maximum fluorescence measured by the FIRe sensor, after gain and blank corrections. QA/QC methods were applied to the data to ensure data quality.

D. Sampling overview

Palmer Deep (PD) is one of the cross-shelf canyons located in the West Antarctic Peninsula (WAP) where there is evidence of increased primary production [11, 12] and localized penguin foraging [13]. The National Science Foundation (NSF) funded Palmer Long Term Ecological Research (PAL-LTER) project [14] has been monitoring this ecosystem since 1991. The dependence of higher trophic levels on primary producers has led to increased efforts to try to understand the link between some of the physical drivers (such as stratification and mixed layer depth, MLD) and phytoplankton dynamics [12, 15, 16].

Part of this project has been focusing on understanding the phytoplankton physiological responses due to physical forcing. Until recently, sampling methods were restricted to discrete samples taken by a rosette or go-flo bottles collected from the ship or zodiac, respectively. This method provides insight into the depth dependent response of phytoplankton physiology, however it requires manual water collection at certain depths and times. A second shipboard method measures physiological parameters continuously using the onboard flow-through system at 5 m depth. This provides higher resolution horizontal maps, but lacks the depth component. The integration of a FIRe system into a glider allowed us to overcome these constrains and to sample *in situ* phytoplankton physiological responses in high-resolution both vertically and horizontally.

By measuring changes in maximal (F_m') and minimal (F_o') fluorescence in the same water mass over a diel cycle, one can get fluorescence values representative of a darkened adapted and relaxed state [17]. Evaluating diel cyles will also allow us to better understand the light effect on phytoplankton physiology by isolating the effect of supra-irradiance during peak daytime hours.

Here we present the results of two FIRe glider missions that have been designed to evaluate physiological responses at different temporal and spatial scales:

a) Temporal evolution – "the drift mission"

b) Spatial variability – "the station keeping mission"

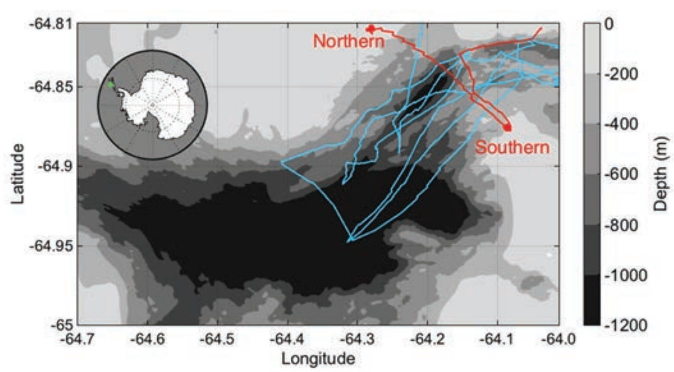

Figure 4: Bathymetry map of Palmer Deep canyon (green dot) in the WAP, Antarctica with the 2 sampling strategies used in the study: 1) drift mission (blue) to evaluate temporal changes in phytoplankton physiology and 2) station keeping mission (red) to evaluate spatial variability in phytoplankton physiology due to physical forcing.

III. EVALUATING TEMPORAL CHANGES

Previous studies have shown that the community structure, such as phytoplankton cell size and taxonomy, has influence on the photosynthetic rates, and therefore on the variable fluorescence signal [18]. In order to better isolate the temporal signal in phytoplankton photosynthetic efficiency, a mission was designed (Figure 4, blue) where the same water mass would be followed. This would allow a better characterization of physiological changes of the same community over time. The principle behind this mission was to conduct drift missions starting southwest of the canyon head as the dominant currents would push the glider towards the head of the canon. Every hour, the glider would perform a corkscrew dive and climb (fin set all the way to starboard side), while drifting at the surface in between dives. This way the same water mass was being followed and, by default, the same phytoplankton community would be evaluated during that drift. Four drift transects were conducted that lasted around 2 diel cycles each.

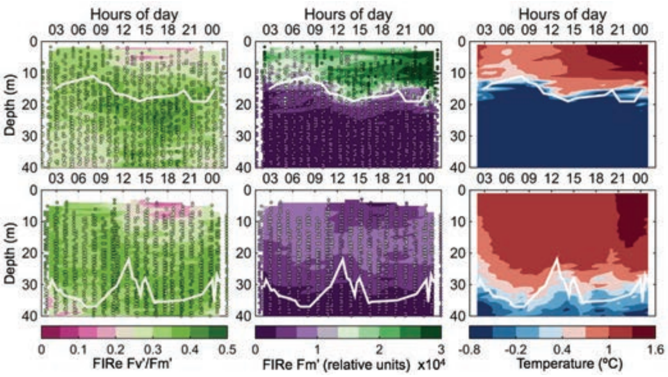

Figure 5: Averaged diel cycles of Fv'/Fm' (Photosynthetic efficiency), Fm' (proxy for phytoplankton biomass) and temperature for 2 different MLD (white line) regimes. Dots represent actual in FIRe glider measurements.

Phytoplankton acclimate to light levels averaged over the MLD. As stratification increases during spring/summer time, cells start to acclimate to the light intensity at each depth. Shallow MLDs provide a relatively stable light environment that allows phytoplankton to photoacclimate on the timescale of 1-2 days [19]. Intense mixing can bring dim-light adapted phytoplankton to the upper MLD where phytoplankton get exposed to supra-optimal irradiances and a decrease in Fm and Fv/Fm is recorded. Non-Photochemical Quenching (NPQ) is evident from reduction in both Fv'/Fm' and Fm' during daytime hours. Under higher irradiance (11:00-22:00 GMT), both Fv/Fm and Fm decrease, with the lowest values and deeper light penetration during peak irradiance hours (15:00-18:00 GMT). NPQ signal is more marked (Fv'/Fm'<0.1) when MLD is deeper as phytoplankton cells are acclimated to a mid-MLD light level, and therefore show higher light stress under supra-optimal irradiances.

IV. EVALUATING SPATIAL VARIABILITY

Spatial variability in the water column structure has been recorded across the head of the canyon [12]. In order to evaluate whether phytoplankton physiological responses are related to physical forcing, a mission was designed (Figure 4, red) where diel cycles of FIRe parameters were recorded at each location together with the standard CTD measurements. The station keeping glider recorded 2 consecutive diel cycles at each location (Figure 6), where at least one out of three dives/climbs would record FIRe data (approximately one FIRe dive an hour). In the remaining dives, the glider would only capture water column physical parameters.

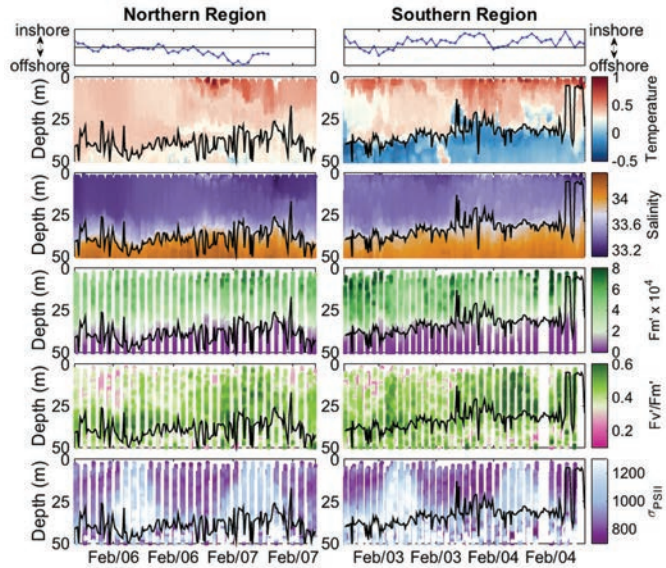

Figure 6: Comparison of 2 diel cycles at each region. Top row indicates dominant surface currents: inshore (oceanic "warm" influence) and offshore (coastal "cold" current). Temperature (°C), Salinity and FIRe parameters Fm' (relative units), Fv'/Fm' and σ_{PSII} (functional absorption cross-section of PSII, Å^2 quantum^{-1}) are presented for both regions. Black line denotes MLD.

V. EVALUATING PHOTOACCLIMATION MECHANISMS

Phytoplankton developed photo-adaptation mechanisms to overcome light-induced stresses, i.e. to optimize light absorption under low light conditions or to reduce total photon utilization under supra-optimal irradiances. Our preliminary analyses have shown different photoacclimation responses resulting from different MLD dynamics due to different solar radiation exposure conditions (both time and intensity).

An exponential relationship was found between Fv'/F_m' and PAR (Figure 7, left). Under low light (nighttime periods and deeper depths) Fv'/F_m' was maximum and equal to F_v/F_m, while under high light (high PAR) Fv'/F_m' decreased, an evidence of light-induced down regulation of PSII. A power fit curve (Equation 2) was applied to the FIRe data to evaluate differences in photoacclimation regimes under two different MLD conditions:

$$\frac{Fv'}{Fm'} = a\, e^{-\frac{PAR}{E_k}} \qquad (2)$$

where Fv'/F_m' is photosynthetic efficiency and PAR is Photosynthetic Available Radiance, both measured by the glider, E_k is light saturation parameter and a is a constant.

By comparing E_k values calculated for each depth/PAR bin, we can begin to distinguish between similar photo-physiologic communities, i.e. communities that have similar photoacclimation regimes and different photo-physiological communities and relate that to the depth of the ML.

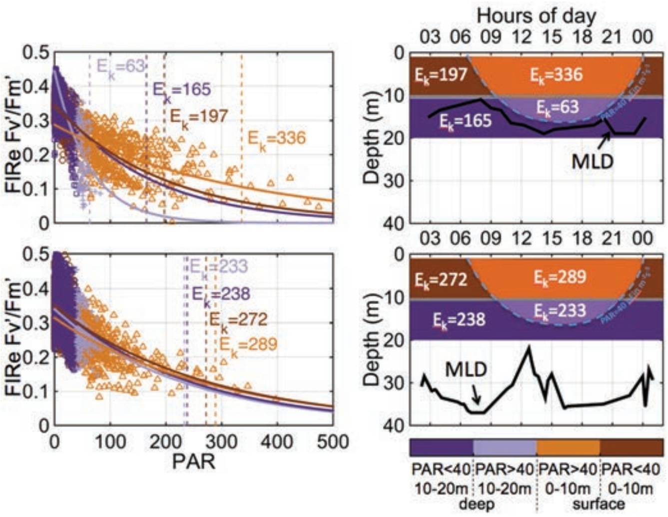

Figure 7: (left) Scatter plots of Fv'/F_m' and PAR with power curve fits for each PAR and depth bins highlighted in the legend. E_k values for each fitting are also presented; (right) schematics on difference in photoacclimation regimes presented in the plots on the left, evaluating the light saturation parameter in relation to the MLD (black line).

When MLD is shallow (Figure 7, top), the two layers show different E_k values. The much higher E_k, seen at the surface, gives an indication of phytoplankton acclimated to high irradiances while the lower E_k seen below the MLD shows low light acclimation. On the other hand, when MLD is deeper, and the 2 layers (0-20 m) fall within the ML, E_k values are much more similar, indicating that phytoplankton have similar photoacclimation regimes in the 2 layers. Note that the E_k of both layers when ML is deeper also fall between the first 2 E_k, indicative of a mid-light level acclimation.

Table 1: Summary on depth-dependent photoacclimation regimes in a nutrient replete environment.

MLD (m)	Stratification max[N^2], s^{-2}	Biomass (FIRe Fm')	Layer 0-10m	Layer 10-20m
Shallow ($\overline{MLD} \approx 16$)	High ($\overline{N^2} \approx 2x10^{-3}$)	High	High-light acclimated (higher E_k)	Low-light acclimated (lower E_k)
Deeper ($\overline{MLD} \approx 32$)	Low ($\overline{N^2} \approx 6.7x10^{-4}$)	Low	Mid-light (MLD) acclimated E_k(0-10m) ≈ E_k(10-20m)	

VI. Conclusions

The integration of a FIRe sensor into a glider allows us to map, with high temporal and spatial resolution, phytoplankton physiological responses to physical forcing. Different missions were designed to evaluate the temporal and spatial variability of phytoplankton physiology by using a drift and a station keeping mission, respectively. Diel cycles collected show a clear diurnal variations driven by incident radiation, with both maximal fluorescence and photosynthetic efficiency (in any light adapted phytoplankton) showing reduced values only in the upper 10-15 meters of the water column at the highest irradiances. Further analyses comparing different MLD regimes have shown different photoacclimation responses (light saturation parameter, E_k) resulting from differences in solar radiation exposure conditions (both time and intensity), reflected in the depth of the ML. Further analyses include determining a method to correct the FIRe glider fluorescence profiles in the upper ocean during daytime by comparing the maximum fluorescence during the highest irradiance (daytime) with the lowest irradiance (nighttime).

Acknowledgments

We would like to thank the Rutgers glider team, Palmer Station personnel and ARSV Laurence M. Gould crew for support in deployments and recoveries. Filipa Carvalho was funded by a Portuguese doctoral fellowship from Fundação para a Ciência e Tecnologia (DFRH - SFRH/BD/72705/2010).

Stratified coastal ocean interactions with tropical cyclones

S.M. Glenn[1], T.N. Miles[1], G.N. Seroka[1], Y. Xu[2], R.K. Forney[1], F. Yu[3], H. Roarty[1], O. Schofield[1] & J. Kohut[1]

Hurricane-intensity forecast improvements currently lag the progress achieved for hurricane tracks. Integrated ocean observations and simulations during hurricane Irene (2011) reveal that the wind-forced two-layer circulation of the stratified coastal ocean, and resultant shear-induced mixing, led to significant and rapid ahead-of-eye-centre cooling (at least 6 °C and up to 11 °C) over a wide swath of the continental shelf. Atmospheric simulations establish this cooling as the missing contribution required to reproduce Irene's accelerated intensity reduction. Historical buoys from 1985 to 2015 show that ahead-of-eye-centre cooling occurred beneath all 11 tropical cyclones that traversed the Mid-Atlantic Bight continental shelf during stratified summer conditions. A Yellow Sea buoy similarly revealed significant and rapid ahead-of-eye-centre cooling during Typhoon Muifa (2011). These findings establish that including realistic coastal baroclinic processes in forecasts of storm intensity and impacts will be increasingly critical to mid-latitude population centres as sea levels rise and tropical cyclone maximum intensities migrate poleward.

Tropical cyclones are among the most destructive weather phenomena on Earth[1]. Declines in hurricane related mortalities[2] reflect improvements in global atmospheric and ensemble modelling approaches[3] that have reduced hurricane track forecast errors by factors of 2–3 (ref. 4). Despite two decades of progress in hurricane track prediction, improvements in hurricane-intensity forecast skill have lagged significantly[4]. The predictions, public response and unexpected devastation patterns related to Hurricane Irene exemplify this dichotomy. Accurate track forecasts days in advance provided time for preparations and coastal evacuations, but Irene's official forecast maximum wind speeds along the Mid-Atlantic coast were consistently $\sim 5\,\mathrm{m\,s^{-1}}$ too high[5]. Irene instead caused catastrophic inland flooding because of heavy rainfall[5], making it the eighth costliest cyclone to hit the United States since 1900 (ref. 6), with damages of $\sim$\$16 billion (ref. 5). These intensity forecast uncertainties have significant negative consequences, ranging from unnecessary preparation costs to future public skepticism[7].

Improved tropical cyclone intensity predictions include dependencies on the rapid space–time evolution of the atmosphere–ocean responses and feedbacks[8]. Coupled atmosphere–ocean models demonstrate that small shifts in sea surface temperature (SST) and stratification, even on small (100 km) horizontal scales, can have significant impacts on storm intensity[9–11]. Several studies have noted[12–16] the relationship between warm and cold mesoscale features in the deep ocean and rapid changes in intensity, but the coastal ocean has received much less attention.

Here, utilizing an ocean observing network to inform ocean and atmospheric model simulations, the role of baroclinic processes on a stratified coastal ocean and their impact on the intensity of Hurricane Irene was quantified. The high percentage of ahead-of-eye-centre[14,17,18] cooling (76–98%) observed in Irene is not reproduced by standard open ocean models that exclude these coastal baroclinic processes. Atmospheric model sensitivity studies indicate that intense in-storm sea surface cooling over a strongly stratified coastal regime is the missing contribution required to reproduce the rapid decay of Hurricane Irene's intensity. The 30-year historical buoy record shows an average of 73% of the in-storm cooling occurs ahead-of-eye-centre on the Mid-Atlantic Bight (MAB) in the stratified season. A Yellow Sea buoy observed up to 85% of in-storm cooling ahead-of-eye-centre during Super Typhoon Muifa (2011). The results demonstrate the importance of rapid ahead-of-eye-centre vertical shear-induced mixing processes and the ensuing ocean–atmosphere feedbacks for generating more accurate simulations of storm intensity.

Results

Synoptic conditions. Hurricane Irene formed east of the Caribbean's Windward Islands on 22 August 2011 and made initial United States landfall in North Carolina as a Category 1 hurricane on 27 August. It re-emerged over the ocean in the MAB before a second landfall in New Jersey as a tropical storm on 28 August (ref. 5), closely following the historical northeastward tracks of hurricanes along the northeast United States[19]. Irene accelerated and lost intensity as it crossed the MAB, moving parallel to the coast with the eye over inner-continental shelf waters (Fig. 1a). Propagation was rapid at $30–40\,\mathrm{km\,h^{-1}}$, requiring only $\sim$9.5 h to cross from North Carolina to New Jersey landfall. Cloud bands extended over 600 km from the eye centre, obscuring the ocean from satellite infrared SST sensors during passage. Differencing 3-day composites of cloud-free satellite imagery before (24–26 August) from after (29–31 August) Irene reveals the regional pattern of MAB sea surface cooling (Fig. 1a and Supplementary Fig. 1A,B). The largest

cooling (5–11 °C) was observed to the right of the eye centre over the MAB's middle to outer shelf. Inner shelf cooling was slightly less, with averages of 3–5 °C of cooling within the 25-km radius eye wall (Supplementary Fig. 1C). Cooling was much less significant on the shelf seas to the south of the MAB, in the deep ocean to the east and, as previously noted in other hurricanes[20], along the very shallow unstratified coast, bays and sounds.

Observations. National Data Buoy Center (NDBC) buoys 44009 and 44065 recorded peak wind speeds (Supplementary Fig. 2) near 20 m s^{-1} from offshore as Irene approached. At these NDBC buoys and at 44100, water temperatures dropped rapidly by 3.8–6.3 °C ahead of eye centre passage (Fig. 1b–d), representing 82–98% of the in-storm cooling at these locations (Supplementary Fig. 3). At Irene's fast propagation speed, the eye was still 150–200 km to the south after the most rapid cooling was complete. As the ocean surface cooled, observed air temperatures were greater than SSTs, indicating air–sea-sensible heat fluxes were from the atmosphere into the ocean.

Atmospheric conditions (Fig. 2a) were recorded just inshore of a Slocum autonomous underwater glider[21,22] measuring subsurface ocean conditions[23] during Irene at the location shown in Fig. 1a (see Supplementary Fig. 4 for a plot of the complete glider track well before, during and after the storm). Winds initially from offshore (90°), with speeds near 20 m s^{-1} ahead of the eye, rotated rapidly to blow from onshore (270°) after the eye passed. Glider-observed subsurface temperatures (Fig. 2b) indicate that initially, typical MAB summer stratification[24] was present, with a seasonally warmed surface layer ($\sim$24 °C) above the MAB Cold Pool[25] ($<$10 °C) separated by a sharp ($<$8 m thick) thermocline. Significant cooling of the surface layer (5.1 °C) and deepening of the thermocline ($>$15 m) was observed under the leading edge of the storm. Little change in thermocline depth and much less cooling (1.6 °C) of the upper layer was observed after eye passage. Thus, ahead-of-eye-centre cooling represents 76% of in-storm cooling observed at the glider (Fig. 2b). Both the glider and buoy data suggest that much of the satellite observed SST cooling (over $\sim$100,000 km^2 of continental shelf) occurred ahead-of-eye-centre.

Ocean surface currents measured by a CODAR high-frequency (HF) radar[26] network[27] illustrated the rapid response of the thin surface layer (Supplementary Fig. 5) to the changing wind direction (Fig. 2a). Time-series of the cross-shelf components of the currents (Fig. 2c) at the glider location, with positive values towards land, indicate that the onshore surface currents began building before the eye entered the MAB, increasing to a peak value $>$50 cm s^{-1} towards the coast before the eye passage. Along-shelf currents throughout the water column were weak (Fig. 2d). After the eye, the winds changed direction and within a few hours, the cross-shelf surface currents switched to offshore. Despite the strong observed surface currents, the depth-averaged current (Fig. 2c) reported by the glider remained small during the storm's duration, with peaks barely exceeding 5 cm s^{-1}. As in deep water, the current response is baroclinic[28,29], but the low depth-averaged current implies a strong offshore flow in the bottom layer. These bottom layer currents were estimated based on the relative layer thicknesses and the requirement that the combined surface and bottom layer-averaged currents matched the glider-observed dead-reckoned depth-averaged current. The estimated bottom layer currents accelerated in the offshore direction as the eye approached, causing significant shear between the two layers at the same time the surface layer was deepening and cooling.

Ocean model simulations. Coastal ocean three-dimensional (3D) model simulations of Irene using the Regional Ocean Modeling System (ROMS) in the MAB[30,31] successfully reproduced the thermocline deepening and surface layer cooling (Fig. 3a) similar to the glider observations (Fig. 2b). The modelled cross-shelf velocity component (Fig. 3b) also has similarities to the combined glider and HF radar data (Fig. 2c). The surface layer flow accelerated shoreward for 12 h until eye passage, while the bottom layer responded more slowly with an offshore counter-flow. A few hours after eye passage, the cross-shelf flows reversed, also consistent with observations. The dominant terms in the cross-shelf momentum balance (Fig. 3g) indicate that the surface wind stress increased as the eye approached and decreased as it receded. Before the eye centre arrival, the presence of a coastline produced an offshore-directed pressure gradient that nearly balanced the wind stress and accelerated the offshore jet in the bottom layer. After the storm passage, the cross-shelf surface current switched to offshore; the cross-shelf pressure gradient also switched sign and was redirected towards the coast. At this point in the storm, the dominant cross-shelf momentum balance was nearly geostrophic (Fig. 3g) with a northward along-shelf surface current (Fig. 3d).

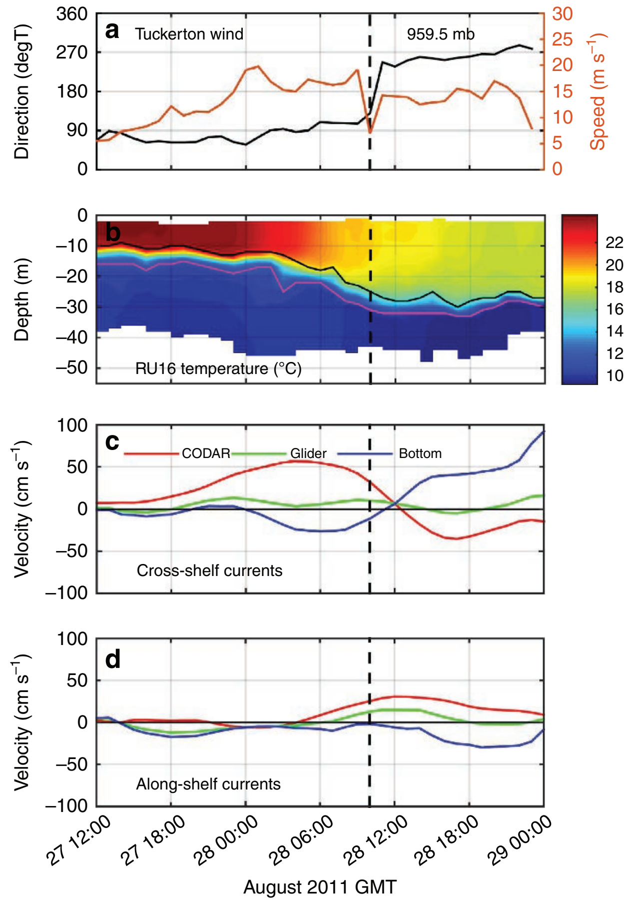

Figure 2 | Data from a local meteorological station, glider and HF radar. (**a**) Tuckerton WeatherFlow, Inc. station 10 m wind speed (orange) and direction from (black) with vertical black dashed line/label indicating the time/value of the minimum air pressure corresponding to landfall time on 28 August at 935 GMT. (**b**) Temporal evolution and vertical structure of the glider temperature during storm conditions with lines indicating top (black) and bottom (magenta) of thermocline. (**c**) Cross-shelf currents (positive onshore, negative offshore) for the surface layer (red) from CODAR HF Radar, depth-averaged (green) from the glider and bottom layer (blue) calculated from the depth-weighted average of the HF radar and glider velocities. (**d**) Same as **c** but for along-shelf currents (positive up-shelf northeastward and negative down-shelf southwestward).

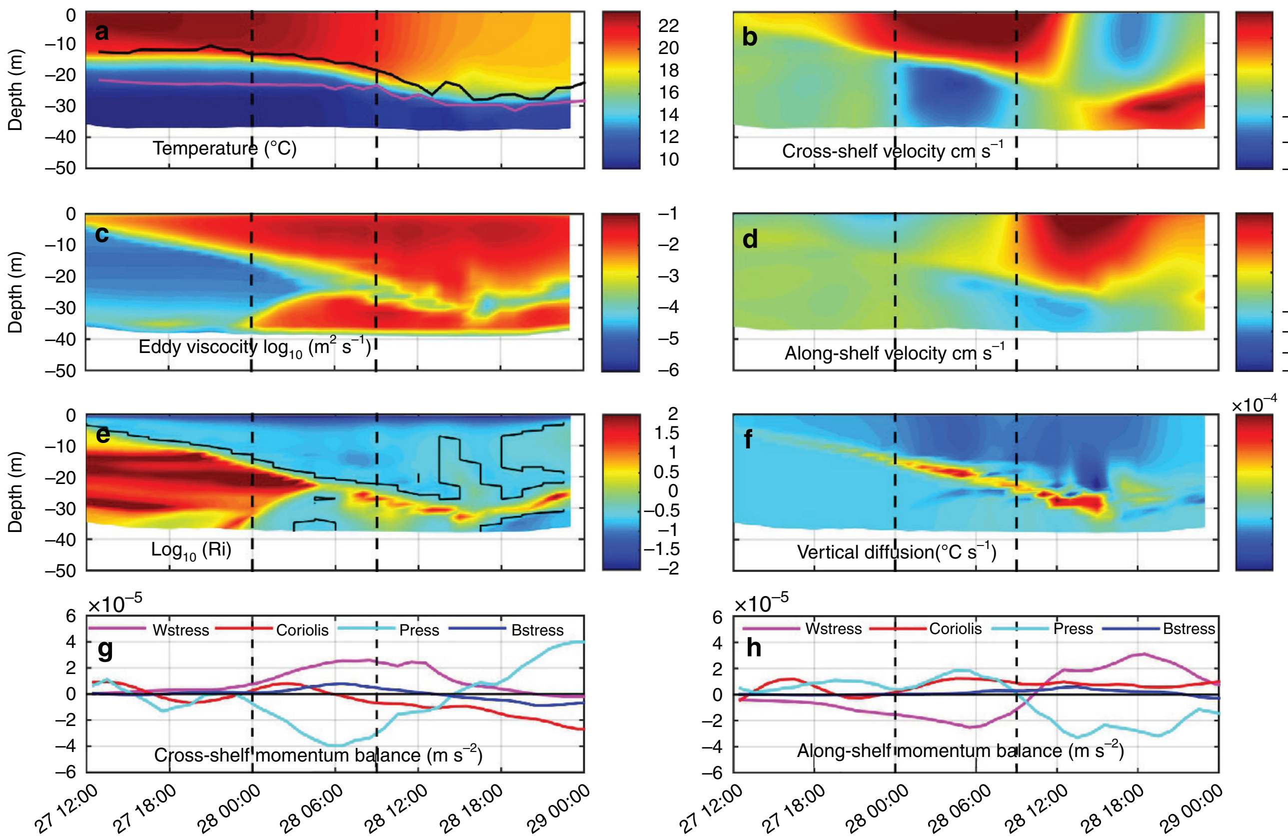

Figure 3 | ROMS ocean simulation results at the glider location. ROMS ocean simulation results at the glider location during the storm period, with first vertical black dashed line indicating initiation of the coastal baroclinic response and second vertical black dashed line indicating eye passage. (**a**) Temperature with top (black) and bottom (magenta) of thermocline as in Fig. 2b. (**b**) Cross-shelf velocity (red/yellow onshore; blue offshore). (**c**) Eddy viscosity. (**d**) Along-shelf velocity (red/yellow northward; blue southward). (**e**) $\mathrm{Log_{10}}$(Richardson number) with black contour indicating Richardson number of 0.25. (**f**) Vertical diffusion temperature diagnostic equation term, showing warming (positive, red/yellow) and cooling (negative, dark blue). (**g**) Dominant depth-averaged cross-shelf momentum balance terms (positive onshore and negative offshore) from wind stress (wstress, magenta), Coriolis force (coriolis, red), pressure gradient (press, cyan) and bottom stress (bstress, blue). (**h**) Same as **g** but for along-shelf momentum balance terms (positive northward, negative southward).

The subsurface cross-shelf circulation within the two-layer coastal ocean had a significant influence on vertical mixing as illustrated by the Richardson number (Fig. 3e) and the vertical eddy viscosity (Fig. 3c). The Richardson number and the eddy viscosity show that the surface layer deepened to meet the stratification at the top of the thermocline as the surface layer accelerated with the approaching storm. As the offshore counter current accelerated in the bottom boundary layer, the lower layer Richardson number also decreased and eddy viscosity increased until the two layers interacted. The most rapid ahead-of-eye-centre cooling and deepening of the surface layer occurred when the small Richardson numbers and large vertical eddy viscosities from the surface and bottom boundary layers overlapped. The model's temperature diagnostic equation indicates that vertical diffusion (Fig. 3f) was the dominant term (Supplementary Fig. 6) acting to deepen the thermocline and cool the surface layer during the event.

Atmospheric model simulations. Atmospheric model simulations of Irene used the Weather Research and Forecasting (WRF)[32] model as applied to the US East Coast for tropical cyclone forecasting[33]. Typical surface boundary approaches in uncoupled atmospheric models use satellite SSTs over water that remain fixed when new data is not available because of cloud cover. A matrix of over 130 simulations revealed ahead-of-eye-centre cooling of the ocean's surface layer has a significant impact on intensity as reflected in the hurricane pressure (Fig. 4) and wind fields (Supplementary Fig. 7). Examining the ensemble of simulations with track errors less than one eye-wall radius, the largest wind and pressure intensity sensitivities were generated using fixed warm pre-storm and cold post-storm SST boundary conditions (Supplementary Figs 8,9). The sea level pressure (SLP) fields at landfall indicate the warm (Fig. 4a) versus the cold (Fig. 4b) SST changed the centre SLP by 7–8 hPa, with the maximum wind speed reduced by $>5\,\mathrm{m\,s^{-1}}$ due to the cooler SST (Supplementary Fig. 7). The minimum SLP time history (Fig. 4c) of selected model runs can be compared with the National Hurricane Center (NHC) best track parameters. The best track central pressure remains constant near 952 hPa until the eye enters the MAB (28 August at about 00 h), followed by a steady increase in the central pressure to 965 hPa 13 h later as the eye leaves the MAB. Once Irene's eye entered the MAB, the cold SST air–sea flux parameterization sensitivities all produce a reduction in intensity that cluster with the best track analysis, while the warm SST air–sea flux parameterization sensitivities maintain a lower minimum SLP with little change nearly until landfall.

The top three model sensitivities are quantified by the envelope width for the minimum SLP (Fig. 4d). For both warm and cold SSTs, sensitivities to the three standard WRF air–sea flux formulations range from 0 to 2 hPa for the 13 h after the eye entered the MAB. The sensitivity to warm and cold SST

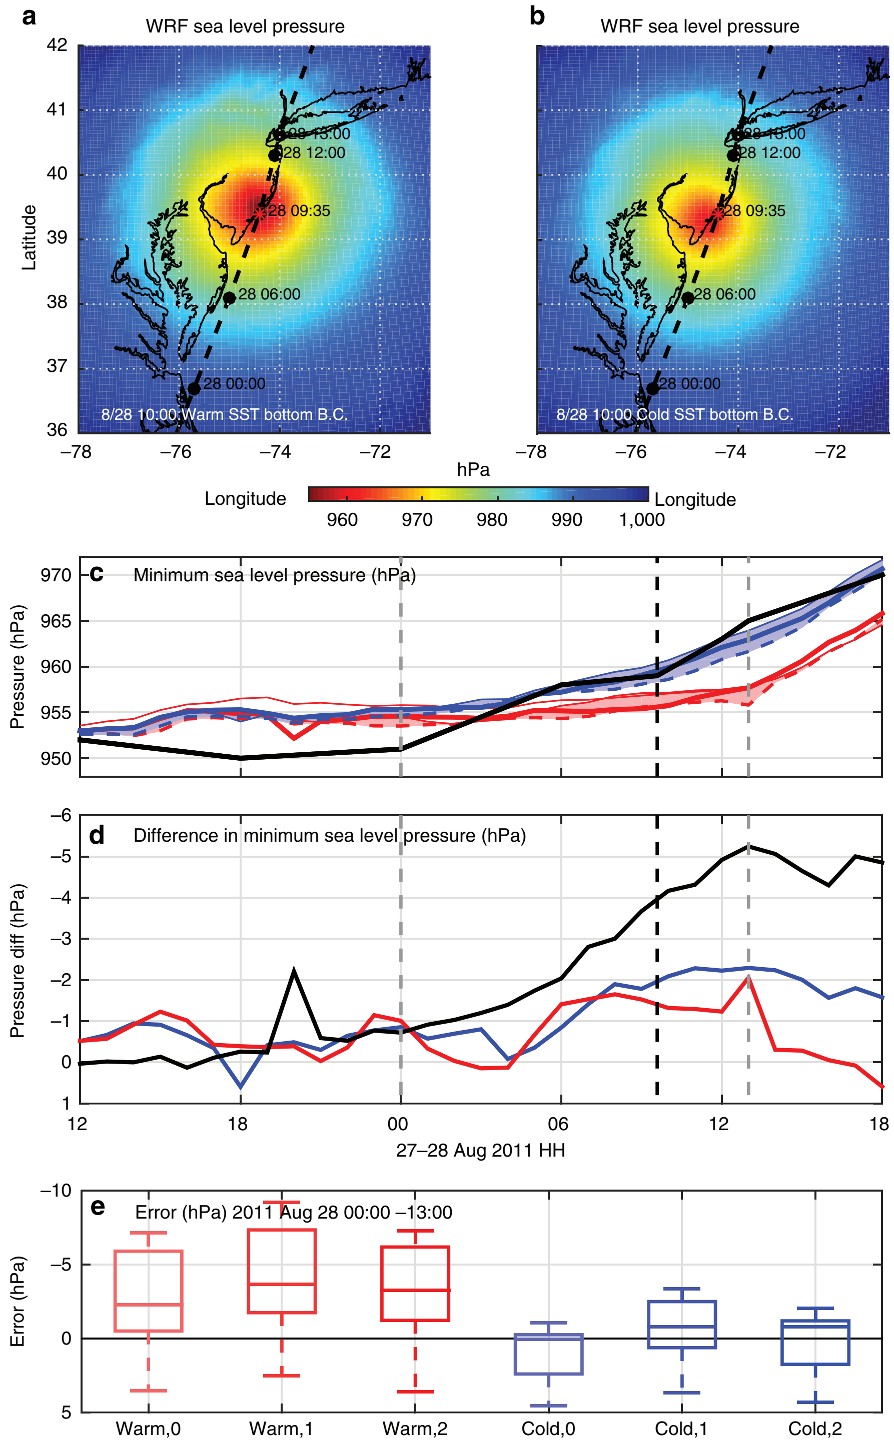

Figure 4 | WRF atmospheric model simulation results. (**a**) WRF model SLP (with surface flux option 2) at landfall (red star) for the warm SST boundary condition with NHC best track drawn as in Fig. 1a. (**b**) Same as **a** but for the cold SST. (**c**) Minimum SLP for NHC best track (black), and WRF's three air–sea flux parameterization options isftcflx = 0 (thin line); 1 (dotted line); and 2 (thick line) for the warm (red) and cold (blue) SST. Vertical grey and black dashed lines indicate eye enters MAB, makes landfall and leaves MAB. (**d**) Model SLP sensitivity to SST (black, warm minus cold SST for isftcflx = 2), and to flux parameterizations (isftcflx = 1 minus isftcflx = 0) for warm (red) and cold (blue) SST. (**e**) Box and whisker plots of SLP deviations from NHC best track when eye is over MAB for warm (red) and cold (blue) SST.

begins growing as the storm nears the MAB, climbing steadily to 5 hPa as it leaves the MAB. Statistical comparisons of each model run to the NHC best track over the MAB are quantified by the box and whisker plots (Fig. 4e) showing the median, inter-quartile range and outliers. The three warm SST air–sea flux sensitivities consistently over-predict the intensity with minimum SLPs that are too low, while the three cold SST air–sea flux sensitivities more accurately reflect the intensity reduction for all of the air–sea flux options.

Table 1 | Sea surface temperature cooling in coastal tropical cyclones.

Storm name	Buoy	Water depth (m)	Ahead-of-eye-centre cooling (°C)	In-storm cooling (°C)	% Ahead-of-eye-centre
Arthur (2014)	44014	48	1.4	2.4	58%

Muifa (2011)	37.045 N 122.66 E	31	4.1	4.8	85%

Ahead-of-eye-centre cooling (°C), in-storm cooling (°C) and % ahead-of-eye-centre observed at nearshore MAB buoys for 11 tropical cyclones that traversed the MAB continental shelf during summer stratified conditions since 1985, additional data from Hurricane Irene and Super Typhoon Muifa.

Discussion

Using Hurricane Irene as a diagnostic case study, a new feedback mechanism on storm intensity in the coastal ocean has been identified. The strong onshore winds occurring ahead-of-eye-centre in tropical cyclones and the coastal wall set up a down-welling circulation that limits the storm surge and results in significant shear across the thermocline. This shear leads to turbulent entrainment of abundant cold bottom water and mixing with warmer surface water. The resulting ocean cooling reduces surface heat fluxes to the atmosphere, weakening the storm.

Rapid tropical cyclone intensity changes over the deep ocean have been correlated with storm passage over warm and cold core eddies[12–16,34]. Also in the deep ocean, SST changes of as little as 1 °C are noted to significantly impact storm intensity[9,35]. During Hurricane Irene, ahead-of-eye-centre cooling of 3.8–6.3 °C was observed with nearshore buoys (Supplementary Fig. 3) and 5.1 °C was observed with a mid-shelf glider (Fig. 2). Storm-induced cooling in deep water is often equally distributed between the front and back half of the storm[36]. Deep ocean simulations of Irene with both a 1D ocean mixed layer model and the 3D Price–Weller–Pinkel[37] model produced 32 and 56% of the in-storm cooling ahead-of-eye-centre, respectively. In Hurricane Irene, 76% (glider) to 98% (buoy 44100) of the in-storm cooling occurred ahead-of-eye-centre, indicating that coastal baroclinic processes are enhancing the percentage of ahead-of-eye-centre cooling in Irene.

To verify that enhanced ahead-of-eye-centre coastal ocean cooling is not unique to Irene, 30 years of historical nearshore buoy data throughout the MAB were investigated. During that time period, ahead-of-eye-centre cooling was observed in all 11 tropical cyclones that tracked northeastward over the MAB continental shelf during the highly stratified summer months (June–August)[24,38] (Table 1 and Supplementary Figs 10–12). The maximum continental shelf buoy observed ahead-of-eye-centre cooling for these 11 storms averages 2.7 ± 1.3 °C, representing an average of 73% of the in-storm cooling.

An 11-year global satellite climatology[39] reveals that the shallow mid-latitude Yellow Sea and northern East China Sea also experience a large 20 °C seasonal SST cycle, similar to the MAB but over three times larger in area. A 1986 Yellow Sea shipboard conductivity temperature and depth survey reports surface to bottom temperature differences approaching 15 °C (ref. 40), also similar to the stratified summer MAB. Maps of western Pacific typhoon tracks (coast.noaa.gov/hurricanes) indicate 26 typhoons have tracked across the northern East China Sea and Yellow Sea during June–August since 1985. Like Irene, the landfalling intensity of Super Typhoon Muifa (2011) was over-predicted by standard models[41]. Satellite SST maps indicate Muifa caused significant in-storm cooling (up to 7 °C) across ~300,000 km^2 of the continental shelf[41]. Nearshore buoy observations show cooling of 4.1 °C (85% of the in-storm cooling observed at that location) was ahead-of-eye-centre (Table 1, Supplementary Fig. 13).

Globally, over the past 30 years, tropical cyclone maximum intensities have migrated poleward[42]. In the North Atlantic, hurricane intensities have increased since the early 1980s and are projected to continue to increase as the climate warms[43–46]. Combined with rapid sea level rise[47], mid-latitude population centres will experience heightened vulnerability to storm surge and inundation from increasingly powerful storms. To mitigate these risks, improved forecasting of tropical cyclone intensity over mid-latitude stratified coastal seas is vital, and will require realistic 3D ocean models to forecast enhanced ahead-of-eye-centre cooling.

Methods

Data source. The Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) is a sustained regional component of the US Integrated Ocean Observing System (IOOS)[48]. Its integrated observation network of satellites, buoys, coastal meteorological stations, HF radar and autonomous underwater gliders provided the data used in this study[49].

Satellite remote sensing. National Oceanographic and Atmospheric Administration (NOAA) Advanced Very High-Resolution Radiometer (AVHRR) satellite data (Supplementary Fig. 1) were acquired through a SeaSpace TeraScan L-Band satellite ground station at Rutgers University. AVHRR data are converted to SST using the multi-channel SST algorithm[50]. To specifically map areas of rapid cooling, a 'coldest-dark-pixel' composite technique is used to identify and remove bright cloud covered pixels while retaining the darker ocean pixels. This is accomplished through the following series of tests performed on AVHRR channels 4 and 2 scans. Pixels are considered contaminated by clouds and removed if (1) AVHRR channel 4 (10.3–11.3 μm) temperatures are <5 °C (3.5 °C) in summer (winter); or (2) near infrared albedo in daytime AVHRR Channel 2 (0.725–1 μm) exceeds 2.3% (an empirically derived threshold specific to the MAB). Further tests are performed on 3 × 3 km grid boxes to account for large changes in temperature over short distances typical of cloud edges. Centre pixels are flagged as potential cloud edges and removed if (1) temperature changes in AVHRR channel 4 scans are $>1\,°C$ across the centre point of each 3×3 grid data; or (2) the change in infrared albedo across the centre of each 3×3 grid box is $>0.15\%$. After declouding is performed, the resulting 3 days of scans between 12:00 to 17:00 GMT are composited with the NASA (National Aeronautics and Space Administration) short-term Prediction Research and Transition centre (SPoRT) 2 km blended 7-day SST product. At each pixel the coldest value is retained between all daytime AVHRR scans for the past 3 days and the SPoRT SST product for that day to ensure retention of coastal upwelling zones and regions that underwent rapid mixing. Consistent with real-time processing protocols, the date assigned to each composite corresponds to the final day of the data window.

Meteorological observations. Meteorological observations were obtained from NOAA NDBC buoys, coastal towers and pier stations, and a WeatherFlow Inc. meteorological tower located in Tuckerton, New Jersey (Fig. 1a). Buoys 44009 (38.461° North and 74.703° West) and 44065 (40.369° North and 73.703° West) included wind speed and direction measured at a height of 5 m, air temperature at a height of 4 m and ocean temperatures at 0.6 m depth. Buoy 44100 (36.255° North and 75.591° West) is a Waverider buoy managed by Scripps Institution of Oceanography that measured ocean temperatures at 0.46 m depth. Station DUKN7 (36.184° North and 75.746° West) is a coastal station that measures air temperature at 15.68 m above mean sea level. The Tuckerton WeatherFlow Inc. meteorological tower (39.52° North and 74.32° West) measured wind speed and direction at 12 m. Meteorological data is plotted at the standard frequencies and averaging intervals reported by these stations.

High frequency radar. A network of over 40 CODAR Ocean Sensors SeaSonde HF Radar stations[26] are deployed along the MAB coast by a consortium of institutions coordinated through MARACOOS[27]. The stations transmit HF radio waves that are scattered off the ocean surface waves and then received back on shore. The Doppler shift in the Bragg peaks of the received signal are used to map the radial components of the total surface velocity field in front of each station[51]. Radial components from multiple stations are combined using an optimal interpolation scheme[52] to produce 1 h centre-averaged hourly surface current maps[53] with a nominal 6 km spatial resolution (Supplementary Fig. 5).

Autonomous underwater gliders. Teledyne Webb Research Slocum gliders are buoyancy-driven underwater vehicles that act as mobile sensor platforms[22]. These instrument platforms adjust small amounts of buoyancy in order to glide through the water column at 20–30 $cm\,s^{-1}$ in a sawtooth pattern. At pre-programmed intervals the gliders come to the surface and transfer data back to Rutgers University in near real-time. The glider used in this study, RU16, was equipped with an un-pumped Seabird conductivity temperature and depth sensor that logged data every 4 s on downcasts and upcasts. Depth- and time-averaged velocity calculations were performed using a dead-reckoning technique typical for such platforms[22,54,55]. The measured pitch angle, fall velocity and a model of glider flight to estimate angle of attack are used to calculate an underwater horizontal displacement during each dive segment. The difference between the calculated horizontal displacement from the final pre-dive location and the actual surfacing location divided by the time underwater provides an estimate of depth- and time-averaged velocity.

A combination of dead-reckoned depth-averaged glider currents and HF radar surface currents are used to estimate bottom currents along the glider track (Fig. 2c). The following algorithm assumes that the HF radar surface currents are representative of the surface layer above the thermocline (defined as the maximum vertical temperature gradient along each profile) and requires that the depth-weighted average surface and bottom layer currents must equal the total depth-averaged glider current:

$$U_b = \frac{U_g(H_s+H_b)}{H_b} - \frac{U_sH_s}{H_b} \tag{1}$$

$$V_b = \frac{V_g(H_s+H_b)}{H_b} - \frac{V_sH_s}{H_b} \tag{2}$$

where H_s and H_b are the layer thicknesses above and below the thermocline, respectively, U_g and V_g are along- and cross-shelf depth-averaged currents, respectively, from glider dead-reckoning, U_s and V_s are surface layer-averaged currents from HF radar, and U_b and V_b are the calculated bottom layer-averaged currents (Fig. 2).

ROMS model setup. The numerical simulations were conducted using the ROMS[31], a free-surface, sigma coordinate, primitive equation ocean model (code available at http://www.myroms.org) that has been widely used in a diverse range of coastal applications. The ESPreSSO (Experimental System for Predicting Shelf and Slope Optics) model[56] covers the MAB from the centre of Cape Cod southward to Cape Hatteras, from the coast to beyond the shelf break and shelf/slope front. Gridded bathymetric data is used to construct a model grid with a horizontal resolution of 5 km (Supplementary Fig. 4) and 36 vertical levels in a terrain-following s-coordinate system. The initial conditions were developed from the same domain ROMS run with strong constrained four-dimensional variational (4D-Var) data assimilation[57]. The meteorological forcing is from the North American Mesoscale (NAM) model 12 km 3-hourly forecast data. Reanalyses of surface air temperature, pressure, relative humidity, 10 m vector winds, precipitation, downward longwave radiation and net shortwave radiation were used to specify the surface fluxes of momentum and buoyancy based on the COARE bulk formulae[58]. Boundary conditions are daily two-dimensional surface elevation, as well as three-dimensional velocity, temperature, and salinity fields from the Hybrid Coordinate Ocean Model Navy Coupled Ocean Data Assimilation forecast system. Inflows for the seven largest rivers are from daily average United States Geological Survey discharge data. Tidal boundary conditions are from the The ADvanced CIRCulation tidal model. The general length scale method k-kl type vertical mixing scheme[59,60] is used to compute vertical turbulence diffusivity.

ROMS momentum balance analysis. We extracted depth-averaged momentum balance terms from ROMS (Fig. 3g–h) at the glider sampling location in order to diagnose the dominant forces during the storm, where the acceleration terms are balanced by a combination of horizontal advection, pressure gradient, surface and bottom stresses and the Coriolis force (horizontal diffusion was small and neglected in this case):

$$\underbrace{\frac{\partial u}{\partial t}}_{\text{Acceleration}} = \underbrace{-\frac{\partial(uu)}{\partial x} - \frac{\partial(vu)}{\partial y}}_{\text{Horizonal advection}} \underbrace{-\frac{1}{\rho_0}\frac{\partial P}{\partial x}}_{\text{Pressure gradient}} + \underbrace{\left(\underbrace{\frac{\tau_s^x}{h\rho_0}}_{\text{Surface}} - \underbrace{\frac{\tau_b^x}{h\rho_0}}_{\text{Bottom}}\right)}_{\text{Stress}} + \underbrace{fv}_{\text{Coriolis}} \tag{3}$$

$$\underbrace{\frac{\partial v}{\partial t}}_{\text{Acceleration}} = \underbrace{-\frac{\partial(uv)}{\partial x} - \frac{\partial(vv)}{\partial y}}_{\text{Horizonal advection}} \underbrace{-\frac{1}{\rho_0}\frac{\partial P}{\partial y}}_{\text{Pressure gradient}} + \underbrace{\left(\underbrace{\frac{\tau_s^y}{h\rho_0}}_{\text{Surface}} - \underbrace{\frac{\tau_b^y}{h\rho_0}}_{\text{Bottom}}\right)}_{\text{Stress}} - \underbrace{fu}_{\text{Coriolis}} \tag{4}$$

where u and v are the along-shelf and cross-shelf components of velocity respectively, t is time, P is pressure, ρ_o is a reference density, τ_s and τ_b are surface and bottom stresses, h is water column depth and f is the latitude-dependent Coriolis frequency.

ROMS heat balance analysis. *Heat balance analysis*. The general conservation expression for the temperature budget in ROMS is given by

$$\frac{\partial T}{\partial t} = -\frac{\partial(uT)}{\partial x} - \frac{\partial(vT)}{\partial y} - \frac{\partial(wT)}{\partial z} + \frac{\partial A_{kt}\frac{\partial T}{\partial z}}{\partial z} + \mathcal{D}_T + \mathcal{F}_T \tag{5}$$

with the following surface and bottom boundary conditions:

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=0} = \frac{Q_{net}}{\rho_0 C_p} \tag{6}$$

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=-h} = 0 \tag{7}$$

Here, T is the temperature, t is time, u, v and w are the along-shelf, cross-shelf and vertical components of velocity. A_{kt} is the vertical diffusivity coefficient, $\mathcal{D}_T$ is the horizontal diffusion term and $\mathcal{F}_T$ is friction. Q_{net} is the surface net heat flux, $\rho_0 = 1025\,kg\,m^{-3}$ is a reference density, $C_p = 3985\,J\,(kg\,°C)^{-1}$ is the specific heat capacity of seawater and h is the water depth.

The ROMS conservation of heat equation was used to diagnose the relative contributions of the different terms responsible for the modelled temperature change. Time-series of the vertical temperature diagnostic terms were investigated along the glider track with emphasis on the temperature evolution between the top of the thermocline depth (the shallowest location where the vertical temperature gradient exceeded $0.4\,°C\,m^{-1}$, black contour in Fig. 3a and Supplementary Fig. 6) and the transition layer depth (the deepest location where the vertical temperature gradient exceeded $0.7\,°C\,m^{-1}$, magenta contour in Fig. 3a and Supplementary Fig. 6). Term-by-term analysis of equation 5 offered additional insights on the temperature source and sink terms. Supplementary Fig. 6A shows the temperature rate of change, which is the sum of the vertical diffusion term (Supplementary Fig. 6B) and advection term (Supplementary Fig. 6C), in which the advection term is separated into along-shelf advection (Supplementary Fig. 6D), cross-shelf advection (Supplementary Fig. 6E) and vertical advection (Supplementary Fig. 6F). The horizontal diffusion term's order of magnitude is much smaller than other terms and is not plotted. The dominant term influencing the surface mixed layer temperature change was the vertical diffusion, which is plotted in Fig. 3f.

WRF-ARW model setup. The Weather Research and Forecasting Advanced Research (WRF-ARW) dynamical core (code available at http://www.wrf-model.org)[32], Version 3.4 was used for the atmospheric simulations in this study. WRF-ARW is a fully compressible, non-hydrostatic, terrain-following coordinate, primitive equation atmospheric model. Our WRF-ARW domain extends from South Florida to Nova Scotia (Supplementary Fig. 14), with grid resolution of 6 km in the horizontal and 35 vertical levels. Lateral boundary conditions used are from the Global Forecast System (GFS) 0.5° initialized at 06 UTC on 27 August 2011.

Our simulations begin at 06 UTC on 27 August 2011 when Hurricane Irene was south of North Carolina (NC) over the South-Atlantic Bight (SAB) and end at 18

UTC on 28 August 2011 as the storm moved into New England. Simulation results shown (Fig. 4c,d and Supplementary Fig. 7C,D) begin at 12 UTC on 27 August 2011, at NC landfall time, after the model has 6 h to adjust to vortex initialization. WRF's digital filter initialization (DFI) was run to determine the sensitivities to different realizations of the GFS initializations. DFI deepened the initial vortex central pressure by over 10–960 hPa, which matches GFS initial central pressure (Supplementary Fig. 15). However, downstream sensitivity to DFI beyond 2 h was minimal.

For our control run, the following are used: longwave and shortwave radiation physics were both computed by the Rapid Radiative Transfer Model-Global scheme; the Monin–Obukhov atmospheric layer model and the Noah Land Surface Model were used with the Yonsei University planetary boundary layer scheme; and the WRF Double-Moment 6-class moisture microphysics scheme was used for grid-scale precipitation processes.

WRF sensitivity to SST. The model was run over 130 times to compare the sensitivity of certain parameter tuning. All sensitivities were compared to the control run (described above), which for surface boundary conditions over the ocean, that is, SST, used the Real-Time Global High-Resolution (RTG HR) SST analysis from 00 UTC on 27 August 2011 fixed throughout the simulation. This is the warm pre-storm SST, and has temperatures across the model domain similar to the AVHRR coldest-dark-pixel composite a day earlier (Supplementary Fig. 1A). By having the control run use Real-Time Global High-Resolution SST fixed throughout the simulation, we are consistent with what the operational NAM 12 km model used for bottom boundary conditions over the ocean.

To show the maximum impact of the ahead-of-eye-centre SST cooling on storm intensity, we compared our control run with a simulation using observed cold post-storm SST. For this, we used our AVHRR coldest-dark-pixel composite, which includes data from 29 to 31 August 2011 (Supplementary Fig. 1B). According to underwater glider and NDBC buoy observations along Irene's entire MAB track, almost all of the SST cooling occurred ahead of Irene's eye centre (Fig. 1b–d). NDBC buoy observations near Irene's track in the SAB (41013, 41036, 41037) also show ahead-of-eye-centre SST cooling, but values are on the order of 1 °C or less (Fig. 1a). Because our model simulations include only 6 h of storm presence over the SAB before NC landfall, and SST cooling in the SAB was significantly less than observed in the MAB (Fig. 1), we can conclude that the main result from our SST sensitivity is due to the ahead-of-eye-centre cooling in the MAB.

WRF sensitivity to air-sea flux parameterizations. The equations for the momentum (τ), sensible (H) and latent heat fluxes (E) are as follows:

$$\tau = -\rho C_D U^2 \tag{8}$$

$$H = -(\rho c_p) C_H U(\theta_{2m} - \theta_{sfc}) \tag{9}$$

$$E = -(\rho L_v) C_Q U(q_{2m} - q_{sfc}) \tag{10}$$

where ρ is density of air, C_D is drag coefficient, U is 10 m wind speed, c_p is specific heat capacity of air, C_H is sensible heat coefficient, θ_{2m} is potential temperature at 2 m and θ_{sfc} is potential temperature at the surface, L_v is enthalpy of vaporization, C_Q is latent heat coefficient, q_{2m} is specific humidity at 2 m and q_{sfc} is interfacial specific humidity at the surface.

Three options exist in WRF-ARW Version 3.0 and later for air–sea flux parameterizations (WRF namelist option isftcflx = 0, 1, and 2; see (ref. 61) for more details). These parameterization options change the momentum (z_0), sensible heat (z_T) and latent heat roughness lengths (z_Q) in the following equations for drag (C_D), sensible heat (C_H) and latent heat (C_Q) coefficients:

$$C_D = K^2/[\ln(z_{ref}/z_0)]^2 \tag{11}$$

$$C_H = \left(C_D^{1/2}\right)[K/\ln(z_{ref}/z_T)] \tag{12}$$

$$C_Q = \left(C_D^{1/2}\right)[K/\ln(z_{ref}/z_Q)] \tag{13}$$

where K is the von Kármán constant and z_{ref} is a reference height (usually 10 m).

Therefore, our SST sensitivity effectively changes the variables θ_{sfc} and q_{sfc} in equations 8–10 above, while our air–sea flux parameterization sensitivities change the equations for the momentum, sensible heat and latent heat coefficients (equations 11–13) going into the respective flux equations 8–10.

For our air–sea flux parameterization sensitivities in this study, we ran isftcflx = 0, 1, and 2 with both the warm (control) and cold SST boundary conditions.

Additional WRF sensitivities. We have discussed SST and air–sea flux parameterizations. WRF-ARW was run over 130 times in total, with various model configuration and physics options turned on and off.

We examined the ensemble of simulations with space/time track errors <25 km (one eye-wall radius) from available NHC best track positional data. Only preserving those simulations with accurate tracks is important because Hurricane Irene tracked close to and parallel to the Mid-Atlantic coast. The remaining sensitivities are shown in central pressure (Supplementary Fig. 8) and maximum winds (Supplementary Fig. 9). These are cumulative hourly sensitivities during Irene's presence over the MAB and NY Harbor (28 August 00-13 UTC). Supplementary Table 1 shows a list of these sensitivities, with the WRF namelist option number alongside its name (control run listed last for each sensitivity).

The sensitivity titled 'latent heat flux <0 over water' requires a brief explanation. In the WRF surface layer scheme code, there is a switch that disallows any latent heat flux less than 0 W m^{-2} (similarly, there is a switch that disallows any sensible heat flux less than -250 W m^{-2}). WRF convention for negative heat flux is downward, or atmosphere to land/water. We run WRF after removing the line of code disallowing negative latent heat flux, and compare to the control run. This switch removal only changes latent heat flux and allows it to be negative over water, as the subsequent WRF land surface scheme modifies fluxes and allows for negative latent heat flux over land.

Ahead-of-eye-centre and in-storm cooling calculations. Ahead-of-eye-centre cooling (Table 1) at NDBC buoys (Supplementary Figs 10–12) and the Yellow Sea buoy (Supplementary Fig. 13) was calculated by taking the difference between the maximum water temperature as the winds increased above 5 m s^{-1} and the minimum water temperature before or at the minimum observed SLP. In-storm cooling was determined as the difference between the same maximum water temperature as the winds increased above 5 m s^{-1} and the minimum water temperature while winds remained above 5 m s^{-1} after the pressure minimum. To calculate the average and standard deviation of cooling for the 11 storms passing through the MAB since 1985, we selected the one buoy on the continental shelf that recorded wind speed, pressure and water temperature and exhibited the greatest ahead-of-eye-centre cooling. For completeness we show Irene cooling statistics (Table 1) and time-series (Supplementary Fig. 3) for buoys 44065 and 44100 used in Fig. 1.

Data availability. Buoy meteorological data used in this study are available through the National Data Buoy Center. Glider and HF Radar data can be found through the MARACOOS THREDDS server at http://maracoos.org/data. Tuckerton meteorological data are supported by WeatherFlow Inc. and can be made available upon request to the corresponding authors. WRF and ROMS model simulations are stored locally at the Rutgers Department of Marine and Coastal Sciences and will be made available upon request to the corresponding authors. The Yellow Sea buoy data are stored at the Institute of Oceanology, Chinese Academy of Sciences.

Abstract- **The Palmer Deep submarine canyon on the Western Antarctic Peninsula provides a conduit for upwelling of relatively warm, nutrient rich waters which enhance local primary production and support a food web productive enough to sustain a large top predator biomass. In an analysis of ten years of satellite-tagged penguins, showed that circulation features associated with tidal flows may be a key driver of nearshore predator distributions. During diurnal tides, the penguins feed close to their breeding colonies and during semi-diurnal tides, the penguins make foraging trips to the more distant regions of Palmer Deep. It is hypothesized that convergent features act to concentrate primary producers and aggregate schools of krill that influence the behavior of predator species. The initial results from a six month deployment of a High Frequency Radar network in Palmer Deep are presented in an attempt to characterize and quantify convergent features. During a three month period from January through March 2015, we conducted in situ sampling consisting of multiple underwater glider deployments, small boat acoustic surveys of Antarctic krill, and penguin ARGOS-linked satellite telemetry and time-depth recorders (TDRs). The combination of real-time surface current maps with adaptive in situ sampling introduces High Frequency Radar to the Antarctic in a way that allows us to rigorously and efficiently test the influence of local tidal processes on top predator foraging ecology**

Index Terms—Ocean observing, Polar ecosystems, Physical oceanography

I. Introduction

Physical processes in the coastal ocean are highly variable in space and time and play a critical role in coupled biological and chemical processes. From events lasting several hours to days on through inter-annual and decadal scales, the variability in the fluid itself structures marine ecological systems. The rapid evolution of the Integrated Ocean Observation System (IOOS) made possible through interdisciplinary partnerships and networked data sharing provides descriptions of coastal ocean hydrography and hydrodynamics at fine scales of space and time and regional spatial extents. These ocean observing networks now sample across these important time and space scales to better understand the physical ocean that structures marine ecosystems. For over a decade ocean observing technologies have been deployed, developed and applied to serve societal goals around US coastal waters. These services include supporting search and rescue, fisheries management, storm response, among others. These coastal observatories are built on regional scale observation and modeling that integrates satellite, HF radar, moored, and autonomous glider networks. The capabilities developed

978-1-5090-1537-5/16/$31.00 ©2016 IEEE

and tested in the coastal waters of the US are now migrating to the poles. Project CONVERGE, funded by the NSF Office of Polar programs, deployed an ocean observing network similar to the US networks in the Antarctic to better understand ecosystem function [1].

II. Background

Food resources in the ocean are extremely diffuse and must be either physically or biologically concentrated to support top trophic levels [2]. Resource concentrating features may include bathymetrically or tidally driven convergence zones [3, 4, 5], the formation of phytoplankton thin layers [6], or swarming and schooling behavior of consumers [7]. Since these concentrating features are ephemeral, marine ecosystems are often characterized by patchy spatial and temporal distributions of both primary producers and their consumers. In the coastal Western Antarctic Peninsula (WAP), the food web is short and characterized by intense phytoplankton blooms that are grazed by krill, a primary prey source for penguins and other predators. Averaged over decades to centuries, penguin hotspots are spatially coherent with submarine canyons and nearshore deep bathymetry [8, 9, 10]. However, within these hotspots (spatial scales <10 km), penguin foraging locations are highly variable, reflecting a patchy distribution of prey resources [11]. Adélie penguin foraging patterns determined from tag data collected over the same season appear to be correlated with the tides [12]. During the diurnal tidal regime, penguins tended to forage within 6 km of their breeding site on Humble Island. As the tidal regime switched to a semi-diurnal regime, the penguins typically remained close to shore for the first 4 days, but then began to move further off, into the head of the Palmer Deep, approximately 12 km away [Figure 1]. The spatial coherence between penguin colonies and deep canyons suggests that resources are preferentially transported to, and/or concentrated within these hotspots. Therefore, hotspots may serve as local refugia that buffer the impact of regional climate change through the persistence of the circulation features that transport and concentrate prey resources. Nearshore canyons and their associated dynamics play disproportionately important roles as biological hotspots and are critical for our understanding of WAP marine ecosystem structure and function.

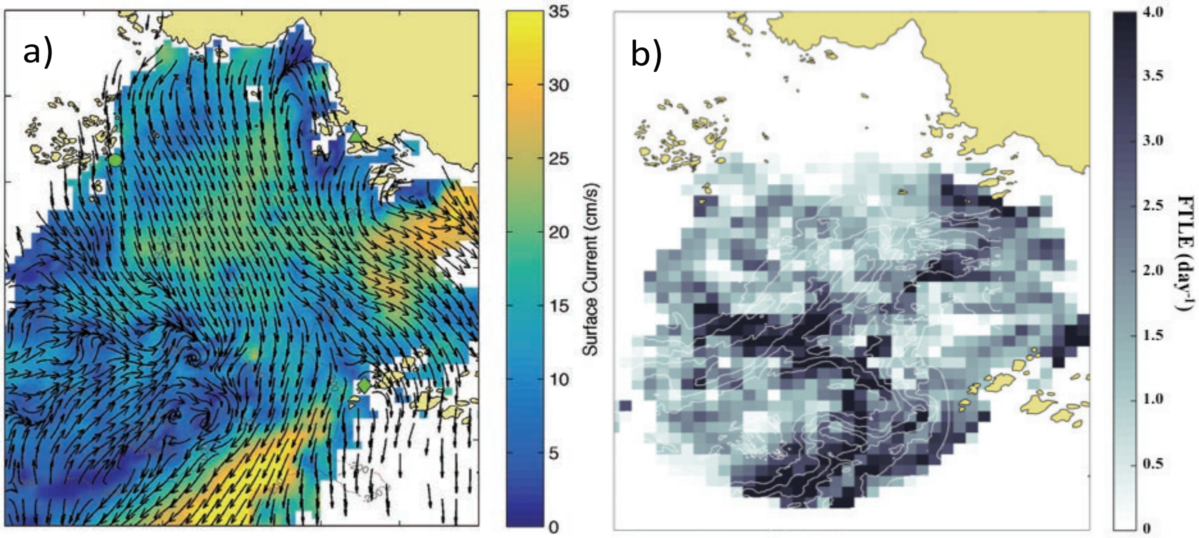

Figure 2. a) Hourly surface current map, January 27, 08:00 GMT 2015. The HF radar sites located at Palmer Station (green triangle) and the Wauwermans (green diamond) and Joubin (green square) island groups are also shown. b) Map of FTLE derived from the trajectories of simulated drifters released in hourly HFR maps (January 27, 2015).

During the austral summer of 2014-2015, project CONVERGE deployed a multi-platform network to sample the Adélie penguin foraging hotspot associated with Palmer Deep Canyon along the Western Antarctic Peninsula. The focus of CONVERGE was to assess the impact of prey-concentrating ocean circulation dynamics on Adélie penguin foraging behavior. Food web links between phytoplankton and zooplankton abundance and penguin behavior were examined to better understand the within-season variability in Adélie foraging ecology.

III. Approach

A. High Frequency Radar Network

A three-site HFR network was deployed in November 2014 at Palmer Deep [Figures 2]. The first site deployed at Palmer Station was powered by the station facilities. The two other sites deployed in the Joubin and Wauwermans Island chains relied on remote power systems that were constructed on site, lightered to shore via zodiac with ship support. The Remote Power Modules (RPMs) generate the required power for the HFRs through a combination of small-scale micro wind turbines and a photovoltaic array with a 96-hour battery backup. The remote power system consisted of a single watertight enclosure, used to house power distribution equipment, the HFR, and the communication gear. Built in redundancies within the power module, wind charging/resistive loads, solar, and independent battery banks ensure that should any one component fail, the unit was able to adjust autonomously. Each site also had 15-minute meteorological measures of air temperature, wind, relative humidity, and solar radiation. Communication between the two remote sites and Palmer Station was with line of sight radio modems (Freewave), which enabled remote site diagnostics and maintenance and provided a real-time data link.

B. Underwater Gliders

Electric gliders were a key component to successfully map in high resolution the upper water column properties

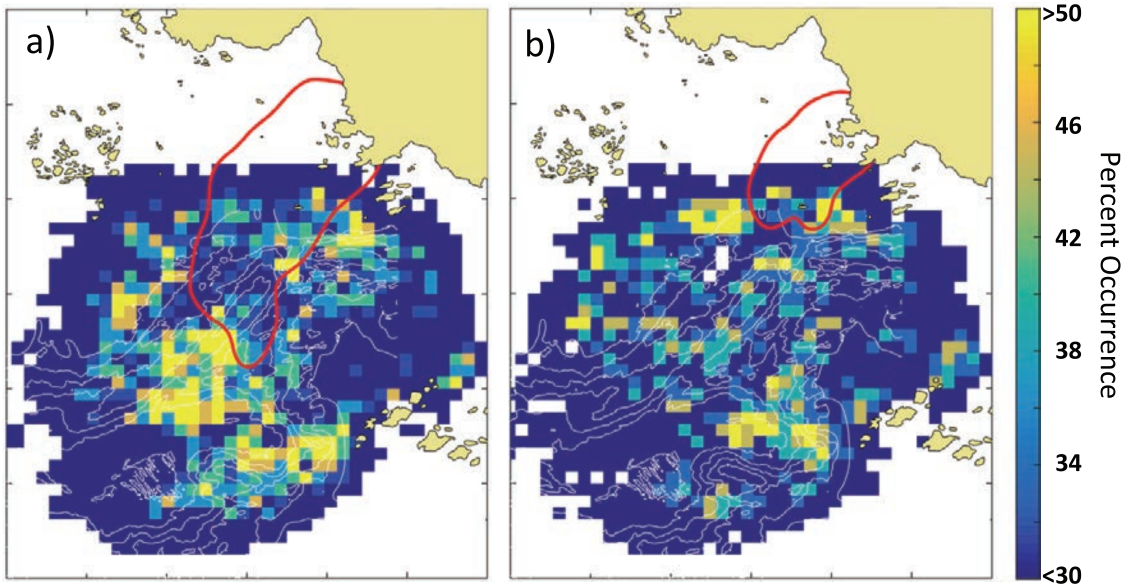

Figure 3. Maps of the percent of occurrence of the strongest quarter of all observed convergent fronts during a) semi-diurnal and b) diurnal days. The spatial density kernels (red contours) based on 10 years of tagged penguin data are shown in panel a for the semi-diurnal days and in panel b for diurnal days (Oliver et al., 2013).

relative to the convergent features identified by the HFR. Glider based sampling provided a continuous presence, through all weather conditions, over the critical spatial domain identified by the HFR network. Simultaneous measurements of physical and biological variables (phytoplankton and krill) from the gliders sampled the spatial and temporal variability over Palmer Deep. We deployed 3 gliders each equipped with a sensor suite to characterize the ecosystem's physical structure (Seabird C, T, D), *in situ* phytoplankton fluorescence and particle backscatter (Wet Labs Eco Triplet configured to measure backscatter of light at 470 nm and 532 nm as well as chlorophyll *a* fluorescence). Three gliders operated as a coordinated fleet to isolate temporal variability captured by a stationary 100 m glider from spatial and temporal variability captured by an along canyon (200 m) and cross canyon (100 m) lines. Both the station keeping glider and the along canyon 200m rated glider carried an additional aquadopp sensor operating at 1 and 2 MHz respectively.

IV. Ecological Connections

A. Mapping Convergent Features

Eddies and fronts were mapped hourly by a High Frequency Radar (HFR) network [Figure 2]. Simulated passive particles released in these hourly maps were used to identify the location and intensity of convergent features during days with diurnal and semi-diurnal tides. Lagrangian Coherent Structures (LCS, specifically Finite Time Lyapunov Exponent [FTLE]) derived from the particle trajectories were used to estimate the location of concentrating features [Figure 2b]. Broadly, Lagrangian Coherent Structures (LCSs) are boundaries in a fluid that distinguish regions of differing dynamics [13]. LCSs are often associated with filaments and mesoscale features, such as eddies, jets and fronts. The location frequency of the strongest fronts associated with the semi-diurnal and diurnal tidal regimes are shown in Figure 3. During the semi-diurnal tidal regime, frontal features are more frequently located offshore, consistent with the offshore Adélie penguin foraging locations. During the diurnal tidal regime, the overlap moves inshore, closer to the colony.

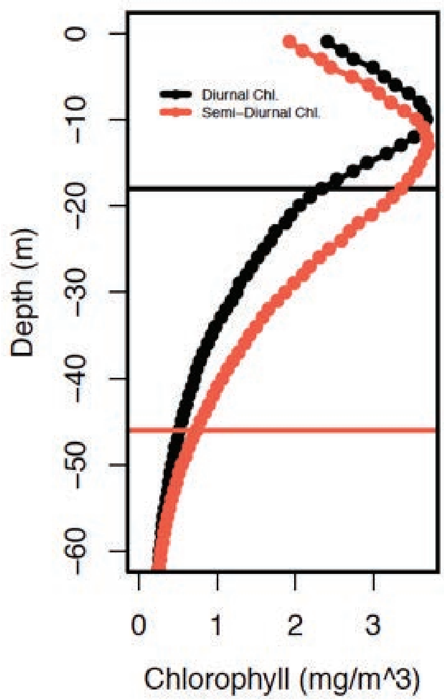

Figure 4. Average profiles of Chlorophyll Fluorescence averaged over all diurnal (Black) and semi-diurnal days (Red) measured from a single glider line along the main axis of Palmer Deep during the Austral Summer of 2014-2015. The horizontal lines indicate the depth of maximum buoyancy frequency from the density profile averaged over all diurnal (black) and semi-diurnal (red) days.

B. Vertical Patterns Linked to Local Tides

The link between the occurrence of these features and the behavior of the satellite-tagged penguins raises important questions about the coupling mechanisms operating throughout the entire food web, including phytoplankton and krill. Concurrent glider sampling shows that the influence of the tidal regime may extend to phytoplankton. The vertical structure in chlorophyll sampled by an along-canyon glider mission in January and February 2014-2015 shows that during days with diurnal tides, the average phytoplankton biomass was more compressed toward the surface than during days with semi-diurnal tides [Figure 4].

C. Anatomy of a Front

While Adélie penguin foraging locations and the occurrence of convergent features covary with tidal regime [Figure 3], it is on the scale of the individual physical features themselves that food web focusing occurs. On January 27, 2015 a glider sampled a convergent front identified in the HFR estimated FTLE field that was also targeted by two foraging penguins [Figure 5]. Hours before the penguins arrived, the glider sampled the sub-surface ocean associated with the convergent feature. The vertical sections of the glider across the front highlight the strong thermal gradient associated with the feature. This front had elevated chlorophyll concentrations associated with a surface bloom [Figure 5c]. While concurrent profiles of the acoustic return crossing the front suggest a peak that could be related to krill feeding on the observed bloom, the frequency (1 MHz) was not ideal for detecting krill [Figure 5d].

V. Conclusions

The spatial coherence between penguin colonies and deep canyons suggests that resources are preferentially transported to, and/or concentrated within these hotspots. Therefore, circulation features associated with the Palmer Deep canyon may enable enhanced food web transfer, termed “trophic focusing” [14]. The tight coupling from the hydrography through the phytoplankton to foraging penguins gives strong inference for the critical role that these physical features may have on food web focusing. Therefore, hotspots may serve as local refugia that buffer the impact of regional climate change through the persistence of the circulation features that transport and concentrate prey resources.

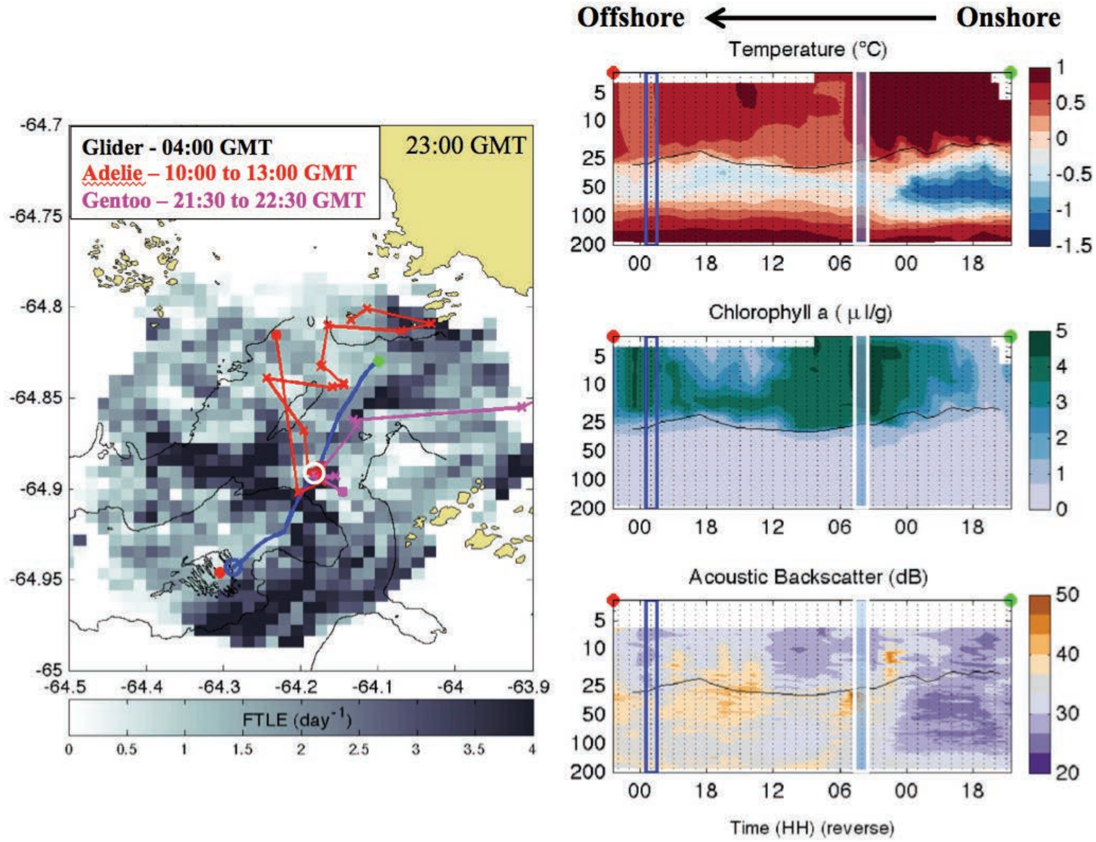

Figure 5. (left) Map showing the location of convergent features in the surface current fields mapped on January 27th, 2015. The track of the glider (blue) and the path of an Adélie (Red) and gentoo (Pink) are also shown. The cross-section data sampled by the glider as it moved offshore along the line highlighted in the map for (Upper Right) Temperature, (Middle Right) Chlorophyll Fluorescence, and Acoustic Backscatter. The glider location that overlaps the penguin foraging is highlighted as a white circle on the map and a white rectangle on the three cross-section plots on the right. The position of the glider at 23:00 GMT is shown as a blue circle on the map and a blue rectangle on the three cross-section plots on the right.

Nearshore canyons and their associated dynamics play disproportionately important roles as biological hotspots and are critical for our understanding of WAP marine ecosystem structure and function.

Factors affecting detection efficiency of mobile telemetry Slocum gliders

Matthew J. Oliver[1*], Matthew W. Breece[1], Danielle E. Haulsee[1], Megan A. Cimino[2], Josh Kohut[3], David Aragon[3] and Dewayne A. Fox[4]

Abstract

Background: Acoustic biotelemetry sensors have been fully integrated into a broad range of mobile autonomous platforms; however, estimates of detection efficiency in different environmental conditions are rare. Here, we examined the role of environmental and vehicle factors influencing detection range for two common acoustic receivers, the VEMCO mobile transceiver (VMT) and a VEMCO cabled receiver (VR2c) aboard a Teledyne Slocum glider. We used two gliders, one as a mobile transmitting glider and one as a mobile receiving glider during the fall in the mid-Atlantic coastal region.

Results: We found distance between gliders, water depth, and wind speed were the most important factors influencing the detection efficiency of the VMT and the VR2c receivers. Vehicle attitude and orientation had minimal impacts on detection efficiency for both the VMT and VR2c receivers, suggesting that the flight characteristics of the Slocum glider do not inhibit the detection efficiency of these systems. The distance for 20% detection efficiency was approximately 0.4 and 0.6 km for the VMT and VR2c, respectively. The VR2c receivers had significantly lower detection efficiencies than the VMT receiver at distances <0.1 km, but higher detection efficiencies than the VMT at distances >0.1 km.

Conclusions: Slocum gliders are effective biotelemetry assets that serve as sentinels along important animal migration corridors. These gliders can help elucidate the relationships between telemetered organisms and in situ habitat. Therefore, estimating the detection ranges of these common telemetry instruments provides an important metric for understanding the spatial scales appropriate for habitat selection inferences.

Keywords: Slocum glider, VMT, VR2c, Range test, VEMCO, Acoustic telemetry

Background

Acoustic biotelemetry is commonly used to monitor the presence and movement of organisms in aquatic environments [1], supporting both regional and international conservation efforts [2]. Location information for acoustic biotelemetry observations is tied to the location of the receiver and its detection range. The detection range of acoustic receivers depends on in situ listening conditions, which are linked to environmental conditions. Tides, currents, winds, stratification, and listening array configuration can impact detection efficiency, thus impacting the study of the presence and movement of organisms using acoustic biotelemetry [3–5].

The issue of acoustic range is further complicated by the use of telemetered autonomous underwater vehicles (AUVs) and other mobile platforms that transit different listening environments. While AUVs often measure environmental conditions that could impact listening conditions [6], moving platforms and dynamic environments create new range of testing challenges. One solution to this challenge is near-real-time triangulation of the acoustic signal using a combination synthetic aperture and known test tag locations [7]. Another solution is using a combination of stereo receivers and near-real-time particle filtering [8], and multiple AUVs to geolocate the acoustic tag on meter scales [9]. These approaches

*Correspondence: moliver@udel.edu
[1] School of Marine Science and Policy, College of Earth Ocean and Environment, University of Delaware, Lewes, DE, USA
Full list of author information is available at the end of the article

can be highly effective for geolocating acoustic signals, but require high-performance, propeller-driven AUVs that are able to precisely control their positions in the water. However, because these propellered AUVs require more energy to operate, they are limited to relatively short deployments due to battery life (<2 days). These propelled platforms are not designed to conduct continuous long-term searches, listening for telemetry signals of dispersed animals.

Observations of acoustically telemetered animals can be infrequent in the ocean environment; therefore, low-power AUVs such as Slocum and wave gliders can play the supporting role of environmental sentinel, targeting ocean features and discovering new areas used by telemetered organisms outside of fixed acoustic arrays with missions that last weeks to months [10–14]. Gliders are easily outfitted with externally mounted, self-contained VEMCO mobile transceivers (VMT) [10, 15], or with vehicle-integrated VEMCO cabled receivers (VR2c) [11, 14]. Critical to their sentinel role is the ability to associate in situ environmental data with acoustic detections, allowing inferences to be made about habitat associations [11]. However, this requires estimates of the range of acoustic detections over the large spatial scales (hundreds of km) covered by these long-lived AUV missions, which is difficult to obtain with moored test tags. In this study, we estimate the detection range of an integrated VR2c and externally mounted VMT on Slocum gliders during the fall along the mid-Atlantic Bight. We used a combination of vehicle attitude, in situ oceanographic data and meteorological observations from nearby NOAA buoys to determine which factors affected the detection efficiency of these common telemetry systems.

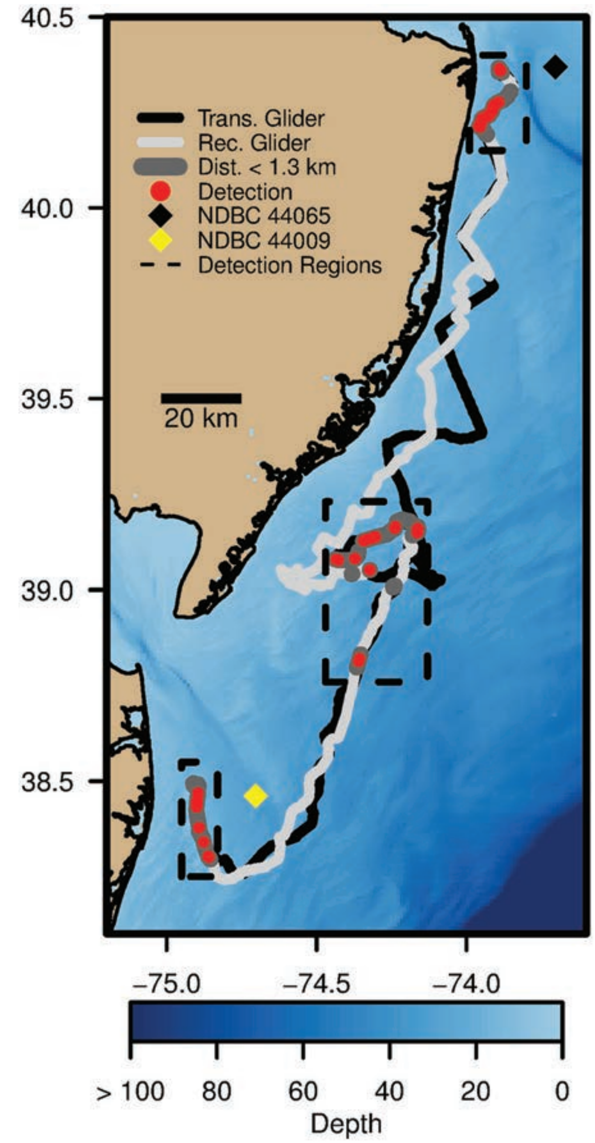

Fig. 1 Paths of the transmitting and receiving glider along New Jersey, Delaware, and Maryland coasts. The gliders transited very similar paths, but were not always close together. *Dark gray* regions indicate when the gliders were within 1.3 km of each other within study boxes, and *red dots* indicate when the receiving glider detected the transmitting glider. *The diamonds* are the location of NDBC buoys used to determine wind speeds. *Dashed boxes* indicate the three regions the receiving glider detected the transmitting glider

Methods

Glider deployments

Slocum gliders are buoyancy-driven vehicles that dive and climb at a nominal 26° angle and travel in a vertical "sawtooth" pattern between predetermined surface events [16]. While the glider is underway, it collects vertical profiles of physical (temperature, salinity), chemical (oxygen), and biological properties (chlorophyll-*a* fluorescence). Two Slocum gliders (Teledyne Webb Research) were deployed off of Sandy Hook, New Jersey, USA, on September 17, 2015, and were recovered off the coast of Delaware, USA, on October 7, 2015 (Fig. 1). For this 20-day mission in the mid-Atlantic coastal ocean, one glider (transmitting glider) was equipped with an externally mounted VEMCO mobile transceiver (VMT, VEMCO Ltd.) programmed to transmit coded acoustic signals (69 kHz, 156 dB) [10]. The second glider (receiving glider) was equipped with an externally mounted VMT programmed to only receive coded acoustic signals, and two hull integrated (1 top and 1 bottom) VEMCO VR2c acoustic receivers [11]. The hydrophones of the integrated VR2c's were normal to the major axis of the glider (pointed upward and downward), while the VMT hydrophone was mounted facing forward, and along the major axis of the glider (Fig. 2). The gliders record vehicle pitch, roll, depth, heading, and total water depth at

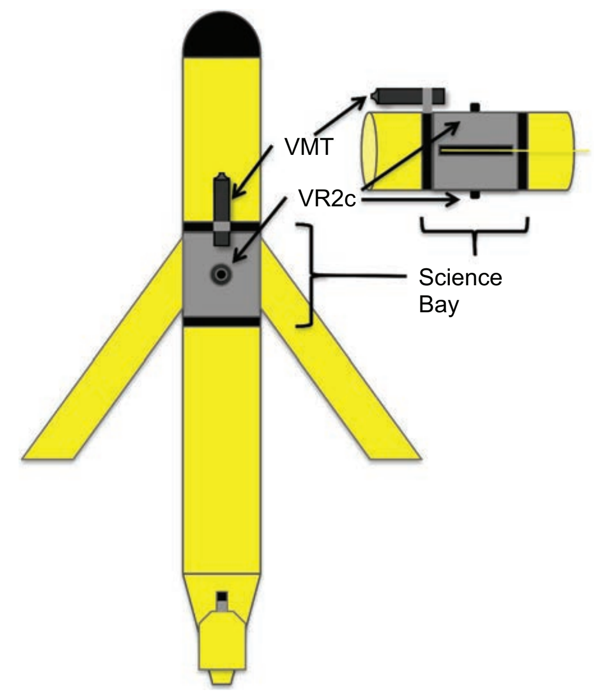

Fig. 2 The mounting orientation of the VMT and VR2c's on the receiving glider from the dorsal (*left*) and the lateral (*right*) view. Two VR2c's are integrated into the central science bay, one pointing up and the other down. The VMT was mounted in a bracket forward of the top VR2c, with its receiver pointing toward the nose of the glider. The transmitting glider had a VMT mounted in a same way

1 Hz throughout the mission. The gliders also estimate depth integrated water currents between surface events by comparing surface GPS locations with dead-reckoning subsurface navigation. The transmitting glider's primary mission objective was to measure full water column dissolved oxygen in the coastal ocean. The receiving glider, deployed at the same time and location, was testing an automated glider path-planning tool. Given these primary objectives, these gliders also served as mobile platforms of opportunity to test the influence of environmental and vehicle factors on acoustic signal detection in the mid-Atlantic coastal ocean. The receiving glider was within 1.3 km (the longest distance of detection between gliders) of the transmitting glider during three distinct time periods, each with different environmental conditions (Fig. 3).

Environmental and vehicle predictors of detection efficiency

The VMT mounted on the transmitting glider was scheduled to transmit a coded acoustic signal at 69 kHz (156 dB) on average every 110 s (range 70–150 s). We hypothesized that reception of coded acoustic signals by either the VMT or integrated VR2c's on the receiving glider would be affected by the distance between gliders, depth of the water, wind speed, current speed, depth of the receiving glider, water column density, pitch and roll of the receiving glider, and the bearing of the transmitting glider to the receiving glider. We computed the distance between the gliders using the rdist.earth function in the fields R package [17]. We used wind speeds measured at NDBC buoys 44065 and 44009 as proxies for wind speeds at the glider locations (Fig. 1). The wind records at these buoys are different, but strongly correlated ($r = 0.81$) (Fig. 3a). We used wind speed from NDBC 44065 as a proxy for wind speed for the northernmost region where the receiving glider was detecting the transmitting glider, and NDBC 44009 for the middle and southernmost regions. We derived water density using the equation of state (temperature, salinity, pressure) measured by each glider [18]. We estimated water column stratification by differencing surface and bottom density. We eliminated predictors that were highly collinear ($|r| > 0.7$). For example, depth of the glider was highly correlated to the altitude of the glider from the bottom because the gliders were in relatively similar depths throughout the mission. Also, the relative depths of the transmitting gliders were not considered because the vertical depth differences were only 2% (max of 30 m) of the horizontal depth differences of detection (up to 1.3 km).

Generalized additive mixed model analyses

To test which predictor variables influenced detection efficiency, we used a generalized additive mixed model (GAMM) framework in the R gamm4 package [19]. A GAMM sums smoother functions (penalized regression splines) to model the binomial presence/absence of telemetry detections compared to the expected number of detections from the transmitting glider. We implemented penalized shrinkage smoothers as an automatic alternative to model selection of environmental predictors. Shrinkage smoothers incorporate a penalty, which may shrink all of the coefficients to zero, effectively penalizing the variable out of the model [20]. We used penalized thin plate regression splines (ts) for non-cyclic predictors and penalized cubic regression splines for cyclic predictors (cc) using the mgcv package in R. We limited the number of knots for each smooth variable in our model to five to prevent overfitting. Model analysis was limited to mission times when the transmitting glider was within 1.3 km of the receiving glider. This was the furthest distance the receiving glider detected the transmitting glider. The receiving and transmitting gliders were within 1.3 km in three distinct regions (northern NJ, southern NJ, and Delaware coasts) (Fig. 1). Therefore, we added these locations as random effects to account for unknown differences inherent to these three locations that are otherwise unaccounted for in our analysis. Finally, we used fivefold cross-validation on these models to determine if the model was

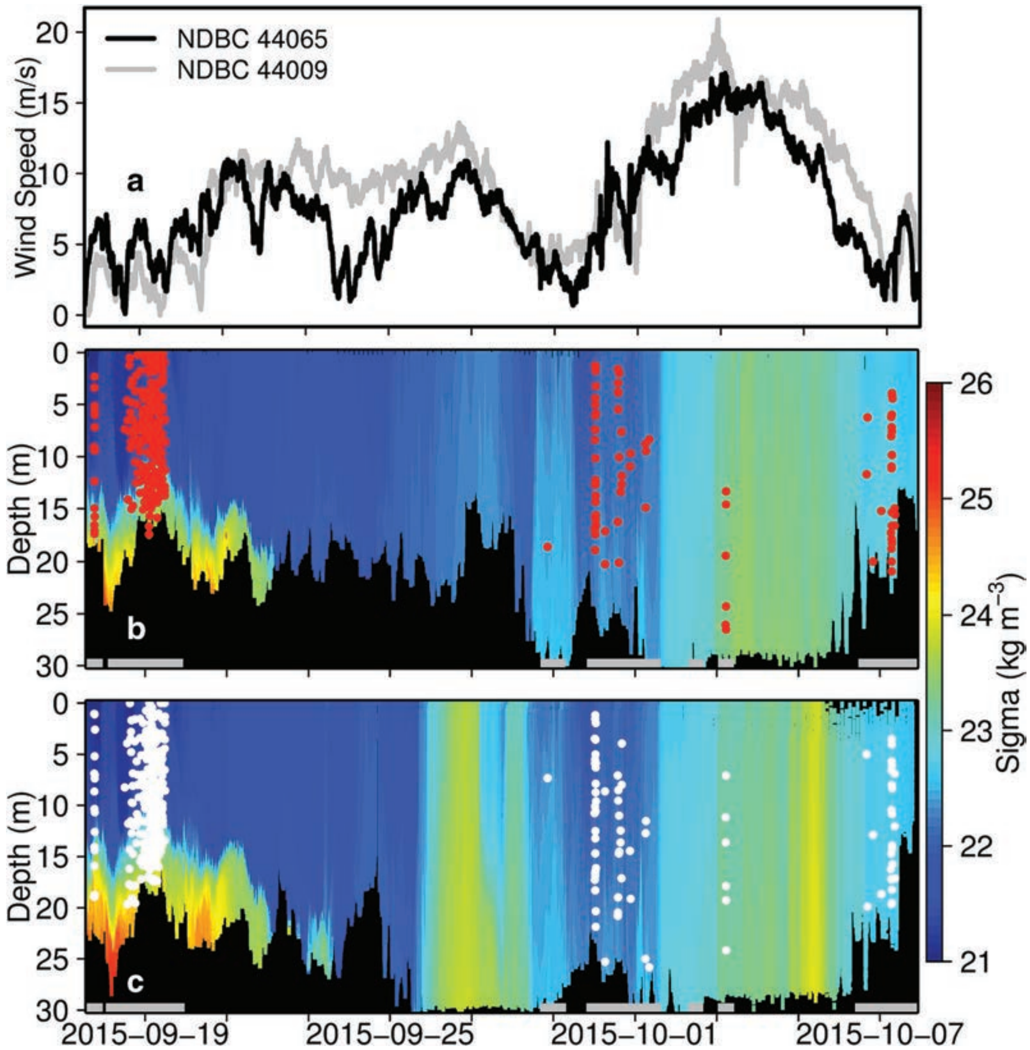

Fig. 3 **a** Wind velocities at the NDBC buoys during the deployment. Sigma (density-1000) cross section of the receiving (**b**) and transmitting (**c**) glider. *Points* indicate the depth of the receiving glider (*red*) and transmitting glider (*white*) when detections were recorded. *Gray bars* indicate when the gliders were within 1.3 km of each other

overfit and to test the performance of the model without each fold of data. This was done by splitting the data randomly into five subsets, reiteratively fitting the model to four of the five subsets (training dataset), and then predicting on the remaining subset (test dataset) to verify the robustness of the models [21]. We estimated the relative predictor importance of these cross-validated models using the BIOMOD2 package [22, 23].

Results

Environmental conditions

The transmitting and receiving gliders made similar, but not identical southward paths starting in coastal NJ waters and ending in DE waters (Fig. 1). These gliders encountered three prolonged wind events >10 m s^{-1} (Fig. 3a), presumably changing the subsurface noise conditions [3]. Stratification of the water column is most pronounced early in the mission, with up to a 4 sigma (4 kg m^{-3}) difference in density between surface and bottom waters. Data collected by the receiving (Fig. 3b) and transmitting (Fig. 3c) gliders show the erosion of the pycnocline and a general increase in density due to cooling over the study period. This erosion of the strong summer pycnocline is well known in this region as a result of seasonal cooling and storm activity [24].

Acoustic detections

The two gliders were within 1.3 km of each other for 90.7 h and got as close as 15 m. Within this distance range, the transmitting glider emitted 2177 coded acoustic signals. The VMT receiver successfully decoded 124 detections (5.6%) of the transmitting glider. The top integrated VR2c receiver decoded 188 detections (8.6%), while the bottom integrated VR2c receiver decoded 175 detections (8.0%). Forty-eight of the transmissions were detected by both the top and bottom integrated VR2c receivers. Treating the integrated VR2c receivers as a single receiving apparatus, removing double detection counts, the integrated VR2c receivers recorded 264 detections (12.1%) of the transmitting glider. There were six other tags detected during this experiment; however, these detections were not intermingled with the detections of the transmitting glider. Therefore, we believe that false-positive detections are not a major factor in this study.

Detection efficiency for the VMT receiver was highest when the distance to the transmitting glider was <0.1 km and decreased with distance (Fig. 4). At distances >0.4 km, VMT receiver detections were sparse. In contrast, the integrated VR2c receivers performed poorly at distances <0.1 km, but were comparable to or better than the VMT at the further distances. Peak detection efficiencies for the integrated VR2c receivers were at 0.2–0.3 km, but dropped markedly past 0.6 km. The low detection efficiencies at distances <0.1 km by the integrated VR2c receivers are likely a result of close proximity detection interference, where the power of the transmission (156 dB in our case) overwhelms the hydrophone and is known to occur in these systems. These detection efficiency patterns create different expectations for the distance of a received transmission by these two sensors known as the "doughnut effect" (Fig. 4) [25]. The integrated VR2c's have a much larger detection area, which scales with the square of the distance between the transmitter and receiver.

Environmental and vehicle attitude predictors of detections

GAMMs were developed for predicting both VMT and integrated VR2c detections using penalized smoothers for continuous predictors. We observed strong stratification during the first glider encounter, but the water column was thoroughly mixed for the rest of the experiment. Models predicting the presence/absence of detections on the VMT and the integrated VR2c receivers (Table 1) had AUC values of 0.96 and 0.89, respectively, indicating good model performance. Fivefold cross-validation of these models had AUC values of 0.95 and 0.89 indicating that these models were not overfit. Variable importance for these models followed similar patterns for the VMT and the integrated VR2c's (Fig. 5). Distance between gliders was the most important predictor of detections for both the VMT (54.2%) receiver and the integrated VR2c (69.6%) receivers (Fig. 5). Wind speed (19.0%) and water depth (15.3%) were similarly important for predicting detections on the VMT receiver; however water depth (16.5%) was more important than wind speed (4.4%) for

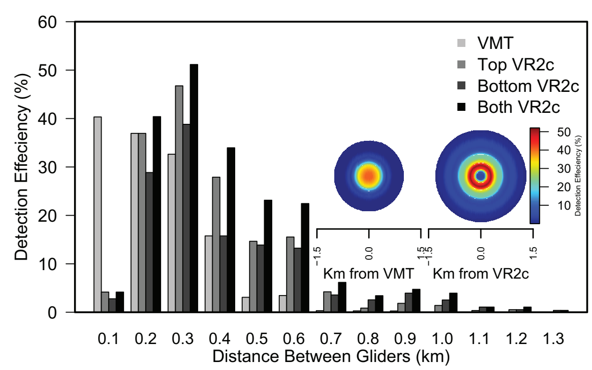

Fig. 4 Detection efficiency of the VMT and integrated VR2c receivers on the receiving glider at distance bins away from the transmitting glider. *The figure inset* is a visual aid for the circular distribution of detection efficiency for the VMT and both integrated VR2c receivers, illustrating the "doughnut effect" [25]

Table 1 GAMMs evaluated to predict the likelihood of acoustic transmission detection by a VMT and integrated VR2c receivers based on environmental conditions

	GAMMs (binomial, knots = 5, penalized smoothers)	Adj. R^2	AIC	AUC
VMT	VMT ~ s(Dist.) + s(Wind) + s(W. Depth) + s(Cur.) + s(Strat.) + s(Bearing) + s(Depth) + s(Pitch) + s(Roll) + s(Den.) + 1| Region	0.385	473.9	0.96
VR2c	VR2c ~ s(Dist.) + s(Wind) + s(W. Depth) + s(Cur.) + s(Strat.) + s(Bearing) + s(Depth) + s(Pitch) + s(Roll) + s(Den.) + 1| Region	0.277	1090.6	0.89

Dist. is the distance between gliders, Wind is wind speed from the nearest NDBC buoy, W. Depth is the depth of the water estimated by the receiving glider altimeter, Density is the density of the sea water measured by the receiving glider, Strat. is the difference between surface and bottom densities measured by the receiving glider, Cur. is the glider estimated depth integrated currents, Depth is the depth of the receiving glider, Pitch is the angle of descent of the receiving glider, Bearing is the bearing of the transmitting glider in relation to the receiving glider, Roll is the roll of the receiving glider, and Region refers to the three major geographic areas where detections occurred in Fig. 1

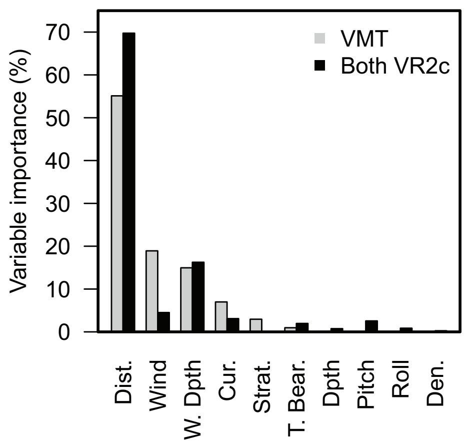

Fig. 5 The relative importance of environmental and vehicle attitude predictors affecting acoustic detections. See Fig. 1 caption for variable abbreviations

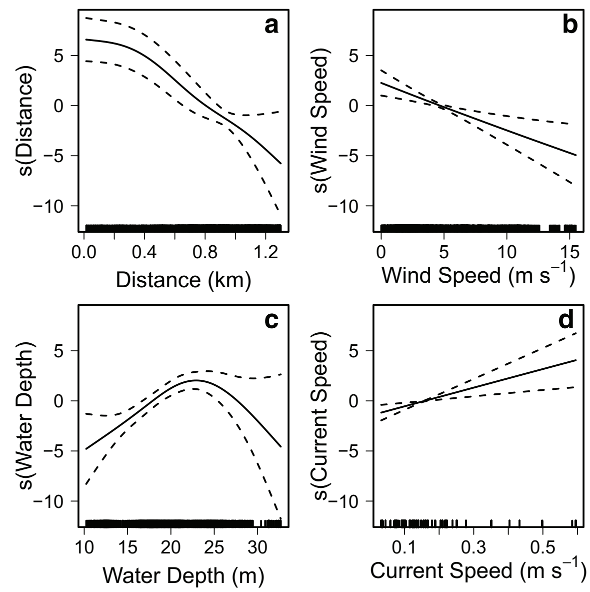

Fig. 6 VMT model response functions of the four most important variables (**a** Distance between gliders, **b** Wind speed, **c** Water depth, **d** Current speed) affecting likelihood of detections on VMT receiver. *Dashed lines* indicate confidence intervals, and *rug plots* indicate observations. *Positive values* indicate conditions that enhance detection efficiency, and *negative values* indicate conditions that suppress detection efficiency

the VR2c model (Fig. 5). Current speed (7.5, 3.1%) was somewhat important for both models, with the rest of the predictors, including vehicle attitude, having less than 3% importance (Fig. 5). Distance, wind speed, water depth, current speed, stratification, and target bearing were significant ($p < 0.05$) predictors of VMT detections (Additional file 1: Table S1). For the integrated VR2c's all predictors were significant except for stratification, AUV depth, and water density (Additional file 1: Table S2).

The response curves of the four most important predictors of detections by the VMT (Fig. 6) and the integrated VR2c's (Fig. 7) exhibit different responses for these two acoustic telemetry systems, especially with respect to distance between the gliders. VMT model predictors showed the expected decline in detection likelihood as distance between the gliders increased (Fig. 6a); however, the VR2c model did not illustrate the same monotonic decline (Fig. 7a). Instead, the response curve showed that the VR2c's were not as effective at very close distances, similar to the results in Fig. 4. Both the VMT receiver and integrated VR2c receivers performed better at low wind speeds, indicating that noise generated by windy conditions might affect detection efficiency (Figs. 6b, 7b). However, confidence intervals around the partial residual plot of the effect of wind on detection efficiency for the VR2c receivers always encompass zero, and therefore, there is low confidence in this relationship. Both the VMT receiver and integrated VR2c receivers performed better as water depth increased; however, deeper than 20 m, the standard error estimates of the response curves increase substantially, making judgments about the response curve in deeper waters difficult (Fig. 6b). This is likely because

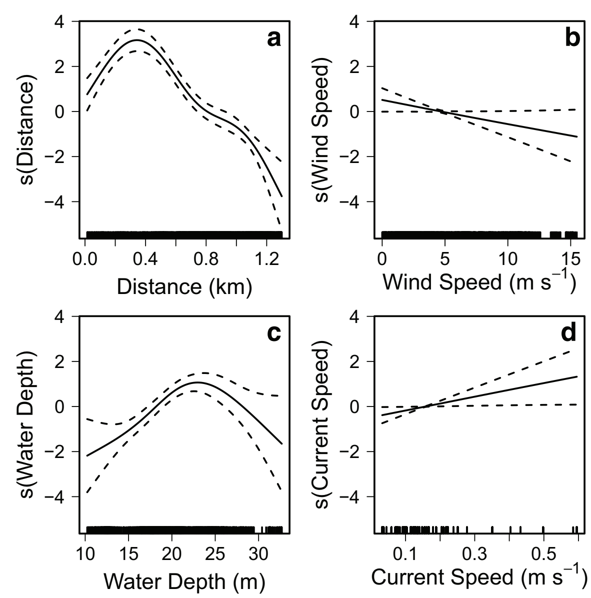

Fig. 7 Model 4 response functions of the four most important variables (**a** Distance between gliders, **b** Wind speed, **c** Water depth, **d** Current speed) affecting likelihood of detection on integrated VR2c receivers. *Dashed lines* indicate confidence intervals, and *rug plots* indicate observations. *Positive values* indicate conditions that enhance detection efficiency, and *negative values* indicate conditions that suppress detection efficiency

only 2.5% of our observations were in waters deeper than 30 m, increasing the spread of the confidence intervals. In addition, the confidence intervals for the effect of current speeds on the detection efficiency of VR2c receivers always included zero, making interpretation of the effects inconclusive (Fig. 7d). Water column stratification played a statistically significant but minor role in VMT detections (Fig. 5; Additional file 2, Additional file 1: Table S1). Stronger stratification reduced the likelihood of VMT detection; however, the confidence intervals include zero, making it difficult to interpret the stratification effect. Vehicle attitude parameters in general were nonsignificant predictors of detection efficiency for the VMT, with the exception of the effect of target bearing being weak but significant (Additional file 1: Table S1). For the integrated VR2c's, vehicle roll, pitch, and target bearing were statistically significant, but weak predictors of detection efficiency (Fig. 5; Additional file 3, Additional file 1: Table S2).

Discussion

The major predictors of detection efficiency for both receiver assets were distance between transmitter and receiver, wind, and water depth (Fig. 5). This is generally in line with previous studies [3–5]. We suspect more studies are necessary during highly stratified periods to estimate the full impact of a stratified water column on acoustic detection efficiency, as stratification played only a minor role in detection efficiency for the VMT. Increased wind speeds decreased detection efficiency for the VMT and VR2c (Figs. 5b, 6b); however, the effect was more pronounced with the VMT. Wind stress has been shown to decrease detection efficiencies of VMTs [26]; however, we do not know why the VR2c appears to be less sensitive to wind in this study. Encouragingly, vehicle attitude and sensor orientation seemed to play a minor role in detection efficiency, indicating that Slocum gliders can play an important role in biotelemetry studies without major concerns of orientation affecting detection efficiency. The effect of target bearing is probably related to the orientation and position of the mounted receivers (Fig. 2). As a result, the VMT receiver had slightly higher detection efficiency when the bearing of transmitting glider was not near 180° (behind the receiving glider). The VMT was mounted slightly forward of the top integrated VR2c receiver, which may have caused some signal blocking from the transmitting glider. For example, the detection efficiency of the integrated VR2c receivers was slightly reduced when the bearing of the transmitting glider was near 0° (ahead of the receiving glider). We view these effects as conditional on the mounting relationship between the VMT and the integrated VR2c's, which could be changed.

The externally mounted VMT and integrated VR2c's had different effective detection ranges. The results of our study suggest the effective detection range to be ~0.4 and ~0.6 km for the VMT and integrated VR2c receivers, respectively, comparable to previous findings for detecting high-power tags (69 kHz, 161 dB) [25]. In addition, our range testing results are similar to estimates using a Slocum glider with integrated VR2c receivers passing by a moored test tag [11]. Studies using VMTs as receivers on AUVs and as animal-borne sensors are becoming more common and often have experimental designs that make range testing impractical [27–29]. Our study gives an upper bound on the scales of interaction that can be inferred between telemetered organisms and their environment as they move through the coastal ocean, outside of established fixed acoustic receiver arrays. Detection efficiency of the VMT and integrated VR2c's differed depending on the distance between the receiver and transmitter. At 0.1–0.2 km, the detection efficiencies of the VMT and VR2c receivers were near 30–40%, which is similar to the mean detection efficiency (33%) reported by fixed arrays in a shallow coastal ocean [3]. However, our detection efficiency was much lower than the 80–90% detection efficiency by high-power tags reported by arrays in an Arctic embayment, fresh water lake, and a subtropical marine reef [25]. A possible strategy to estimate detection efficiency using gliders throughout their mission would be to fly them in formation, one acting as a transmitter and the other as a receiver to estimate the detection efficiency distance decay curve. The detection efficiency "doughnut effect" we observed with the integrated VR2c receivers indicates that one system (VMT vs. integrated VR2c) might be preferable over the other depending on the science question. If the science question depends on localization, then the VMT might be preferred; however, if the science question depends on broader scale presence or absence, then the integrated VR2c receivers may be better suited as a result of their larger detection range.

Conclusion

Our analysis suggests that Slocum gliders can operate as effective and efficient acoustic telemetry sentinels outside fixed receiver arrays, whether they are using VMT or integrated VR2c receiver technology. The effective range for the VMT and VR2c receivers does not appear to be affected by vehicle attitude, but rather distance between transmitter and receiver, and environmental conditions. With the expectation that more Slocum gliders will be being used to map habitat associations of telemetered fishes during their migrations outside fixed receiver arrays, these estimates should provide valuable insights into study design and increase the precision of estimates.

This study outlines important length scales when considering the inferred relationships between telemetered organisms and their habitat.

Defining the ecologically relevant mixed-layer depth for Antarctica's coastal seas

Filipa Carvalho[1], Josh Kohut[1], Matthew J. Oliver[2], and Oscar Schofield[1]

[1]Department of Marine and Coastal Sciences, Rutgers University, New Brunswick, New Jersey, USA, [2]College of Earth, Ocean, and Environment, University of Delaware, Lewes, Delaware, USA

Abstract Mixed-layer depth (MLD) has been widely linked to phytoplankton dynamics in Antarctica's coastal regions; however, inconsistent definitions have made intercomparisons among region-specific studies difficult. Using a data set with over 20,000 water column profiles corresponding to 32 Slocum glider deployments in three coastal Antarctic regions (Ross Sea, Amundsen Sea, and West Antarctic Peninsula), we evaluated the relationship between MLD and phytoplankton vertical distribution. Comparisons of these MLD estimates to an applied definition of phytoplankton bloom depth, as defined by the deepest inflection point in the chlorophyll profile, show that the maximum of buoyancy frequency is a good proxy for an ecologically relevant MLD. A quality index is used to filter profiles where MLD is not determined. Despite the different regional physical settings, we found that the MLD definition based on the maximum of buoyancy frequency best describes the depth to which phytoplankton can be mixed in Antarctica's coastal seas.

1. Introduction

The surface mixed layer is a portion of the upper ocean where turbulent mixing processes form an upper density layer distinct from the layer below. The depth of these layers varies greatly across the world's ocean in time and space and plays an important role in interpreting the environmental factors driving phytoplankton blooms [*Behrenfeld and Boss*, 2014]. Mixed-layer depth (MLD) is therefore a central metric for understanding phytoplankton dynamics [*Sverdrup*, 1953] especially in Antarctica's coastal seas [*Fragoso and Smith*, 2012; *Venables et al.*, 2013]. The depth of the surface mixed-layer can regulate the amount of solar radiation available to the phytoplankton community [*Denman and Gargett*, 1983; *Mitchell et al.*, 1991]. From below, water column stability at the base of the ML has been linked to the flux of nutrients to the surface layer [*Ducklow et al.*, 2007; *Prézelin et al.*, 2000; *Prézelin et al.*, 2004]. A recent study by *Smith and Jones* [2015] showed that vertical mixing and phytoplankton biomass in the Ross Sea are consistent with the critical depth concept formalized by *Sverdrup* [1953]. This critical depth is a function of incoming radiation, which in the poles shows a marked seasonality, and is an important factor controlling phytoplankton dynamics in polar seas [*Smith and Sakshaug*, 2013]. Similar conclusions relating the critical depth hypothesis with phytoplankton growth were found for the West Antarctic Peninsula [*Carvalho et al.*, 2016; *Cimino et al.*, 2016; *Vernet et al.*, 2008].

While seasonal mixed-layers have been widely used to better understand the critical links between the physical structure of the water column and primary production, there are a wide range of methods and metrics used to estimate this important parameter. MLD calculations are based on temperature, salinity, or density. Common methods used in MLD calculations in Antarctic waters are based on either a difference or gradient in the target variable, and every study justifies their specific method. Estimates of MLD from a difference measured at two depths use a range of values. Temperature thresholds vary from 0.8°C [*Kara et al.*, 2000] to 0.2°C [*de Boyer Montégut et al.*, 2004; *Dong et al.*, 2008], while potential density thresholds vary from 0.01 kg m^{-3} [*Smith and Jones*, 2015], 0.03 kg m^{-3} [*Sallée et al.*, 2010], and 0.05 kg m^{-3} [*Venables et al.*, 2013]. The reference depths over which these differences are estimated can vary from the near surface [*Venables et al.*, 2013] to as deep as 10 m [*Smith and Jones*, 2015]. All these differences in criteria and method can potentially yield different estimates of MLD. This is especially troublesome when trying to compare results between studies and distributed seas within which local physical conditions lead to different optimal methods to estimate local MLD. In this study, we use concurrent profiles of hydrography and chlorophyll *a* (chl *a*) fluorescence during the austral spring/summer season in three coastal regions around Antarctica and propose a standard and ecologically relevant metric of

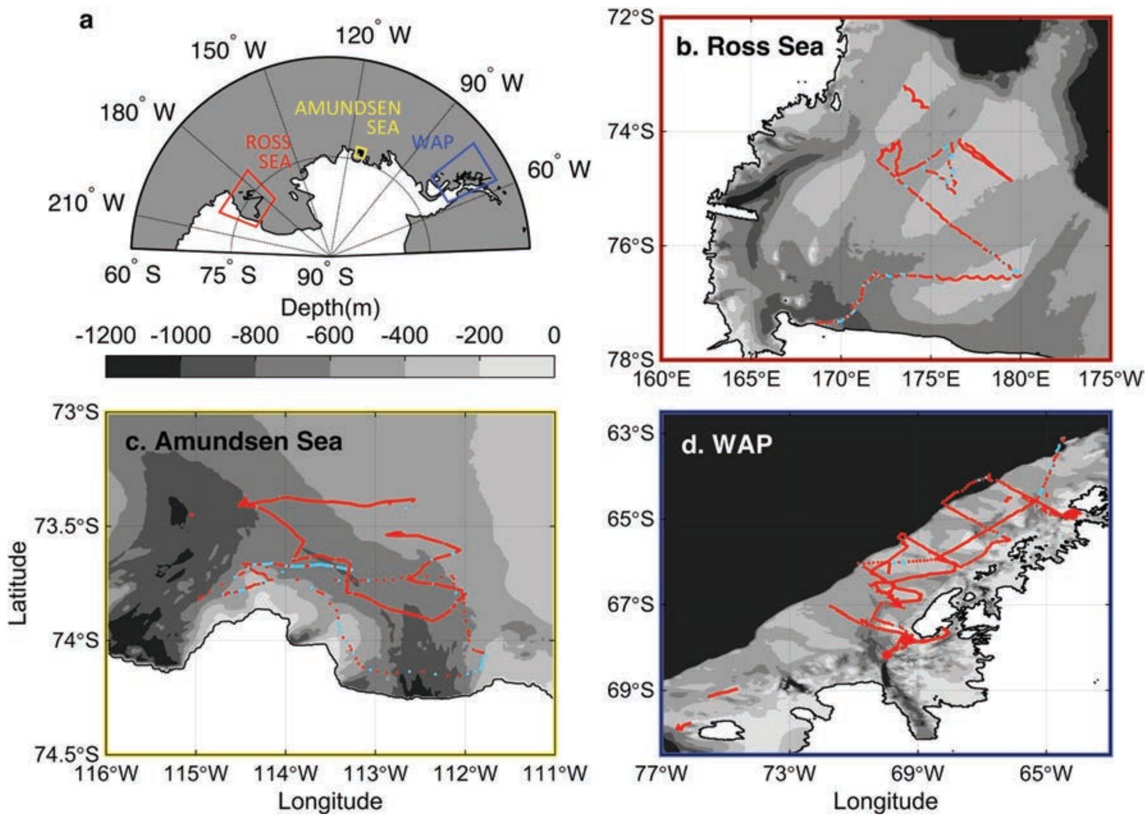

Figure 1. Location of glider data used in the analysis: (a) glider tracks in the three main regions. (b–d) Bathymetry maps overlaid with the detailed location of each individual glider profile (dots) for the regions shown in Figure 1a: (b) Ross Sea, (c) Amundsen Sea, and (d) WAP. Red dots: MLD quality index (QI) > 0.5 (see section 2.2 for details); blue dots: remaining profiles not considered for the MLD analysis (QI < 0.5).

MLD as it consistently captures the lower vertical limit of phytoplankton distribution across the Amundsen Sea (AS), the Ross Sea (RS), and the shelf along the Western Antarctic Peninsula (WAP) that facilitate comparisons between studies.

2. Data and Methods

2.1. Slocum Gliders

Slocum electric gliders are 1.5 m torpedo-shaped buoyancy-driven autonomous underwater vehicles that provide high-resolution surveys of the physical and bio-optical properties of the upper water column [*Schofield et al.*, 2007]. All gliders used in this analysis were equipped with a Seabird conductivity-temperature-depth (CTD) sensor and carried WET Labs Inc. Environmental Characterization Optics (ECO) pucks, which measured chl *a* fluorescence. Glider-based conductivity, temperature, and depth measurements were compared with a calibrated ship CTD sensor on deployment and recovery to ensure data quality, as well as with a calibrated laboratory CTD prior to deployment (as described in *Kohut et al*. [2014]). Each glider profile was averaged into 1 m bins and assigned a midpoint latitude and longitude. Only profiles with 50 bins or more were considered for the analysis. Glider profiles start at 2–4 m depth. In the AS, three missions collected 2247 profiles (December 2010 to February 2011 and January 2015). In the RS, three missions collected 2212 profiles (December 2010 to January 2011). Along the WAP, 26 missions collected 16,673 profiles (December–March, 2009 through 2015). Overall, these data include 21,132 profiles, 465 days at sea and 9836 km flown during the austral spring/summer (Figure 1).

2.2. Mixed-Layer Depth

We evaluated an ecologically relevant MLD definition based on comparisons with concurrent chl *a* fluorescence profiles (described below). We show a detailed analysis on the MLD estimated based

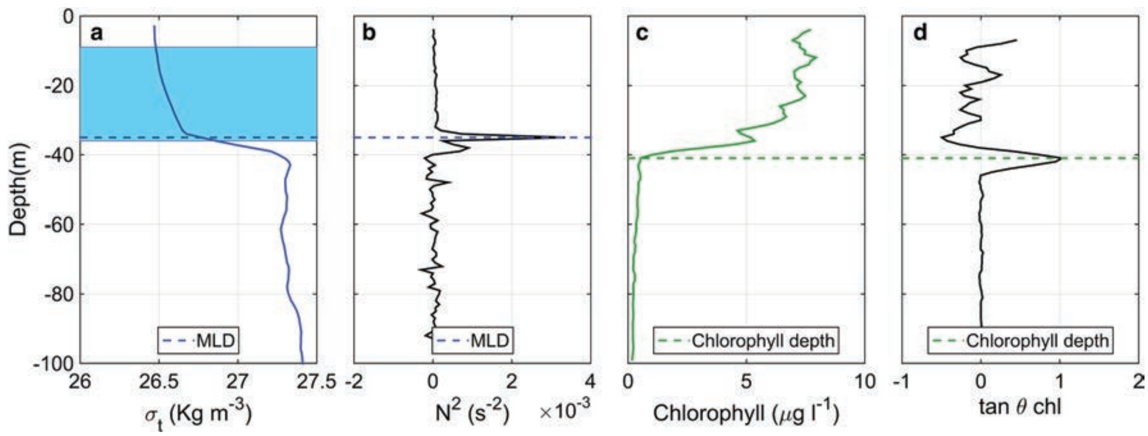

Figure 2. Determination of mixed-layer depth (MLD) and chl *a* depth (Z_{chl}) from a glider profile (located at 64.827°S, 64.286°W at GMT 4:29 on 6 January 2014). (a) Density profile (solid blue line) with MLD (blue dashed line) calculated by max (N^2) and range of MLD (shaded blue) calculated using methods described in Table 1; (b) calculated buoyancy frequency (N^2) profile and MLD; (c) chl *a* profile (solid green line) with Z_{chl} (green dashed line) defined by the maximum angle method [*Chu and Fan*, 2011], or the max ($\tan_{\theta(chl)}$), and (d) calculated $\tan_{\theta(chl)}$ and Z_{chl}.

on the maximum of buoyancy frequency (max(N^2) or stability frequency). For each profile (Figures 2a and 2b), MLD was determined by finding the depth of the maximum water column buoyancy frequency. The same analysis was conducted for the most commonly used estimates of MLD in Antarctica's coastal seas and presented in the supporting information as a comparison against our proposed MLD definition.

The determination of MLD is based on the principle that there is a near-surface layer characterized by quasi-homogeneous properties with a standard deviation of the property within this layer close to zero. Below the MLD, the variance of the property should increase rapidly. To clarify the relationship between MLD and chl *a* in such a high-resolution data set, a quality index (QI) (equation (1)) by *Lorbacher et al*. [2006] was used to evaluate our MLD calculations and filter out profiles where MLD could not be resolved:

$$\mathrm{QI} = 1 - \frac{\mathrm{rmsd}(\rho_k - \overline{\rho})|_{(Z_1, Z_{\mathrm{MLD}})}}{\mathrm{rmsd}(\rho_k - \overline{\rho})|_{(Z_1, 1.5 \times Z_{\mathrm{MLD}})}} \tag{1}$$

where ρ_k is the density at a given depth (k), Z_1 is the first layer near the surface, and rmsd() denotes the standard deviation from the vertical mean $\overline{\rho}$ from Z_1 either to the MLD or $1.5 \times$ MLD. This index evaluates the quality of the MLD computation. Using this, MLDs can be characterized into estimates determined with certainty (QI > 0.8), determined but with some uncertainty ($0.5 <$ QI < 0.8) or not determined (QI < 0.5). Example of profiles for data removed from the analysis (QI < 0.5) can be found in the supporting information (Figure S2). This QI metric does not consider the strength of stratification, just homogeneity of the surface layer above the defined MLD. Therefore, by definition, the MLD estimate is close to the lower boundary of that vertically uniform layer. Following the thresholds set by *Lorbacher et al*. [2006], for the analyses presented in this study, a quality index of 0.5 was used to reasonably warrant a calculation of MLD. The quality index threshold of 0.5 was determined based on the insensitivity of the slope of the trend lines using higher QI values (0.8).

Apart from the depth of the ML, stratification also plays an important role in phytoplankton dynamics [*Holm-Hansen and Mitchell*, 1991; *Mitchell et al*., 1991]. The differences in the vertical physical structure setting seen in the temperature (T) and salinity (S) plots (Figure 3) result in differences in stratification. To identify the profiles with the highest stability at the base of the MLD in each region, stability was normalized independently for each region by dividing the buoyancy frequency at the base of MLD of that profile by the regional average of buoyancy frequency at the base of the MLD. The normalized stability was calculated to find the magnitude of each point as it relates to the overall stability in each region. This allows the regional differences due to the vertical structure of the water column to be removed.

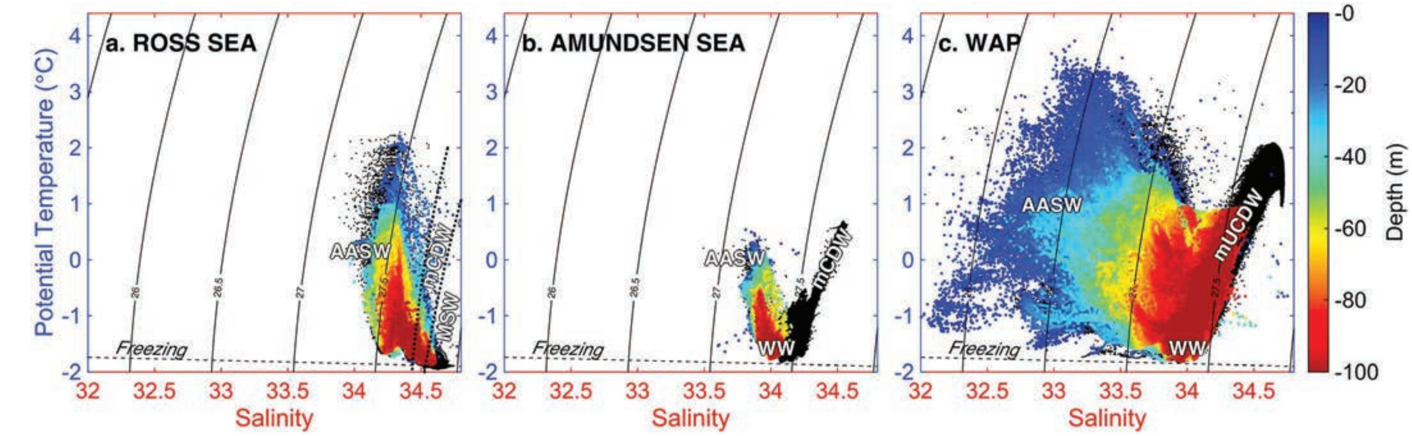

Figure 3. The θ-S scatters plots for all three areas shown in Figure 1: (a) Ross Sea, (b) Amundsen Sea, and (c) WAP. Color indicates depth of the water column measurement in the upper 100 m of the water column. All data between 100 and 1000 m are plotted in black. Primary water masses sampled are indicated and labeled (WW = Winter Water; MSW = Modified Shelf Water; AASW = Antarctic (summer) Surface Water; mUCDW = modified Upper Circumpolar Deep Water.

2.3. Chlorophyll *a* Fluorescence

Chl *a* fluorescence, as measured by the glider ECO pucks, is our indicator of phytoplankton biomass. Discrete in situ water samples were collected from several depths from casts during each glider deployment and recovery. Water samples were filtered onto 25 mm Whatman GF/F filters and extracted using 90% acetone, and chl *a* concentration was then measured using a fluorometer. For each deployment, the structure and magnitude of chl *a* measured by the glider puck was verified against both the independent discrete measurements and an independent calibrated fluorometer deployed from a collocated ship station. While the complex relation between fluorescence versus biomass was not fully evaluated, we provide an accurate characterization of the observed fluorescence, fully realizing that our measurements may not accurately represent phytoplankton biomass. Also, since our analysis focuses on the bottom of the phytoplankton biomass layer, daily nonphotochemical quenching of chl *a* fluorescence is not a factor in our analysis.

Following a method adapted from the maximum angle principle used to calculate MLD [*Chu and Fan*, 2011], the depth of lower boundary of chl *a* was estimated, referred to as chlorophyll depth (Z_{chl}) in the analysis. This method is based on three main steps: (1) fitting the profile data with a vector (pointing downward and with n points) from shallower depths to a certain depth k and a second vector from that depth to deeper depth ($k + 1 + n$); (2) identifying the tangent angle ($\tan_\theta$) between the two vectors for each depth k; and (3) defining the MLD by determining the maximum angle in each profile. Here we apply the same principle using the maximum angle, as we are interested in calculating the depth of the deepest inflection point in the chl *a* profile. Using a vector of $n = 7$ data points, the depth of the max($\tan_\theta$) of the chl *a* profile was determined and used as the Z_{chl} (Figures 2c and 2d). A quality index (QC) (equation (2)) was also applied to the chlorophyll data to evaluate the Z_{chl} computation. A modification to equation (1) was made to account for the homogeneity occurring below the Z_{chl} and not above:

$$\mathrm{QC} = 1 - \frac{\mathrm{rmsd}\left(\mathrm{CHL}_k - \overline{\mathrm{CHL}}\right)\big|_{(Z_{\mathrm{chl}}, Z_D)}}{\mathrm{rmsd}\left(\mathrm{CHL}_k - \overline{\mathrm{CHL}}\right)\big|_{(Z_D - 1.5(Z_D - Z_{\mathrm{chl}}),\ Z_D,)}} \qquad (2)$$

As both variables have errors in them and linear relationships are expected between both variables [*Holm-Hansen and Mitchell*, 1991; *Mitchell et al.*, 1991], model 2 regressions were applied to concurrent MLD and Z_{chl} calculations to evaluate the MLD determination of the definitions chosen by comparing it to a 1:1 line.

3. Results and Discussion

Each region had a different distribution of water masses as indicated in temperature (*T*) and salinity (*S*) space (Figure 3). Surface water in the RS and AS were similar, but quite different from the WAP while at depth, AS and WAP showed similarities. Compared to the WAP, both Ross and Amundsen Seas showed overall colder and saltier waters with the latter being on average saltier. The warmer, saltier and deep modified Upper

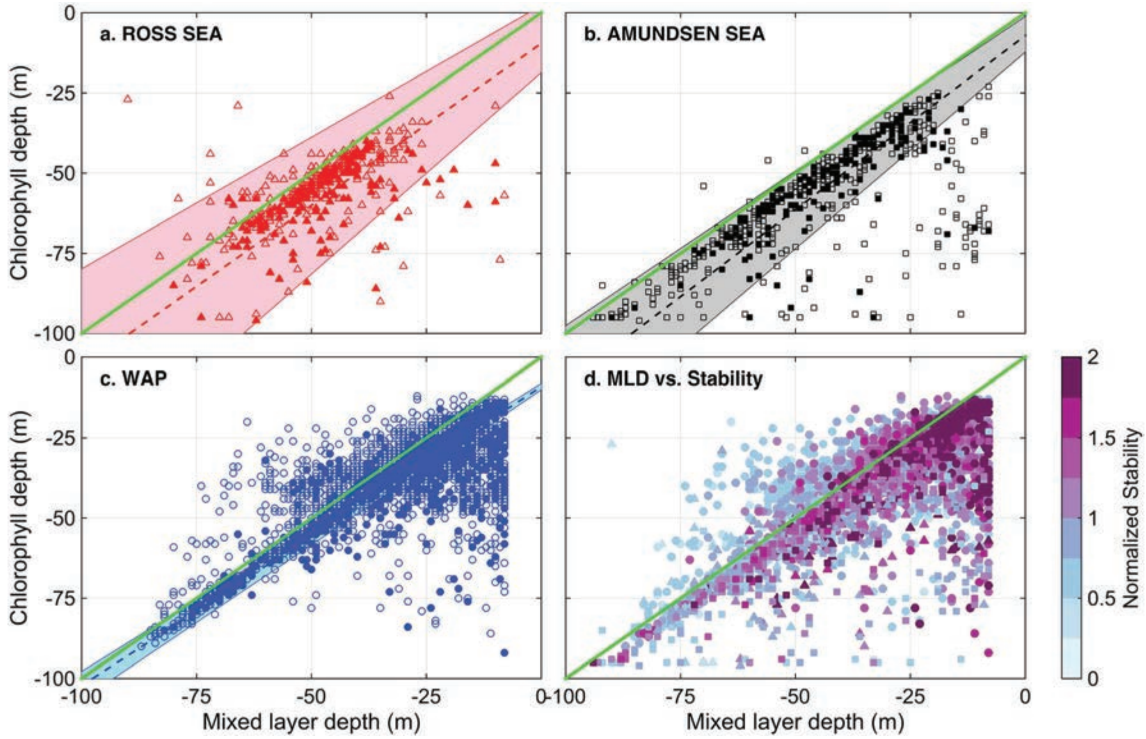

Figure 4. Correlation between MLD and Z_{chl} for all glider profiles with quality index (QI) over 0.5 (open marker) and over 0.8 (filled marker) for all three regions: (a) Ross Sea (triangle); (b) Amundsen Sea (square); (c) WAP (circle); (d) comparison between all three Antarctic regions (QI > 0.5) with normalized stability frequency colored. Ninety-five percent confidence intervals (shaded area) and model 2 regression line are shown for QI > 0.8 (dashed line). A quality index of 0.5 was also applied to chl *a* (QI_{chl}) profiles, and only profiles with $QI_{chl} > 0.5$ are shown above. Line 1:1 is shown in green.

Circumpolar Deep Water (mUCDW) found at shallower depths in the WAP was not seen in the upper 100 m (colored dots in Figure 3) in RS and AS. In both the latter regions, T_{min} was found generally in the deepest sampled waters (red). The WAP (Figure 3c), with the widest range of T-S properties as it is located at lower latitudes, spans entire seasonal cycles due to more sustained sampling and is more influenced by coastal inputs.

We compared our MLD estimation based on N^2 and chlorophyll depth, described in section 2.3, across each of the coastal regions. Profiles with QI and QC values less than 0.5 [*Lorbacher et al.*, 2006] were removed as MLD and Z_{chl} were not clearly defined. The remaining profiles were characterized as "estimated with uncertainty" ($0.5 < QI < 0.8$; Figure 4, open markers) and "estimated with certainty" ($QI > 0.8$; Figure 4, filled markers). A linear, model 2 regression was applied to each regional data set, and the line and corresponding R^2 are reported in the supporting information (Table S2). Although some regional differences were found in the MLD ranges, all three regions showed an MLD-chl *a* relationship close to 1:1 with 95% confidence (compare dashed trend lines with green), i.e., the deeper the MLD, the deeper the lower boundary of the chl *a* profile. The observed differences in the depth of the ML across regions (Figure 4) were mostly influenced by the timing of the measurements, i.e., uneven sampling in time in different regions. Nevertheless, the MLD calculations are within range of those reported for each region [*Schofield et al.*, 2015; *Smith et al.*, 2014; *Vernet et al.*, 2008].

Given the disproportionately greater number of profiles collected in the WAP (Figure 4c), this region showed the widest range of MLDs estimated with certainty ($QI > 0.8$) of all three regions, ranging from 8 to 65 m of depth. It showed, on average, the shallowest MLD ($\overline{MLD}$ = -33 m ± 13) and a trend line ($y = 0.93175x - 9.0415$; $R^2 = 0.82$; $p < 0.0001$) close to the 1:1 line (green line). The RS (Figure 4a) showed the deepest MLD ($\overline{MLD}$ = -49 m ± 9), but regardless, the relationship between MLD and chl *a* ($y = 1.0098x - 9.5745$; $R^2 = 0.60$; $p < 0.0001$) was similar to those seen in the other two regions. The AS that exhibited the smallest number of data points, however, showed a high R^2 ($y = 1.0849x - 7.125$; $R^2 = 0.78$;

Table 1. Examples of Criteria Used to Define MLD in Waters Around Antarctica

Author	Area studied	MLD Threshold Criterion
Kara et al. [2000]	Global ocean	$\Delta T = 0.8°C \Delta\sigma_\theta = \sigma_\theta (T + \Delta T,S) - \sigma_\theta (T,S)$ with $\Delta T = 0.8°C$
de Boyer Montégut et al. [2004]	Global ocean	$\Delta T = 0.2°C \Delta\sigma_\theta = 0.03$ kg m^{-3}
Dong et al. [2008]	Southern Ocean (open ocean)	$\Delta\rho = 0.03$ kg m^{-3} $\lvert\Delta T\rvert = 0.2°C$
Sallée et al. [2010]	Southern Ocean (open ocean)	$\Delta\sigma_\theta = 0.03$ kg m^{-3}
Long et al. [2012]	Ross Sea	$\Delta\sigma_\theta = 0.05$ kg m^{-3}
Smith and Jones [2015]	Ross Sea	$\Delta\sigma_\theta = 0.01$ kg m^{-3}
Fragoso and Smith [2012]	Ross and Amundsen Seas	$\Delta\sigma_\theta = 0.01$ kg m^{-3}
Schofield et al. [2015]	Amundsen Sea	max(N^2)
Vernet et al. [2008]; *Prézelin et al.* [2004]	WAP	Not specified
Venables et al. [2013]	Margarite Trough (WAP)	$\Delta\sigma_\theta = 0.05$ kg m^{-3}
Moline et al. [1997]; *Cimino et al.* [2016]	Anvers Island (WAP)	max($\partial\rho/\partial z$)
Walsh et al. [2001]	Northern WAP	Not specified
Mitchell and Holm-Hansen [1991]	SW Bransfield Strait (WAP) and Drake Passage	$\Delta\sigma_\theta = 0.05$ kg m^{-3} (in 5 m window)

$p < 0.0001$) for both quality indices used. This region shows again a wider range of MLD comparatively to the Ross Sea, but has also, on average, deeper MLDs ($\overline{MLD}$ = -41 m ± 13) than the WAP. All three regions showed slopes not significantly different than the 1:1 line (Table S2).

Comparing the trends obtained using both indices (QI > 0.8 compared to QI > 0.5, corresponding to 26–31% and 80–87% of the profiles, respectively) showed little differences (Table S2). Higher QIs are observed during summer and fall, where sharp gradients at the base of the seasonal mixed layer are present [*Lorbacher et al.*, 2006]. A maximum MLD difference of 3 m for the AS was observed when using QI > 0.5 compared to a higher MLD quality index, QI > 0.8; and overall, this difference was much smaller for the remaining two regions. This ensures that even though we are using a lower quality index to include more data in the analysis (QI > 0.5, the minimum threshold set by *Lorbacher et al.* [2006] for determining MLD), we are capturing the same patterns. Points that are closer to the trend line show, on average, much higher water stability (Figure 4d), with the shallowest MLD showing the highest water stability due to freshwater input from meltwater [*Martinson and Iannuzzi*, 1998]. Since our gliders measurements start at a minimum of 2 m depth and our Z_{chl} computation relies on a 7-point vector, it was not possible to evaluate the biophysical relationship in this study within the upper 7 m. This is a constraint on our method of evaluating the correlation between MLD and chlorophyll depth and not on the actual MLD determination. Studies in the region have also shown that most Z_{chl} occur deeper than 7 m [*Moline et al.*, 1997; *Smith et al.*, 2013]. Note that, as this method captures the maximum stability frequency of the water column profile, its accuracy depends both on the vertical resolution and the vertical extent of the measurements. This is especially important in the presence of meltwater lenses in the surface layer, which our gliders were not able to capture. This method relies on the implicit assumption of a two-layer ocean. Cases where the surface ocean has a well-defined (and deeper) ML and a surface active mixing layer [*Brainerd and Gregg*, 1995], this method will capture the depth of the strongest water column stability and therefore a lower QI may be determined based on this two-step surface ML if the base of the ML has a stronger N^2 value.

To determine the value of our combined method linking physical MLD with chl *a* depth, we evaluated several MLD methodologies. The most commonly used MLD criteria in polar waters (Table 1) were tested for each individual profile and matched against the Z_{chl}. The range of MLD calculated using the different criteria are presented for a representative profile as the shaded area in Figure 2a.

Using a model 2 linear regression, we were able to evaluate the various MLD definitions (Table S1 and Figure S1 in the supporting information) and concluded that the most ecologically relevant MLD determination method across all regions based on the strength of the correlation with the lower boundary of the chl *a* profile was the maximum of buoyancy frequency (section 2).

Independent of the different water mass compositions and dynamics present in each region, the biophysical relationship between MLD and chl *a* remains the same in all three regions. With slopes not significantly different from the 1:1 line (within the 95% confidence intervals of the model 2 regression fit) in all three regions suggests that the MLD definition we are using is a good predictor of the depth of the inflection point in the chl *a* profile (lower boundary of the chl *a* patch in the water column) and is therefore an important parameter in phytoplankton dynamics studies.

4. Conclusions

Understanding the spatial and temporal variability of phytoplankton is important, especially to assess ecological dynamics of marine food webs. Historically different MLD calculations have been applied in Antarctic continental shelves and linked to phytoplankton dynamics [*Mitchell and Holm-Hansen*, 1991; *Smith and Jones*, 2015; *Vernet et al*., 2008]. These calculations were based on different subjective thresholds (sometimes linked to local hydrography) for the same regions. This leads to significant variability in MLD estimations, making comparisons between studies and regions problematic. MLDs calculated from buoyancy frequency were similarly correlated with our adapted estimate of Z_{chl} across all three coastal regions. Given the variability in water mass distribution and volume between the RS, AS, and along the WAP, this biophysical relationship was similar in all regions, which suggests that the maximum of stability frequency (or max(N^2)) is an appropriate and robust metric to compare and contrast biophysical processes across all three Antarctic regions.

Acknowledgments
We thank the crews of R/V Nathaniel B. Palmer, ARSV Laurence M. Gould, R/V Araon, Palmer Station support staff, and the Rutgers glider team for facilitating our long-term data collection efforts. We also wish to thank five anonymous reviewers for their suggestions regarding the analysis in this paper. The research was supported by the National Science Foundation grants ANT-0823101 (Palmer-LTER), ANT-1327248, and ANT-1326541 (CONVERGE), ANT-0839039 (SEAFAReRS), ANT-0838995 (ASPIRE), and the Korean Polar Research Institute grant PP1502 (KOPRI). Filipa Carvalho was funded by a Portuguese doctoral fellowship from Fundação para a Ciência e Tecnologia (DFRH - SFRH/BD/72705/2010). Glider data can be accessed at ERDDAP server at http://erddap.marine.rutgers.edu/erddap/info/.

***Abstract*— The new and emerging use of Slocum gliders in oceanographic data collection has brought about a progressive new way to record in-situ oceanic data. This piece of technology has been used by the Rutgers University Department of Marine Science through over 400 deployments, including a deployment during Hurricane Sandy in late October 2012. Data being collected during this deployment was done by Slocum glider RU23, which recorded measurements such as backscatter, fluorescence, water velocity, conductivity, temperature and depth. The dynamics of water motion RU23 flew in caused an unforeseen additional dataset to be collected by the glider. Because RU23 flew during intermediate type ocean waves, the orbital motion of the water potentially caused fluctuations seen in the dive and climb profiles of RU23's pressure record. Analysis can be done on the signal seen in the pressure record, by viewing its pressure fluctuation in the frequency spectrum. From this, wave period can be extracted. Accuracy of the glider's extracted wave period will be done by comparing the glider wave period to recorded wave period done by nearby NDBC buoys. Also analyzed was the glider's response to the turbulent water dynamics gauged by its performance in its attitude measurements.**

***Keywords*—Slocum gliders; intermediate-water hurricane; wave period; particle motion; power spectral density analysis**

I. INTRODUCTION

Due to its higher latitude, the New Jersey region historically has a low probability of being hit with a major hurricane. With only three category 1 hurricanes (74-95 mph wind speeds) hitting the New Jersey region in the past century, it is no surprise that Hurricane Sandy of late October 2012 was given the name 'Superstorm Sandy'. At its peak, Sandy was classified as a category 3 hurricane, and when it made landfall in New Jersey, it had wind speeds recorded around 80mph. An unusual characteristic of Hurricane Sandy was its perpendicular path to the eastern coast when it made landfall in New Jersey, meaning the storm moved inland cross-shelf, vs. parallel to the coastline. Statistical simulations show Hurricane Sandy's actual path having a probability of happening once every 700 years [1]. This hurricane was the most destructive and one of the rarest natural disasters New Jersey has faced on record, while also being the second costliest hurricane in United States history. Its infliction of billions of dollars' worth of damage includes 346,000 homes being destroyed and erosion across the entire New Jersey coastline [2].

To mitigate the intensity uncertainty associated with these hurricanes and tropical cyclones, Rutgers University's COOL group (Center for Ocean Observing Leadership) deploys Teledyne Webb Research Slocum gliders during these events to collect oceanographic data about the storm. From CTDs measuring conductivity, temperature & depth, to acoustic current profilers, measuring water column current profiles, to ECO (Environmental Characterization Optics) pucks measuring fluorescence, backscatter, and more, the Slocum gliders provide a plethora of in-situ data to be used and distributed throughout the oceanographic and meteorological community. Rutgers has utilized the capabilities of oceanographic observing with gliders in all 7 continents, from Antarctica to Svalbard, Norway. Though using gliders for science is relatively new, this new perspective of the oceanic and atmospheric interaction can help further improve hurricane forecasting and data collecting.

Operating gliders in storm conditions, notably intermediate water conditions, which is based off of water depth and wavelength, has brought about observations concerning the gliders flight dynamics. How well the glider flies, ways to improve this flight for future, and measurements derived from how the glider and the surrounding water interact will be the focus of this paper. This paper will review how well Slocum glider 'RU23' flew during Hurricane Sandy by looking statistically at how much has changed in its flight dynamics before, during, and after the storm passed over the glider. Also to be discussed will be new variables, such as dominant wave period, which can potentially be derived from the gliders unique flight dynamics during intermediate water storms. This will be done by assessing the frequency spectrum of the signal caused by the passing wave in RU23s pressure record. From this, the dominant wave period can be extracted for each dive and climb profile this signal is present in, and a time series of wave period can be created. This time series will be compared to nearby National Oceanic and Atmospheric Association (NOAA) National Data Buoy Center (NDBC) stations and an assessment of the extracted wave period from RU23 will be done. Finally, this paper will review the limits of acquiring wave period from Slocum gliders based off the required environment conditions, the sampling rate of the glider, and more.

II. METHODS

A. Slocum Gliders

978-0-692-94690-9/$31.00 ©2017 MTS

Gliders are remotely operated underwater vehicles which have become an important tool concerning oceanographic data collection. They can be deployed remotely and can continue to be controlled from a desktop computer in the comfort of an office or home. They are essential when during dangerous and long duration missions, like collecting data during hurricanes or sampling in the middle of the ocean 1000 meters deep, as a human not need be present for this piece of technology to be operated. A glider will sample a planned mission autonomously until it is complete, while sending a mission report periodically as an update to its flight engineer. This is to benefit during a storm where loss of contact due to high waves becomes prevalent.

Slocum gliders also have the opportunity to be customized to a mission's needs. If the turbidity of the water must be measured during a mission, the glider can be equipped with an ECO puck and measure exactly this. On the other hand, if this measurement is not needed for a subsequent mission, the ECO puck can be removed, or turned off to conserve battery. The way a Slocum glider moves and collects data is primarily through a change in density, ascending and descending the height of the water column to a predetermined depth. The flight path of a Slocum glider thus looks similar to a zig-zagged triangle profile, as seen as the black line in Fig. 5.

Before Hurricane Sandy hit New Jersey, Slocum glider RU23 was deployed at 19:44 UTC on 25 October 2012 from Rutgers University for approximately 10.92 days, until 17:44 UTC on 5 November 2012. During its deployment, RU23 was equipped to measure CDOM (colored dissolved organic matter), chlorophyll, fluorescence, backscatter (700 nm), temperature, conductivity, and depth, and was outfitted with an Aquadopp current meter. Some differences will arise in the way data are collected by the glider due to there being two computers operating the glider. The two data collection methods are first through the science bay computer, collecting scientific data such as CDOM and current velocities, and second through the flight controller, collecting engineering and flight performance data such as pitch and roll. This causes repeated measurements, such as for time, and depth, with different sampling rates — an average sampling rate of 2.02 seconds for science bay and an approximate sampling rate of 4-5 seconds for flight bay.

B. *Statistical Analysis*

Statistical analysis of the collected data from RU23 is done in MATLAB. RU23's DbdGroup is loaded into MATLAB and the "not a number" (NaN) data points are filtered accordingly. Next, a two-dimensional grid, using the array of time, from RU23's collected data during the entirety of its Hurricane Sandy mission, and the array of water depth, from the top inflection depth to the bottom inflection depth per profile, is created to produce the coordinates of a rectangular grid. After this, an analyzed moving window standard deviation function is applied. This function creates a size 3 windowed standard deviation of the statistical array to be analyzed (i.e. this will find a moving standard deviation of pitch or roll during RU23's flight). The size of the window is determined by the appropriate amount of smoothing required to analyze this dataset. The statistic gridded on a time and depth axis can now be plotted using colored plots to be analyzed in upcoming sections of this paper.

C. *Wave Type and Particle Motion*

Wave theories will be used to determine the type of wave motion felt by RU23 during its Hurricane Sandy mission. The trajectories of a particle's motion, induced by a wave, is dependent on the wave type. The limits of applicability of types of waves will be bases off the book, *Introduction to Physical Oceanography* by John A. Knauss, and Newell Garfield. In this book, it is stated that the limits of applicability depend on the ratio of depth of water 'h' to wave length 'L' as shown in Fig. 1 [3]. The ratio of water depth to wavelength must be greater than 0.25 to be classified as a deep-water wave, whereas this ratio must be less than 0.05 to be classified as a shallow-water wave. If the ratio falls in between the previous two, from 0.25 to 0.05, the wave is classified as an intermediate-water wave.

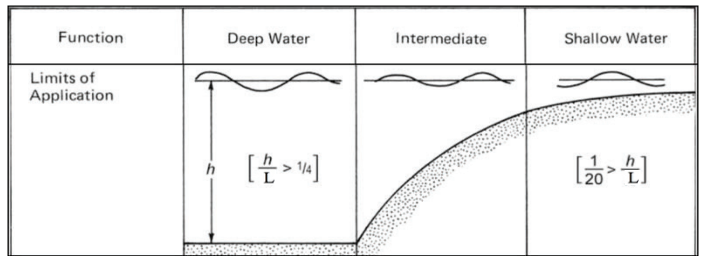

Figure 1: Limits of applicability for determining the classification of a wave [3]. Wavelength is represented as 'L' and water depth is represented as 'h'.

The average water depth RU23 flew in during its Hurricane Sandy mission was approximately 43 meters (approximately 141 feet), according to the total water column depth data collected from RU23. The closest NDBC buoy to RU23, station 44025, recorded the average wave period as 12.14 seconds. These data used to determine this average were collected and made freely available by the NOAA NDBC. The wave period calculated from the NDBC buoy is the average wave period over the number of days a signal from Hurricane Sandy is present in RU23's data, from approximately 05:48 UTC on 29 Oct 2012 to the 21:32 UTC on 30 Oct 2012. From this, the ratio of water depth to wavelength can be approximated using methods from the Shore Protection Manual [4]. Initially, a deep-water wavelength, L_0 must be calculated using the following equation:

$$L_0 = \frac{g \cdot T^2}{2\pi} \tag{1}$$

In (1), T is the known wave period, 12.14 seconds, and g is the gravitational acceleration constant, 9.81 m/sec^2 (32.2 ft/sec^2). Solving gives the deep-water wavelength (L_0) equal to 230.19m (755.23 feet). Next, the water depth to deep-water wavelength ratio (h/L_0) can be calculated as 0.19, using 43 meters (141.1 feet) as h. An approximation can now be determined graphically for the ratio of wavelength to water depth as a function of h/L_0 by referencing a figure from *Coastal Protection* not shown in this paper [5]. This gives a ratio as approximately h/L = 0.20, therefore, RU23 felt intermediate-water waves during its Hurricane Sandy mission. Further investigation into determining the wave period in the pressure record from RU23 will be done under the conclusion that RU23s mission was performed in intermediate-type waves.

The characteristics of motion a particle will feel in deep, intermediate, and shallow water waves differs in shape, from circular to elliptical, as shown in Fig. 2 [3, 6]. In an intermediate-water scenario, the shape is elliptical, with the minor radius decaying with depth until it reaches zero. The major radius will also decay with depth, but does not reach zero. This wave signal increases intensity with depth, as shown in Fig. 3, as the elliptical motion shape horizontally flattens more greatly with depth. The Results section will discuss this concept in more detail. The signal received in the pressure record from RU23 will be what is analyzed and compared to NDBC buoys. Shown in the left subplots of Fig. 3 is a typical dive profile of depth for a Slocum glider. As the sample number representing time progressed, the glider descends in depth on a fairly straight dive plane. However, noticed during Hurricane Sandy the pressure record becomes erratic. We surmise that this is from the types of motion induced by the wave field above the glider and wish to analyze the resulting pressure record fluctuation through frequency analysis.

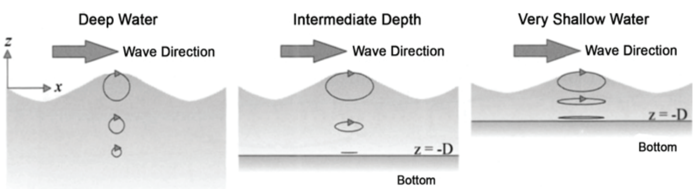

Figure 2: Orbital motion of a particle in deep, intermediate, and shallow water type waves. 'z' represents bottom depth and 'D' represents depth in water column [6].

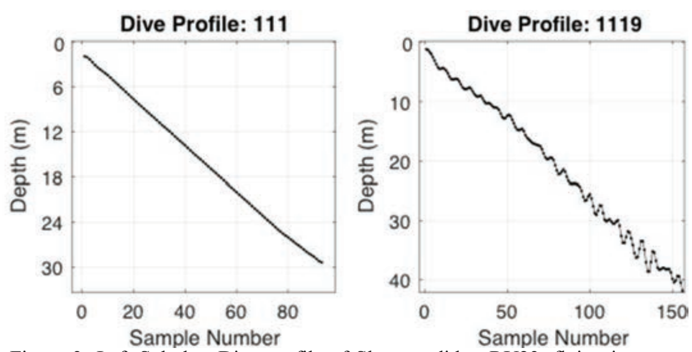

Figure 3: Left Subplot: Dive profile of Slocum glider, RU23, flying in water undisturbed by waves. Right Subplot: Dive profile of RU23 flying in intermediate-type waves, which signal is present in pressure data.

D. Signal Processing

The frequency analysis of the periodic signal, present in RU23's pressure data, is extracted and analyzed using Welch's overlapped averaging estimator. A power spectral density for the pressure record, recorded by the science bay, is determined for each dive and climb profile RU23 performed, using the function 'pwelch' from MATLAB. Inputs into this function are determined individually based on characteristics of each profile to limit bias.

Once the power spectral density is found per profile, a filter is applied to determine the dominant wave period felt during the dive or climb. This filter removes the signal created from the inflection and deflection pattern of the glider's vertical flight path. A demonstration of this power spectrum density plot for dive profile 1119, before the filter is applied, is shown in Fig. 4, where 'f' is the frequency. Here, it can be seen that the dominant signal is 15.6 seconds, or 0.6Hz.

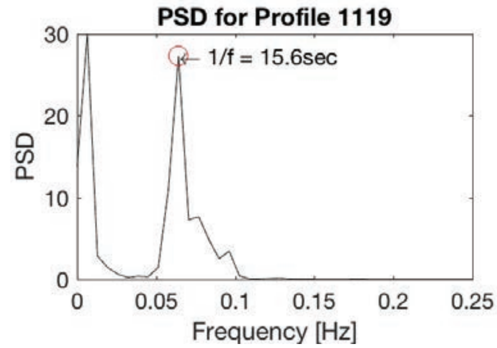

Figure 4: Power spectral density for the signal found in the pressure record of profile 1119 from RU23. 'f' indicated frequency. The circled peak correlates to a recorded signal of 15.6 seconds.

III. Results

A. Glider Performance

Understanding the dynamics of the Slocum gliders flight performed during its mission is important for understanding the data the glider collects. Some background information must be established first. The pitch, roll, and yaw of an aeronautical vehicle are the principle axis of rotation. The pitch of a Slocum glider can be controlled via adjusting a weight in the fore of the body, the yaw can be controlled via adjusting the rudder at the rear, and the roll of the glider cannot be controlled. The Slocum glider is ballasted as close to 0° in roll as possible, and change to this axis while in flight can only be done through the influence of an outside force. An example of the standard roll, pitch and depth profiles recorded from a glider, vs. examples during a storm or turbulent water, are seen in Fig. 5.

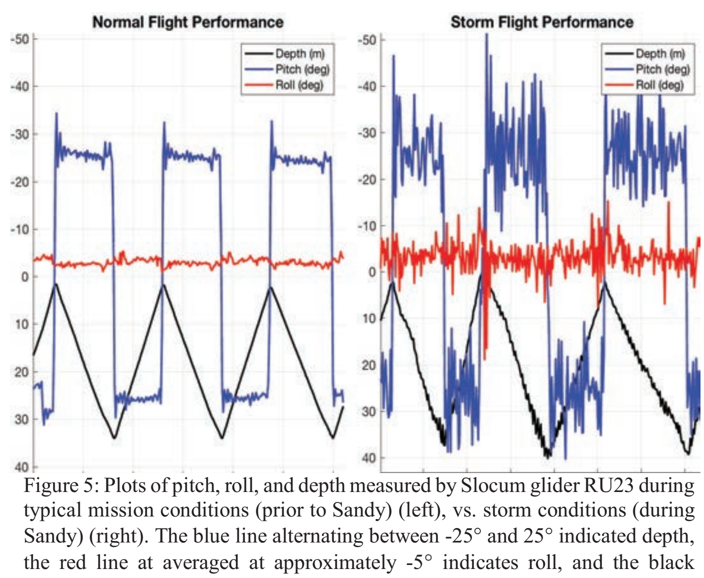

Figure 5: Plots of pitch, roll, and depth measured by Slocum glider RU23 during typical mission conditions (prior to Sandy) (left), vs. storm conditions (during Sandy) (right). The blue line alternating between -25° and 25° indicated depth, the red line at averaged at approximately -5° indicates roll, and the black triangle shape line indicates depth.

In the left subplot, the standard record of pitch, in blue, is stable at -25° and 25° when RU23 transitions to and from a dive position and climb position during typical flight conditions. Roll can be seen in the same plot during the same conditions as the red line, remaining stable near -5°, and the pressure record, indicating depth, can be seen as the black line, remaining steady as the glider ascends and descends the water column. In the right subplot, the three variables are all influences significantly by the outside environmental force of the storm, causing extreme variability in the measurements.

If change in roll is seen in the gliders flight data, then it is known that there is an outside influence on the glider. This could indicate mixing, turbulence, or another outside force. The extent to which a change in roll is seen in the glider data, could show how deep the mixing is, and to which depths the water column is being affected by the storm. A plot of the standard deviation of roll from RU23 is shown in Fig. 6 as the top subplot. This plot also includes a record of wind intensity, in knots, collected from the nearby NDBC station 44025 as the overlaid solid line. As the intensity of wind increases, caused by the approaching Hurricane Sandy, the standard deviation of roll increases. One benefit to this is the ability to measure potential mixing or turbulence without the need for an additional sensor, and the extent of depth to which this is occurring.

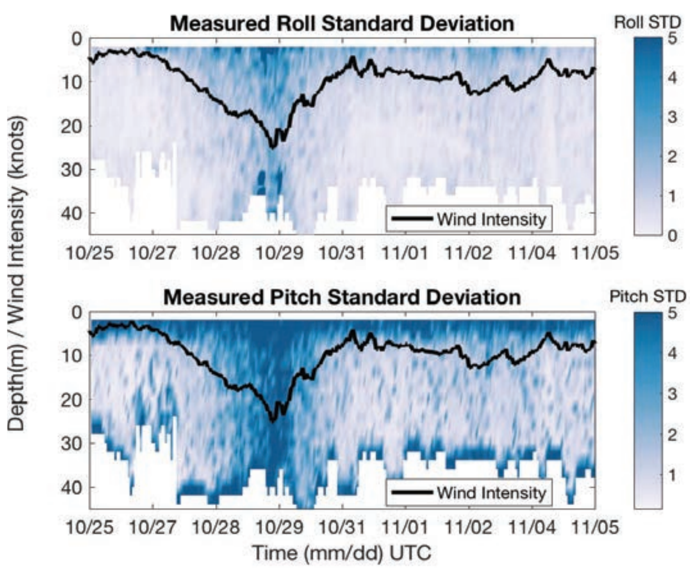

Figure 6: Top: Plot of the standard deviation of roll with depth recorded from RU23. Bottom: Plot of the standard deviation of measured pitch with depth recorded from RU23. Record overlaid on the standard deviation plot is wind intensity recorded from NDBC station 44025, with a peak at 25kt on 29 Oct 2012.

Worth noting is that gliders are considered a quite stable platform. However, during storms we have continuously noticed they are often affected by the surrounding water to varying degrees. Not only in pressure as analyzed before, but in attitude as well [7]. This could make attitude related sensors, such as turbulence probes, current profilers, and acoustic sampling devices, more difficult to operate.

The pitch of Slocum gliders is expected to only change at each inflection and deflection during its mission, but, as with roll, the surrounding environment can have an effect. Because Slocum gliders have the ability measure and change its pitch, readjustments were made by RU23 during its Hurricane Sandy mission when an error in pitch was too significant. The standard deviation of measured pitch recorded from RU23 can be seen as the bottom subplot in Fig. 6. This shows that as the intensity of wind increases, there is greater fluctuation in the measured pitch angle from RU23. It is important to keep in mind this change in pitch when analyzing the fluctuating pressure record. Suspicion that the fluctuation is caused by the changes in pitch will be discussed in the next section. Similar to the changes seen in roll, changes seen in pitch can indicate how deep mixing or turbulence is felt throughout the depths of the water column.

B. Wave Period

Besides the pressure from incoming waves, a possibility which could cause the fluctuations in the pressure record, as seen in the right subplot in Fig. 3, is the change in pitch angle caused by a turbulent environment. Slocum gliders detect an error in pitch, and if the error is too significant, a commanded adjustment to its pitch angle will be made. Changes to pitch, either caused by the environment, or due to commands, increases or decreases the flight angle of the glider. To rule out the possibility that the fluctuations in the pressure record are due to the change in pitch, the dive and climb profiles of RU23 are recreated based off the pitch angle, assuming a constant velocity per profile. Doing so accurately displays the dive and climb profiles of RU23, but fluctuations in depths are no longer present in this representation. Had the changes in pitch been the cause to the fluctuating pressure record, the signal would have continued to be present in the recreated dive and climb profiles. Therefore, suspicion that the fluctuation in pressure is due to changes in pitch can be ruled out, further indicating the likelihood that these observed pressure changes are induced by waves.

In a case where deep-water waves are present, no signal from the above passing waves can be seen in the pressure record from a glider, as noted from previous glider deployments done by Rutgers University's COOL group. As a wave passes over the glider, the glider moves with the wave in a circular motion, as seen in Fig. 2. This mimicking orbital motion done by the glider in a deep-water wave, cancels any additional pressure brought on by the passing wave, therefore, no flux in the pressure record is present. The vertical motion is the important reasoning behind a wave signal present, or not present, in a pressure record. If the vertical displacement of the glider is the same as the vertical flux of water caused by the passing wave, then detection of this wave will not be present in the data. In a case where intermediate-water waves are present, as the circumstance for RU23s Hurricane Sandy mission, the vertical displacement of the glider is not equal to the vertical influx of water from the wave, therefore some additional pressure brought on by the wave is present in the data, as seen in Fig. 3.

Analysis can be done on this fluctuating pressure record to determine the wave period. This is done by evaluating the frequency spectrum of the signal from the pressure record. Doing so for each dive and climb profile from RU23 with a present wave signal can give a time series of wave period. Accuracy of this wave period time series from RU23 is determined by a comparison with nearby NDBC buoys. Discrepancies in wave period between RU23 and nearby NDBC buoys could result from either fault in the methods of extracting wave period, or differences in environment from the locations of the buoys to that of RU23. Fig. 7 displays the track of RU23 as a solid blue line, in addition to the track of Hurricane Sandy as a dashed red line, and the location of the NDBC buoys as green triangles [8]. Note the substantial geographic difference in location of the NDBC buoys in comparison to the track of RU23. This can contribute to errors seen in the comparison of wave period data, with the closest NDBC buoy being 38km away near the start of RU23s mission [8].

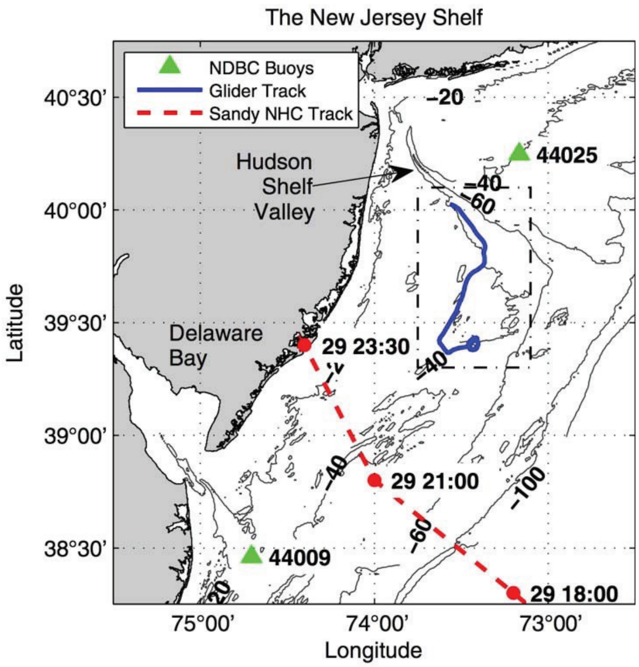

Figure 7: Plot of the New Jersey shelf with bathymetric contours measured in meters. Dashed red line indicates track of Hurricane Sandy; red dots on the dashed lines indicate corresponding times Hurricane Sandy is at each location. The solid blue line shows the mission track of Slocum glider RU23. The green triangles show locations of two nearby NDBC stations [8].

Visualization of the extracted wave period data from RU23, in comparison with two NDBC stations, can be seen in Fig. 8. Within the figure, similarities in trends are revealed, and matching peaks and valleys in data can be seen. If a discrepancy in RU23's wave period data is seen in comparison to Station 44025 during a certain time, it is likely that at this same time, an agreement in data can be seen with Station 44009, and vice versa. An example of this is demonstrated in Fig. 8 on 28 October 2012, at approximately 21:00 and on 29 October 2012, at approximately 11:00. Reason for this difference between the glider and Station 44009 is likely due to Station 44009 being located on the opposite side of the storm track as RU23. The winds are blowing in the opposite direction at Station 44009 compared to where RU23 flew, and the location of Station 44025, and thus rapidly reduced the wave period by blowing against to the mean wave direction. Station 44025 was on the same side of the storm as the glider, and therefore the results are more consistent. Overall, there is considerable agreement between the NDCB station's wave period data and the extracted RU23 wave period data. What is interesting about the buoy's data are the large changes in measured wave periods from 13 seconds to 9 seconds in a short time span. RU23's pressure record does not show these short span changes. It would be worth investigating why wave period would change rapidly only to return to its previous values.

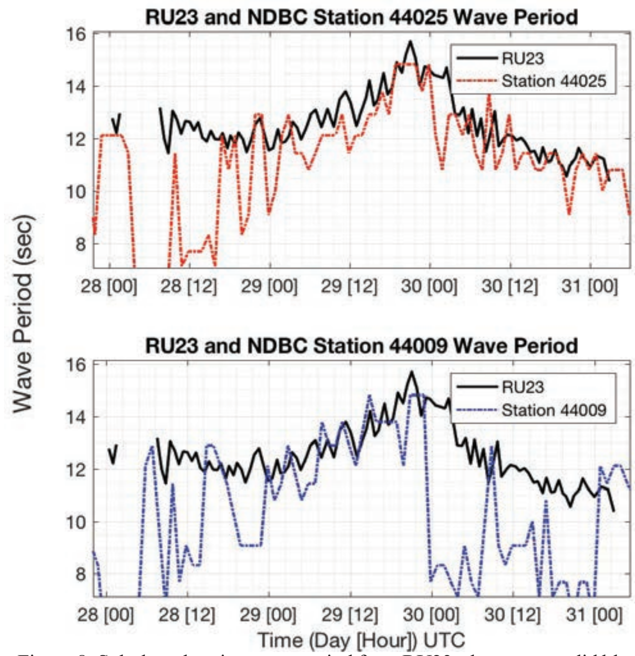

Figure 8: Subplots showing wave period from RU23, shown as a solid black line, and from NDBC Stations, shown as a dashed red or blue line. Top subplot shows data from Station 44025 (red) in comparison with RU23, and bottom subplot shows data from Station 44009 (blue) in comparison with RU23.

C. Limitations for Sampling

Acquiring wave period from Slocum gliders is limited to restrictions in glider sampling rates, and certain required environmental characteristics. The restrictions in glider sampling rates due to the Nyquist frequency will determine which signals the glider can and cannot detect. For example, if a device were to sample something that occurs at 1Hz, this device would need to sample at 2Hz, or twice as fast, minimum. To put this into the context of the paper, if the glider were to sample a 15 second wave period ($0.0\overline{6}$ Hz), the minimum sampling rate the glider must have would be 7.5 seconds ($0.1\overline{3}$Hz). This frequency is the minimum frequency a device must record at to see frequencies double to the recording frequency, without drastic error. Because the Slocum glider's science bay records at 0.5Hz, or every 2 second as mentioned previously, theoretically, the glider should be able to detect 4 second period waves, or waves passing at 0.25Hz. This is not reflected in the data, as shown in Fig. 8. We surmise that the shorter period waves were caused by smaller waves, which were not large enough to cause a signal in the glider's pressure record.

The minimum wave period RU23 was able to detect during this mission was near 10-11 seconds. Periods recorded by RU23 lower than this, as determined by the NDBC buoys, are recorded as errors, or are not present in the extracted wave period data. Reasoning behind this could be due to changing dynamics of orbital partial motion, from intermediate-water waves to deep-water waves, thus allowing the glider to fly smoother through the water column during these periods. This change in orbital motion will lessen the additional pressure felt on the glider by the waves, thus changing its pressure profile from the right subplot in Fig. 3 to the left subplot in the same figure, therefore causing the signal to be lost. When wave heights were below 4 m, as per the NDBC stations, the signal for detecting the wave period in the pressure record appeared to diminish to undetectable states. This loss of signal can be the reason why no data is present from approximately 03:00 28 October 2012 to 06:00 28 October 2012 in Fig. 7. An alternative reasoning behind the lack of accuracy in low period waves could be due to fault in methods for extracting wave period from each dive and climb pressure profile, as explained in the methods section of this paper.

IV. Conclusions

Slocum gliders are useful in many situations. They can collect in-situ oceanographic data in the roughest conditions without the need for a human to be present. Examples of data a Slocum glider can collect include water velocity, particle size, backscatter, flouresence, and more. In certain conditions though, Slocum gliders can also collect wave period using its pressure sensor by methods described in this paper. Though wave periods below 10-11 seconds inflict error in the extracted wave period data, wave periods above this threshold were recorded with considerable accuracy in the conditions RU23 faced during its Hurricane Sandy mission in October of 2012. The benefits to this ability to extract wave period during certain conditions include the lack of need for an additional instrument on the glider, because a Slocum glider is always equipped with a pressure sensor in its CTD, and an additional measurement of wave period for comparison with surrounding instruments. Further work is being done to see if any kind of wave height measurements can be calculated using wave theories from the vehicle's pressure record. Water depth, wave period, wavelength are known. Also it would be interesting to see if wave period can be measured for smaller waves in more shallow water. There is a variety of storm data available, typically Nor'Easters which could facilitate this investigation.

Acknowledgment

Great appreciation goes out to the COOL team at Rutgers University for the unlimited amount of assistance and guidance during this research project, and all other projects I have had the fortunate opportunity to work on with. Special thanks go out to Dave who help step me through this project, everyone who were nice enough to help me through this writing process, including persons at Rutgers University, and Texas A&M University.

Key Points:

- Autonomous underwater vehicles provide measurements of mesoscale features (~10 km) in the Antarctic with high-spatial resolution
- Mesoscale eddy-like features contribute significantly to the heat budget of the west Antarctic Peninsula continental shelf
- Upper Circumpolar Deep Water consistently intrudes onto the WAP shelf in bathymetric depressions

Abstract We use autonomous underwater vehicles to characterize the spatial distribution of Upper Circumpolar Deep Water (UCDW) on the continental shelf of the West Antarctic Peninsula (WAP) and present the first near-synoptic measurements of mesoscale features (eddies) containing UCDW on the WAP. Thirty-three subsurface eddies with widths on the order of 10 km were detected during four glider deployments. Each eddy contributed an average of 5.8×10^{16} J to the subpycnocline waters, where a cross-shelf heat flux of 1.37×10^{19} J yr^{-1} is required to balance the diffusive loss of heat to overlying winter water and to the near-coastal waters. Approximately two-thirds of the heat coming onto the shelf diffuses across the pycnocline and one-third diffuses to the coastal waters; long-term warming of the subpycnocline waters is a small residual of this balance. Sixty percent of the profiles that contained UCDW were part of a coherent eddy. Between 20% and 53% of the lateral onshore heat flux to the WAP can be attributed to eddies entering Marguerite Trough, a feature in the southern part of the shelf which is known to be an important conduit for UCDW. A northern trough is identified as additional important location for eddy intrusion.

1. Introduction

Most of the glaciers along the West Antarctic Peninsula (WAP) have retreated since the early 1950s [*Cook et al.*, 2005], and the rate at which ice sheets have been losing mass has accelerated over the past decade [*Rignot et al.*, 2014]. The glacial retreat has been attributed to calving events, linked to warming atmospheric temperatures, and melting from below, attributed to the onshore transport of warmer ocean water [*Rignot and Jacobs*, 2002; *Jenkins et al.*, 2010; *Pritchard et al.*, 2012; *Cook et al.*, 2016]. Atmospheric temperatures over the WAP have warmed at an approximate rate of 0.5°C per decade since the 1950s [*Meredith and King*, 2005; *Turner et al.*, 2006; *Bromwich et al.*, 2013], although recent observations show a reversal of the warming trend since the late 1990s, consistent with the large variability of the system [*Turner et al.*, 2016]. Summertime upper ocean water temperatures rose by more than 1°C between the mid-1950s and mid-1990s [*Meredith and King*, 2005] and continued to increase at a rate of 0.1–0.3°C per decade since the 1990s [*Schmidtko et al.*, 2014]. This warming reflects the effects of changes in atmospheric temperatures. Recent observations, however, suggest that glacier retreat on the WAP is driven primarily by deep ocean temperatures [*Cook et al.*, 2016] which can also supply heat to the atmosphere [*Venables et al.*, 2016].

Upper Circumpolar Deep Water (UCDW) is the largest source of ocean heat to the WAP continental shelf [*Hofmann et al.*, 1996]. This water mass is characterized by potential temperatures exceeding 1.7°C and salinities greater than 34.54 [*Martinson et al.*, 2008], and is the warmest deep water mass observed on the WAP continental shelf. UCDW is found just off the shelf at depths between 200 and 600 m within the Antarctic Circumpolar Current (ACC), an eastward-flowing current that runs directly along the continental slope of the WAP [*Klinck*, 1998; *Klinck et al.*, 2004]. While surface water properties on the continental shelf vary seasonally with the growth and melting of sea ice and variable wind mixing [*Hofmann et al.*, 1996], water below the permanent pycnocline is kept warm throughout the year by frequent intrusions of UCDW from the offshore ACC [*Smith et al.*, 1999; *Martinson et al.*, 2008].

Overlying the relatively warm deep water on the shelf is Winter Water. This cold water mass is generated from a combination of sea ice growth, sensible heat loss to the atmosphere, and deep vertical mixing driven by winds during the winter and is persistent in most parts of the shelf throughout the summer. In the winter, it extends from the surface to around 200 m. Beginning in the spring, relatively fresh sea ice meltwater creates a shallow surface layer that overlies the Winter Water and warms throughout the summer. As UCDW intrudes onto the shelf, it loses heat to the surrounding water and overlying Winter Water through both diapycnal and isopycnal mixing [*Smith et al*., 1999]. Over the course of the year on the continental shelf, there is a net flux of heat out of the surface ocean with a magnitude estimated between 6 W m^{-2} (using data from 1993 only) [*Smith and Klinck*, 2002] and 19 W m^{-2} (averaged over 1993–2004) [*Martinson et al*., 2008]. The cross-pycnocline heat flux from UCDW-warmed water into the Winter Water balances this heat loss to the atmosphere. The temperature gradient that drives this vertical diffusion of heat is preserved by subpycnocline along-isopycnal heat transport from off the shelf [*Klinck et al*., 2004].

Several mechanisms have been suggested for delivering UCDW to the WAP. Upwelling of offshore UCDW is evidenced in hydrographic data by shoaling of the permanent pycnocline [*Martinson et al*., 2008]. Topographically induced or wind-driven upwelling events have been linked to large diatom blooms on the shelf [*Prézelin et al*., 2000]. However, shoaling may not always indicate upwelling; it can also be produced when a subsurface eddy moves onto the shelf and deflects isopycnals [*Martinson and McKee*, 2012]. Indeed, with the high-temporal resolution of mooring observations in Marguerite Trough and the neighboring shelf, and the increased spatial resolution of regional models, mesoscale eddies have emerged as the most prominent mechanism of heat delivery to the WAP shelf [*Dinniman et al*., 2011; *Martinson and McKee*, 2012]. While upwelling has not been ruled out as a potential delivery mechanism [*Martinson and McKee*, 2012], the apparent shelf-wide flooding of UCDW documented in coarsely resolved hydrographic surveys [*Prézelin et al*., 2004] was shown to actually be the result of coherent eddies moving on to the shelf and dissipating heat [*Moffat et al*., 2009; *Dinniman et al*., 2011; *Martinson and McKee*, 2012].

Eddies are carried onto the shelf during episodic advective intrusions of UCDW, which may occur during periods of intense wind stress [*Dinniman et al*., 2011]. Modeling studies and observations indicate that, with a strong enough forcing, when the mean shelf break flow encounters curving bathymetry, some of the water flowing in the ACC along the shelf break is carried by momentum onto the shelf [*Dinniman and Klinck*, 2004; *Klinck et al*., 2004]. Evidence from a high-resolution model also suggests that Rossby waves at the shelf break can interact with a trough to produce features consistent with eddies [*St-Laurent et al*., 2013].

Moorings in Marguerite Trough and on the surrounding shelf have recorded eddies passing by at rates of three to four per month [*Moffat et al*., 2009; *Martinson and McKee*, 2012], but presence elsewhere on the shelf is largely unknown. Existing data sets in the region were collected using traditional shipboard sampling, with measurements typically made at coarser resolution than that required to resolve mesoscale eddies on the WAP. Weak subsurface stratification of the shelf combined with the effects of high-latitude result in a small radius of deformation which determines the length scale of eddy dynamics [*Chelton et al*., 1998]. Eddies shed from the ACC have diameters of $\sim$10–20 km [*Klinck and Dinniman*, 2010].

Here we use data from four deployments of Slocum-Webb autonomous underwater vehicles (gliders) to map the spatial distribution of UCDW on the shelf. Some of the UCDW is contained in subsurface mesoscale eddies with widths on the order of 10 km. Glider profiles are 1 km apart, on average, providing sufficient spatial resolution to define the horizontal boundaries of mesoscale features. These data allow us to identify previously undetected pathways of intrusion for eddies onto the shelf, and allow us to estimate their relative importance to the WAP continental shelf heat budget.

We place these glider deployments in the context of annual shelf-wide hydrographic data from repeat cruises conducted each January from 1993 to 2008 [*Smith et al*., 1995; *Ducklow et al*., 2012]. Hydrographic stations occupied during these cruises were rarely closer than 20 km apart, so they lack the spatial resolution to detect eddies on the shelf, but they allow us to construct a subpycnocline heat budget from which we can estimate the contribution of subsurface eddies carrying UCDW and discuss their impact on the warming trend observed across the shelf over the last several decades.

2. Methods

This study uses data obtained from four deployments of Slocum Webb deep gliders from Palmer Station, Antarctica (64°46′S, 64°03′W) during austral summers 2010–2011, 2011–2012, and 2012–2013. Deployments lasted between 29 and 62 days and covered distances up to 1600 km in the coastal waters west of the

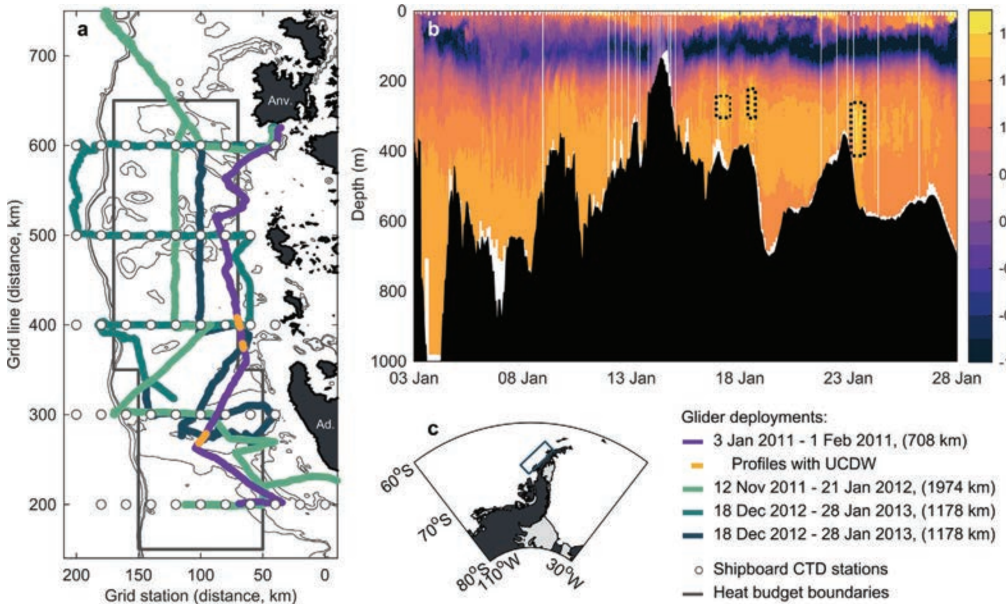

Figure 1. (a) The region of the WAP continental shelf discussed in this analysis. Shipboard CTD profile locations used in the heat budget calculations are shown as circles. The gray box encloses stations used to calculate the change in shelf heat over time and the vertical heat flux to the winter water layer. Lateral diffusion is measured across the right box boundary and lateral onshore heat flux is calculated across the left box boundary. Green and purple lines show tracks of the four glider deployments. Temperature data from the purple track are shown in Figure 1b with yellow dots indicating profiles where UCDW was found. Bathymetry contours are plotted at the 500, 600, and 1000 m isobaths. Anvers (Anv.) and Adelaide (Ad.) Islands are labeled. (b) Temperature section from the glider deployment shown in purple in Figure 1a. Dotted boxes show the extent of UCDW in the three mesoscale features detected on this deployment. (c) Regional map, with boundaries of plot a shown.

Antarctica Peninsula (Figure 1). Gliders are buoyancy-driven autonomous underwater vehicles that move from the surface to a depth of up to 1000 m with an average horizontal speed of 1 km h^{-1} [*Davis et al*., 2002; *Schofield et al*., 2007]. All gliders used in this study were equipped with a Seabird CTD to measure conductivity, temperature, and depth with a sampling resolution of 4–6 measurements per vertical meter. Data from each dive or climb were averaged into 1 m depth bins and the latitude/longitude of the entire profile was set to the average latitude/longitude of the climb or dive.

In each of the four deployments, gliders traveled generally southward along the peninsula. We restrict our focus to profiles taken on the continental shelf, which we define as shoreward of the 600 m isobath (Figure 1a). Among the shelf profiles, UCDW ($T > 1.7$°C and $S > 34.54$, *Martinson et al*. [2008]) was often encountered below the permanent pycnocline as part of distinct boluses with characteristics consistent with subsurface eddies (Figure 1b).

Studies of subsurface eddies in the North Pacific [*Pelland et al*., 2013] and North Atlantic [*Bower et al*., 2013] suggest that a Gaussian distribution model is appropriate for defining the horizontal boundaries of those features. We use it to measure chord lengths of the eddy-like boluses encountered by the gliders. From here forward, we will refer to the boluses as "eddies." The model assumes that the cross section of an eddy along an isopycnal is circular and that its temperature is greatest at its center and decays in the radial direction. This geometry is described by the following equation:

$$T' = T_{\max} \cdot e^{-\left(\frac{(x-x_0)}{r}\right)^2}, \tag{1}$$

where T' is the temperature anomaly at position x, T_{max} is the maximum value of the anomaly at the eddy center, x_0, and r is the eddy radius.

Following the methods of *Zhang et al*. [2015], who calculated widths of subthermocline eddies in the North Pacific using Argo float profiles, we interpolated temperature profiles onto surfaces of constant potential density separated by 0.01 kg m^{-3}. For each isopycnal surface, using only observations on the shelf, we calculated the mean temperature and anomalies from the mean. We then identified every shelf profile that

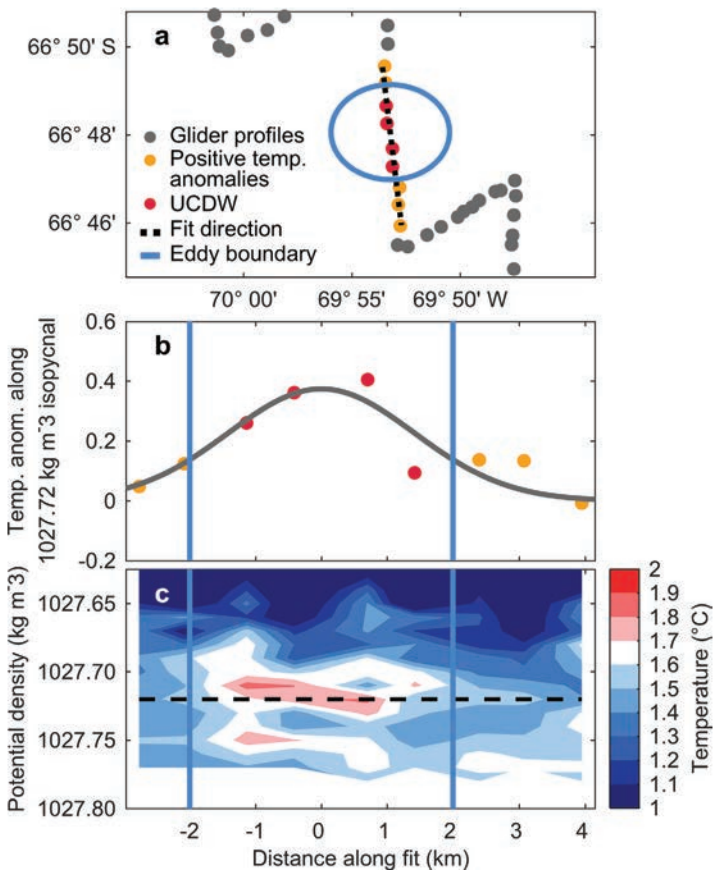

Figure 2. Example of method used to define eddy width. (a) Profiles containing UCDW at any depth are identified based on temperature and salinity values (red dots). One isopycnal surface is selected and the surrounding profiles that contain positive temperature anomalies along that surface are identified (yellow dots). A least-squares line is fit to these profiles (black dashed line). (b) A Gaussian curve is fit to the positive temperature anomalies along the chosen isopycnal in the direction of the least squares fit. Eddy width is defined by equation (1) as twice the radius, enclosing 84.3% of the heat (vertical blue lines). (c) Temperature section with vertical blue lines showing the calculated eddy width. Dots in Figures 2a and 2b show the locations of each glider profile (a single dive or climb).

contained UCDW at any depth and fit Gaussian curves to the positive temperature anomalies surrounding these profiles on each of fifteen isopycnal surfaces between 1027.63 kg m^{-3} (approximating the base of the winter mixed layer and the shallowest isopycnal where UCDW was found) and 1027.77 kg m^{-3} (the deepest isopycnal that at least 50% of glider profiles extended to).

We used the MATLAB "fit" function to calculate the radii of the eddies according to equation (1) (Figure 2). Distances (x) were measured along the least squares fit line through all points on the isopycnal surrounding the UCDW profile that had positive temperature anomalies (Figure 2a). This method was repeated for every profile containing UCDW and every potential density surface between 1027.63 and 1027.77 kg m^{-3}, resulting in several fits to the same feature; we chose the best as the fit with the lowest rms/mean. Isopycnals representing the best fits ranged from 1027.70 to 1027.76 kg m^{-3}.

Eddy chord lengths were defined according to equation (1) as twice the radius, r, which encloses 84.3% of the temperature anomaly in the fit (Figure 2b). These lengths are used as an estimate for eddy width, but since we do not know how closely the glider passed through eddy centers, nor do we know the direction of eddy movement, there is error in this estimate. Drawing random lines through a stationary circle to measure the diameter would result in an average estimate that is 68% of the true diameter, but eddies are not assumed to be stationary during the time the glider spent sampling them. Width is likely to have been underestimated (overestimated) during times when the glider passed through an eddy as it was carried by the mean flow in the opposite (same) direction as the glider motion.

The heat content of each eddy was calculated relative to the average shelf temperature, T_{ref}:

$$Q = \int_{z_1}^{z_2} (T - T_{ref}) \rho_z c_p \pi r^2 dz, \tag{2}$$

where z_1 and z_2 are the shallowest and deepest depths where UCDW was observed within a single eddy. These depths averaged 221 and 346 m on the shelf across all glider deployments. The reference temperature, T_{ref}, was calculated as the average potential temperature below the permanent pycnocline of all non-UCDW profiles on the shelf and had a value of 1.2°C. Since the reference temperature includes every profile where the maximum potential temperature was below 1.7°C and does not demand that the profile be cooled any further, heat calculated relative to this temperature represents a lower bound of the heat delivered to the shelf by eddies.

Temperature profiles were also taken during annual cruises in January 1993 and 1995–2015 as part of the Palmer Long Term Ecological Research (LTER) project. The LTER grid is made up of lines running along the peninsula spaced 100 km apart and stations running perpendicular to the shelf spaced 20 km apart (Figure 1a). The lines are named according to distance from a point south of this particular study area: the 200 line extends out from south of Adelaide Island and, 400 km northeast of that, the 600 line extends out from south of Anvers Island (Figure 1). The same temperature and salinity criteria ($T \geq 1.7°C$, $S \geq 34.54$) used to identify UCDW in the glider data were used to identify UCDW in the shipboard CTD data, and the same potential density surfaces were used to calculate the heat content of every profile. These data were used to investigate the spatial patterns of UCDW on the shelf. They were also used to create a volume-averaged heat budget for the WAP shelf in order to determine the importance of the subsurface eddies as a source of heat to the shelf.

3. Results and Discussion

3.1. Locations of UCDW Intrusions

Hydrographic measurements on the WAP, taken from both traditional ship platforms and glider deployments, reveal a consistent pattern of intrusion locations onto the shelf (Figure 3). Both data sets show a heightened presence of UCDW on the shelf in deep areas, mostly confined to the region around Marguerite Trough (300 and 400 lines). In both data sets, observations of UCDW drop off with distance from the shelf break toward the coast, as expected, since processes on the shelf lead to the modification of UCDW.

Ocean gliders have significantly improved the spatial resolution of hydrographic measurements along the Antarctic Peninsula, allowing us to resolve features smaller than the spacing of a typical ship-based survey [*Heywood et al.*, 2014; *Erickson et al.*, 2016]. The increased sampling resolution of the gliders increases the likelihood of encountering the small-scale features containing UCDW. The glider data confirm our understanding of UCDW intrusion locations but indicate that studies based solely on hydrographic surveys with profiles separated by 20 km or more have underestimated the quantity of unmixed UCDW on the shelf (Figure 3, blue bars versus red bars). During some LTER cruises, no UCDW was seen on the shelf, but it easily could have been missed; a single CTD cast from a ship is meant to represent a 20 km $\times$ 100 km area of ocean, within which it is possible for several mesoscale features to exist but go undetected. Glider surveys consistently encountered more UCDW per unit effort (profiles measured) than did shipboard surveys.

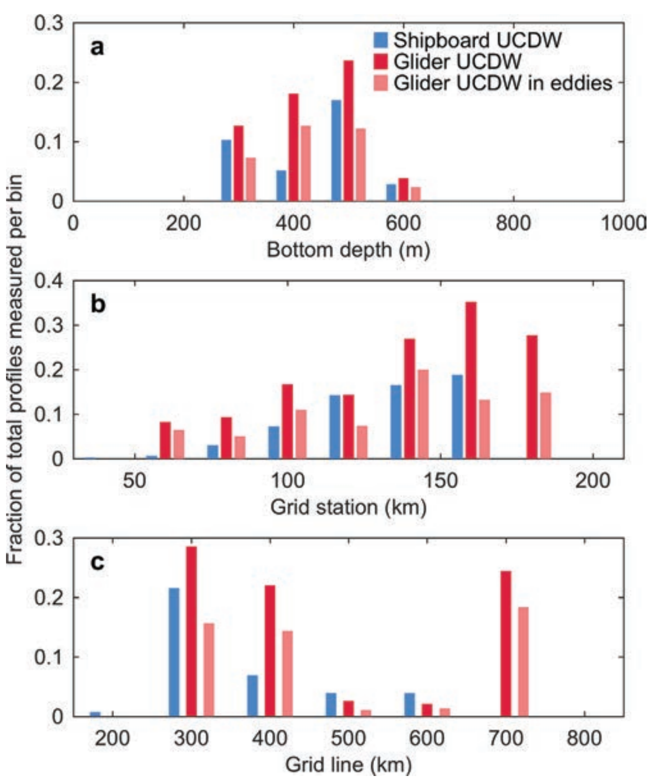

Figure 3. Fractions of (blue) total shipboard CTD profiles that contained UCDW, (red) total glider CTD profiles that contained UCDW, and (pink) total glider CTD profiles that were part of an eddy, that were found in bins of (a) bottom depth, (b) grid station, and (c) grid line. Eddy profiles were identified by fitting Gaussian curves to temperature anomalies, as described in section 2.

The glider data allow us to separate UCDW that appears in coherent eddies from UCDW present outside eddy-like structures. Coherent features carrying UCDW were seen in each of the four glider deployments. Of all profiles containing UCDW, 60% occurred as part of eddies (Figure 3, pink bars versus red bars). The UCDW found outside of eddies was present either near the shelf break spread over tens of kilometers, which may be evidence of a mean advection across the shelf break,

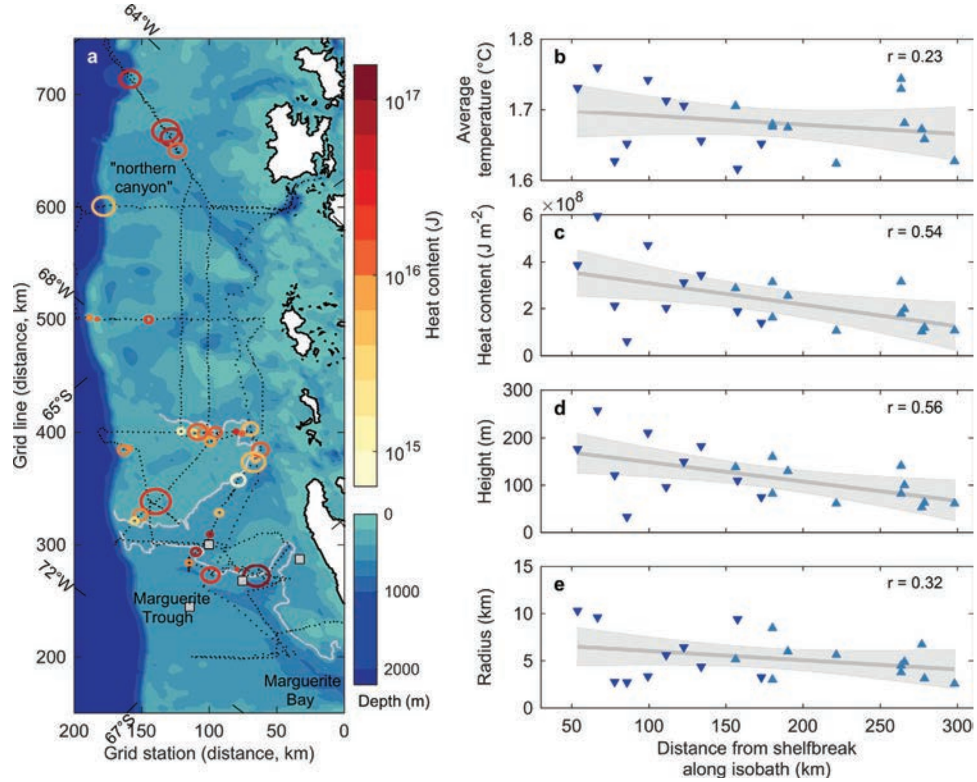

Figure 4. (a) Map of WAP continental shelf with overlaid eddies detected by the gliders, colored by the average heat content of the profiles measured within them. Dotted black lines show glider tracks. Gray squares show the locations of SO GLOBEC moorings [*Moffat et al.*, 2009] and LTER [*Martinson and McKee*, 2012] moorings that have been used in previous studies to measure frequency of eddy intrusion into Marguerite Bay. Gray lines trace the (top) 400 m and (bottom) 500 m bathymetric contours representing "upper" and "lower" paths of Marguerite Trough. Dark blue downward-pointing triangles in Figures 4b–4e show data from eddies lying along lower contour, and light blue upward-pointing triangles show data from eddies lying along upper contour. Gray lines and shading in Figures 4b–4e represent least squares fit to data and 95% confidence bounds. Correlation coefficients are given.

or as isolated profiles near the locations where eddies were found, which may represent remnants of larger features that had dissipated or instances of interleaving.

Mooring observations from the vicinity of Marguerite Trough previously identified eddies there [*Moffat et al.*, 2009; *Martinson and McKee*, 2012]. Glider observations confirm that this canyon is important for the advection of eddies onto the shelf and identify an additional, previously undetected, intrusion pathway to the north. The "northern canyon" (Figure 4a) is a cross-shelf canyon that lies outside the boundaries of the LTER grid, so no observations of UCDW had been made there in LTER time series. Mesoscale features containing UCDW were found along the northern wall of this canyon. Similarly, UCDW eddies were found along the northern wall of the entrance to Marguerite Trough. Eddies that enter the shelf at Marguerite Trough appear to follow one of two pathways onto the shelf: an upper pathway follows the 400 m isobaths to the northeast and a lower pathway follows the 500 m isobaths the southeast (Figure 4a). The highest percentage of UCDW on the shelf was measured in areas with depths near 500 m (Figure 3a), which is the approximate depth of both Marguerite Trough and the northern canyon where they cross the shelf break.

3.2. Properties of UCDW Eddies

Overall, 14% of the profiles measured by the gliders on the shelf contained UCDW. Of these, 60% were contained in 33 coherent Gaussian features with properties consistent with subsurface eddies. The majority of these features were found in or around Marguerite Trough, but the northern canyon also appears to be a conduit for transport of eddies onto the shelf (Figure 3a). Fewer observations were made in that canyon than in Marguerite Trough.

The mean value of all chord lengths was 11.3 ± 5.1 km with a median value of 10.3 km. It is important to note that eddy widths measured here are an estimate of true diameters since we do not know how close the glider came to the center or the direction of eddy travel. However, these estimates are within the range of eddy sizes predicted by the internal deformation radius [*Chelton et al*., 1998] and are similar to the size of eddies measured by moorings on the shelf [*Moffat et al*., 2009; *Martinson and McKee*, 2012].

Subsurface eddies entering the shelf contained as much as 1.93×10^{17} J of heat relative to the reference temperature (1.2°C). Eddies lose heat to the overlying winter water and to the cooler shelf waters as they are carried in the mean flow. In the general circulation pattern in the southern half of the grid, water enters onto the shelf through Marguerite Trough and makes a counter-clockwise loop following the northern branch of the canyon [*Smith et al*., 1999; *Dinniman and Klinck*, 2004; *Savidge and Amft*, 2009]. A second branch carries water into Marguerite Bay via the southern branch of the canyon [*Klinck et al*., 2004]. The properties of eddies detected by the gliders are consistent with this pattern.

In Figure 4, plots b–e show properties of eddies that enter Marguerite Trough as a function of distance from the shelf break along one of two isobaths. Heat content per unit area and height are most strongly correlated with distance. Eddy height is defined as the vertical distance separating the shallowest and deepest observations of UCDW within the eddy. Radius and average temperature are weakly correlated with distance. Again, the interpretation of these relationships must include a consideration of the chord-length sampling error. An eddy that a glider passed through the edge of would appear to have a shorter radius and a cooler average temperature than if the eddy had been sampled through the middle. The observations suggest that subsurface eddies enter onto the shelf with widths on the order of 10 km and are modified as they travel along an isobaths. They dissipate most of their heat vertically and less of it laterally. Slower rates of lateral diffusion and the resulting effects of lateral spreading may explain the weak correlation between eddy width and distance traveled.

3.3. Heat Balance on the WAP

A simple two-dimensional heat budget was constructed for the region of the WAP shelf where glider and CTD observations were made (Figure 5). This region extends 500 km along the coast and 100 km across the continental shelf (Figure 1a). Vertical limits are between the depth of the permanent pycnocline, which has an average depth of 160 m and generally corresponds to the 1027.63 kg m^{-3} isopycnal, and the seafloor, which are separated by an average distance of 280 m. The height of the heat budget box is defined as this average distance. Following the assumption of *Klinck et al*. [2004], we assume the alongshore advection is

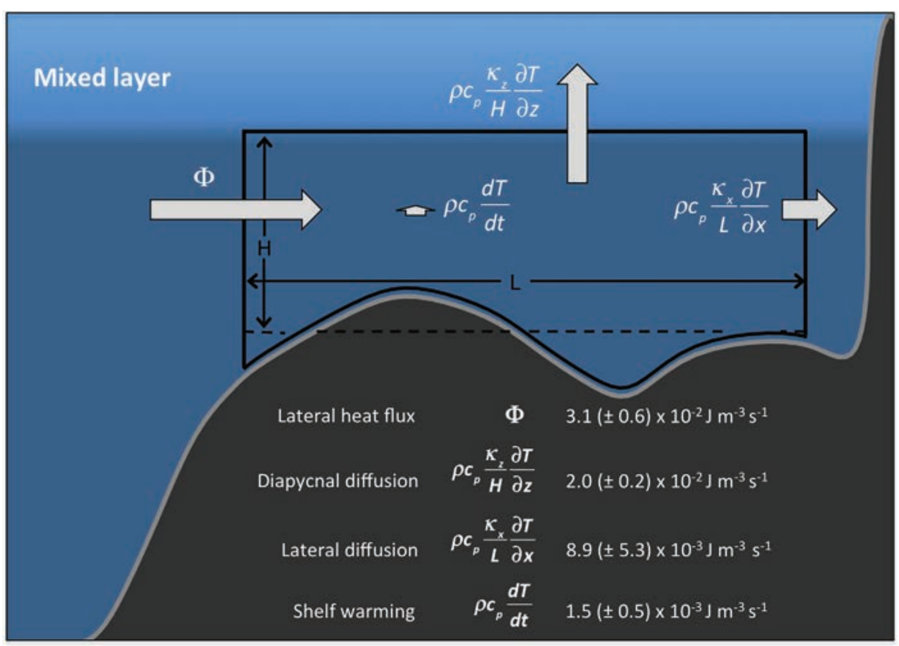

Figure 5. Schematic illustrating the components of the heat budget on the WAP continental shelf. Values shown are calculated using $\kappa_x = 100$ m^2 s^{-1}. All other values are listed in Table 1. We use the average bottom depth of the WAP, indicated by the dashed line, as height, *H*. Arrow lengths are proportional to the relative contributions of each term to the heat budget.

Table 1. Coefficients and Variables Used Throughout the Text

Symbol	Description	Value
T_{ref}	Reference seawater temperature	1.2°C
P	Reference seawater density	1027.7 kg m^{-3}
c_p	Specific heat of seawater	4000 J kg^{-1}°C^{-1}
H	Height of heat budget box	280 m
L	Across-shelf extent of heat budget box	100 km
W	Along-shelf extent of heat budget box	500 km
κ_z	Vertical diffusivity	10^{-4} m^2 s^{-1}
κ_x	Lateral diffusivity	100 (37,200) m^2 s^{-1}
$\frac{\partial T}{\partial t}$	Time rate of change of shelf temperature	3.61 ($\pm$1.15) $\times$ 10^{-10}°C s^{-1}
$\frac{\partial T}{\partial x}$	Midshelf to inner-shelf temperature gradient	2.18 ($\pm$1.28) $\times$ 10^{-6}°C m^{-1}
$\frac{\partial T}{\partial z}$	Diapycnal temperature gradient	0.014 $\pm$ 0.002°C m^{-1}

small and that there is no heat flux at the bottom or directly at the coast, although we do calculate lateral diffusion between the midshelf and nearshore stations. The heat balance below the permanent pycnocline on the shelf is the sum of lateral fluxes across the shelf break, diapycnal diffusion into the overlying winter water, and isopycnal diffusion across the shoreward box boundary (Figure 1a). Here we extend the analysis to include all years between 1993 and 2008, during which the overall heat content of the shelf increased [*Martinson et al.*, 2008]. Therefore, we also include a shelf warming term. Temperatures below the permanent pycnocline on the WAP shelf during the 1993–2008 sampling period warmed at an average rate of 0.01°C per year.

We integrate the advection-diffusion equation over the width (L) and depth (H) of the shelf, ignoring vertical advection and including a warming trend. We then divide by the width and depth to arrive at the volume-averaged heat budget equation:

$$\Phi-\rho c_p\left(\frac{\kappa_z}{H}\frac{\partial T}{\partial z}+\frac{\kappa_x}{L}\frac{\partial T}{\partial x}\right)=\rho c_p\frac{dT}{dt}. \tag{3}$$

The lateral temperature gradient, $\frac{\partial T}{\partial x}$ is the time series average gradient of temperatures between midshelf and inner-shelf stations. Similarly, $\frac{\partial T}{\partial z}$ is the shelf-wide time-averaged temperature gradient across the permanent pycnocline at each station. H is the average vertical distance between the permanent pycnocline and the seafloor and Φ is the total flux across the shelf break. Values for all heat budget terms are listed in Table 1.

Values for the lateral and vertical diffusivities, κ_x and κ_z, respectively, are taken from the literature. *Howard et al*. [2004] estimated a shelf-wide average diapycnal diffusivity of 10^{-5} m^2 s^{-1} based on fall and winter cruises in 2001, however this value is thought to underestimate the true mixing on the shelf which is dominated by isolated wind events [*Howard et al*., 2004]. Estimates based on shelf-wide budgets suggest a value closer to 10^{-4} m^2 s^{-1} [*Klinck*, 1998; *Smith et al*., 1999; *Smith and Klinck*, 2002; *Martinson et al*., 2008] and not exceeding 7.7 $\times$ 10^{-4} m^2 s^{-1} [*Klinck et al*., 2004]. As the shelf waters have warmed, the magnitude of κ_z has decreased [*Martinson et al*., 2008]. We use 10^{-4} m^2 s^{-1} as an average value for the shelf over the time series, which leads to an appropriate eddy-decay time scale of eddies advected with the mean flow in Marguerite Trough [*Moffat et al*., 2009]. Estimates of isopycnal diffusivity on the shelf range from 37 m^2 s^{-1} [*Klinck*, 1998] to 200 m^2 s^{-1} [*Smith et al*., 1999] to an unrealistic maximum of 1600 m^2 s^{-1} [*Klinck et al*., 2004]. According to mixing length arguments, lateral diffusivity scales as κ vl [*Prandtl*, 1925]. Using a typical subpycnocline current speed of 1–5 cm s^{-1} [*Howard et al*., 2004; *Klinck et al*., 2004] and a typical eddy width of 10 km, mixing length arguments indicate that lateral diffusivity should be on the order of 100–500 m^2 s^{-1}. This gives us confidence to use the 37–200 m^2 s^{-1} range in our calculations.

Using values listed in Table 1, we calculate the average diapycnal diffusion across the permanent pycnocline, the average lateral diffusion across the inner heat box boundary, and the rate of shelf warming over the 1993–2008 shipboard sampling period. The magnitude of diapycnal diffusion is about twice that of lateral diffusion and the shelf warming term is, comparatively, very small. Of the heat that enters the shelf below the permanent pycnocline, approximately two-thirds is diffused vertically across the permanent pycnocline and one-third reaches the coastal waters by lateral diffusion.

We calculate the horizontal lateral flux, Φ, required to balance the other terms, to be 1.36×10^{19} J yr^{-1} (ranging from 0.97×10^{19} to 2.23×10^{19} J yr^{-1} depending on the lateral diffusivity, and including error estimates). This value is found by multiplying Φ in equation (3) by the volume of the heat budget box, and represents the total lateral heat flux from various mechanisms, including eddies transported onto the shelf. The average heat content of eddies observed near the shelf break is 5.8×10^{16} J. The total annual heat flux onto the shelf is equivalent to 150–342 eddies with an average temperature of 1.7°C across a diameter of 12 km (the average temperature and width of observed eddies within 50 km of the shelf break) coming onto the shelf each year.

Year-round mooring observations at a fixed location north of Marguerite Trough led to estimates that 35–40 eddies containing UCDW passed by the mooring location each year during 2007, 2008, and 2010 [*Martinson and McKee*, 2012]. Observations from a mooring shoreward of that location, within the trough itself, showed similar numbers of eddies passing there [*Moffat et al*., 2009]. Our results show that eddies occur at similar densities to the north and south of the Marguerite Trough entrance so, assuming the trough is a conduit for 70–80 eddies per year, it alone could serve as the entryway for 20–53% of the necessary heat flux to the shelf. The northern canyon appears to be an additional location of eddy intrusion, although further observations there will be necessary to quantify its contribution as an eddy delivery pathway. In 186 days on the shelf, our gliders encountered 33 eddies suggesting that a lower-limit estimate of eddy intrusions onto the WAP shelf each year is around 64, which would account for 19–43% of the range of lateral heat flux estimates.

4. Conclusions

High-resolution measurements from Slocum Webb deep gliders deployed along the west Antarctic Peninsula confirm that warm water from the ACC is intruding onto the continental shelf as distinct mesoscale features [*Moffat et al*., 2009; *Martinson and McKee*, 2012; *St-Laurent et al*., 2013; *Graham et al*., 2016]. The high-spatial resolution of the glider data allows us to present the first near-synoptic cross sections of mesoscale eddies on the WAP. We estimate the eddy-like boluses to be on the order of 10 km wide and 125 m thick. Intrusions tend to occur at Marguerite Trough and a second cross-shelf canyon in the northern part of the study area. The annual shipboard CTD measurements also indicate these two canyons act as primary conduits for heat transport, but they are unable to resolve the spatial extent of the intrusions.

Glider measurements have allowed us to capture warm water features over a larger area of the WAP continental shelf than was previously available, but we still lack information about the mechanism by which the warm deep water, once on the shelf, reaches the coastal surface waters. Recent research using gliders suggests that bathymetry plays an important role in local mixing of deep and surface waters and may be important in the transformation of water masses across the entire shelf [*Venables et al*., 2016]. Melting of the glaciers on the West Antarctic Peninsula could raise global sea levels by up to 69 ± 5 mm [*Huss and Farinotti*, 2014] and most of the glacier retreat since the 1990s can be attributed to interactions with the ocean [*Cook et al*., 2016]. Understanding the rate at which heat contained in the ocean is melting the ice is crucial to predicting how much ice will be lost in the warming climate. The UCDW features described here may account for up to 50% of the onshore heat flux, with the remainder likely to come from upwelling and advection of the ACC onto the shelf. Future efforts will focus on a better understanding of the eddy dissipation processes and the mechanisms responsible for bringing the remaining heat to the shelf.

Acknowledgments
Glider data used in this study are available through the Rutgers University Center for Ocean Observing Leadership (RUCOOL) webpage http://marine.rutgers.edu/cool/auvs/ and the MARACOOS assets page http://maracoos.org/data. Data sets are also available upon request to ncouto@marine.rutgers.edu. We gratefully acknowledge support from the National Science Foundation (NSF/PLR Award 0823101), from Teledyne Webb Research for providing graduate student funding and from the RUCOOL glider technicians and pilots for their tireless work during deployments. We would also like to thank Darren McKee for several productive conversations and our anonymous reviewers for their careful criticism that helped to improve the manuscript.

Coastal ocean circulation during Hurricane Sandy

Travis Miles[1], **Greg Seroka**[2], **and Scott Glenn**[1]

[1]Department of Marine and Coastal Sciences, Rutgers University Center for Ocean Observing Leadership, New Brunswick, New Jersey, USA, [2]Ocean Prediction Center, NOAA/NWS/NCEP, College Park, Maryland, USA

Key Points:

- Tropical cyclones can have a large impact on coastal ocean circulation
- Sandy was an extreme event that drastically altered the water column characteristics through cross-shelf advective processes
- Integrated ocean observing systems and regional modeling are critical tools to resolve coastal ocean circulation in tropical cyclones

Abstract Hurricane Sandy (2012) was the second costliest tropical cyclone to impact the United States and resulted in numerous lives lost due to its high winds and catastrophic storm surges. Despite its impacts little research has been performed on the circulation on the continental shelf as Sandy made landfall. In this study, integrated ocean observing assets and regional ocean modeling were used to investigate the coastal ocean response to Sandy's large wind field. Sandy's unique cross-shelf storm track, large size, and slow speed resulted in along-shelf wind stress over the coastal ocean for nearly 48 h before the eye made landfall in southern New Jersey. Over the first inertial period (~18 h), this along-shelf wind stress drove onshore flow in the surface of the stratified continental shelf and initiated a two-layer downwelling circulation. During the remaining storm forcing period a bottom Ekman layer developed and the bottom Cold Pool was rapidly advected offshore ~70 km. This offshore advection removed the bottom Cold Pool from the majority of the shallow continental shelf and limited ahead-of-eye-center sea surface temperature (SST) cooling, which has been observed in previous storms on the MAB such as Hurricane Irene (2011). This cross-shelf advective process has not been observed previously on continental shelves during tropical cyclones and highlights the need for combined ocean observing systems and regional modeling in order to further understand the range of coastal ocean responses to tropical cyclones.

Plain Language Summary Hurricane Sandy (2012) was the second costliest tropical cyclone to impact the United States and resulted in numerous lives lost due to its high winds and catastrophic storm surges. Despite its impacts little research has been performed on the circulation of the coastal ocean as Sandy made landfall. In this study integrated ocean observing assets and regional ocean modeling were used to investigate the coastal ocean response to Sandy's large wind field. Sandy's unique cross-shelf storm track, large size, and slow speed resulted in powerful alongshore winds over the coastal ocean for nearly 48 h before the eye made landfall in southern New Jersey. These winds transported cold bottom waters offshore and left the coastal ocean uniformly warm and mixed. This circulation pattern has not been observed previously during tropical cyclones and highlights the need for a continued focus on coastal ocean observing systems and numerical modeling during storm events.

1. Introduction

Tropical cyclones (TCs) are among the deadliest and costliest natural hazards on earth. In the US alone they are responsible for nearly half of all billion dollar natural disasters, and account for over 3000 deaths between 1980 and 2016 (https://www.ncdc.noaa.gov/billions/). Globally, individual storms can be extremely deadly such as Nargis, which lead to over 100,000 fatalities in Myanmar in 2008 [*Fritz et al*., 2009]. TC track forecasts have improved dramatically since 1970, yet similar dramatic progress has not been made in TC intensity prediction [*DeMaria et al*., 2014; *Cangialosi and Franklin*, 2016]. Predictions of TC rapid intensification or deintensification just before landfall remain a critical challenge within this intensity gap. Rapid intensification in the hours before landfall has the potential to catch coastal communities off guard, while unexpected rapid deintensification may erode future forecast credibility among the public [*Considine et al*., 2004]. Uncertain modeling of the ocean response to and feedback on TCs remains a critical factor that has limited improvement in intensity forecasts [*Emanuel et al*., 2004; *Yablonsky and Ginis*, 2009; *Emanuel*, 2016], particularly in the coastal ocean just prior to landfall [*Glenn et al*., 2016; *Seroka et al*., 2016]. This manuscript contributes to a growing body of work that details the response of the coastal ocean to TCs. Specifically, this work focuses on the stratified coastal ocean response ahead of and during Hurricane Sandy, the second costliest storm to impact the US (~$68 billion USD in damages and 159 lives lost https://www.ncdc.noaa.gov/billions/).

Small changes in sea surface temperature (SST)—~1°C—can impact TC intensity [*Price*, 1981; *Emanuel*, 1999; *Bender and Ginis*, 2000; *Emanuel et al*., 2004; *Yablonsky and Ginis*, 2008], as the ocean provides a source of heat for atmospheric convection [*Black et al*., 2007; *Jaimes and Shay*, 2015]. In the deep ocean, TCs have been found to drive upwelling and mixing of cold nutrient rich water to the sea surface since the mid 1900s [*Hidaka and Akiba*, 1955; *Fisher*, 1958; *Leipper*, 1967]. These events, frequently referred to as "cold wakes," are typically observable by satellite [*Stramma et al*., 1986; *Cornillon et al*., 1987] and can produce large phytoplankton blooms in the days following storm passage [*Wang and Zhao*, 2008]. Focused field campaigns such as the Coupled Boundary Layer Air-Sea Transfer Experiment (CBLAST) have used a combination of atmosphere and ocean observations and modeling to show that storm-driven mixing over the deep ocean can reduce heat transfer to the atmosphere [*Black et al*., 2007; *Chen et al*., 2007]. Extensive literature exists detailing both the deep ocean response to TCs as well as storm surge impacts, yet comparatively little work has been done over continental shelves. One of these few studies has indicated that in some coastal regions rapid intensification is expected to increase as the planet warms [*Emanuel*, 2016]. Others have focused on TCs entering midlatitudes, and have shown that rapid deintensification occurs when storms cross the highly stratified continental shelves [*Glenn et al*., 2016]. Existing operational coupled atmosphere-ocean TC models have failed to accurately capture the ocean response that leads to this rapid deintensification.

The source of the cold water on the Mid Atlantic (MAB) Bight shelf, which can be mixed to the surface and lead to rapid storm deintensification [*Glenn et al*., 2016; *Seroka et al*., 2016], is a seasonal feature known as the summer Cold Pool [*Houghton et al*., 1982]. The Cold Pool is a near bottom water mass that extends from the southern edge of Georges Bank along the MAB continental midshelf and outer-shelf to Cape Hatteras, NC. The Cold Pool is formed in the spring as thermal heating develops a seasonal thermocline over cold remnant winter water. This thermocline reaches its peak strength in July and August when surface to bottom temperature differences can exceed 15°C and the surface mixed layer is typically between 10 and 20 m thick across the shelf [*Castelao et al*., 2008]. This stratification begins to break down in September through a combination of reduced solar heating, falling atmospheric temperatures, and most notably fall transition storms, which periodically vertically mix the water column [*Houghton et al*., 1982; *Lentz*, 2003, 2017; *Glenn et al*., 2008].

Hurricane Irene in 2011 was a relatively heavily sampled storm that impacted the MAB continental shelf and serves as an ideal case study of rapid deintensification. Irene made landfall in New Jersey in late August of 2011 [*Avila and Cangialosi*, 2012] when MAB stratification was near its peak. A study by *Glenn et al*. [2016] showed that onshore winds forced the surface mixed layer toward the NJ coastline setting up an offshore-directed pressure gradient that forced an offshore bottom layer flow, enhancing vertical shear and mixing over the midshelves and outer-shelves where stratification was greatest. SSTs were reduced ahead-of-eye-center by over ~4.5°C at a coastal buoy, accounting for 82% of the total storm cooling at that location. This study showed that out of the 11 storms that have traversed the MAB between 1985 and 2016 during the summer stratified season, 73% of the overall cooling across all storms at selected coastal buoy locations occurred ahead-of-eye-center with an average cooling of 2.7°C. In Irene, this cooling represented the largest factor contributing to the storm's deintensification just prior to its NJ landfall—not track, wind shear, or dry air intrusion [*Seroka et al*., 2016].

Hurricane Sandy made landfall in New Jersey 14 months after Irene in nearly the same location [*Blake et al*., 2013]. Despite its catastrophic damages, Hurricane Sandy also weakened and was designated as posttropical as it crossed the continental shelf of the MAB. Unlike Irene, MAB SSTs during Sandy were only reduced by ~2°C. Coupled ocean-atmosphere model hindcasts [*Zambon et al*., 2014] showed Sandy's weakening was linked to large-scale synoptic atmospheric circulation and was insensitive to air-sea coupling. This study hypothesized that the MAB had already undergone its fall transition, limiting the impact of the MAB ocean on atmospheric processes. Yet, observations from an autonomous underwater glider deployed ahead of Sandy showed the Cold Pool and stratification was still present on the MAB shelf, although to a lesser degree than in Irene [*Miles et al*., 2015]. The dichotomy between the ocean's impact on the intensities of Irene and Sandy indicates that more focused studies of the stratified coastal ocean response to a wide range of landfalling TCs are critical. In this manuscript, we investigate the coastal ocean response of the

Cold Pool to Sandy's powerful and long-lasting winds as the storm crossed the MAB continental shelf. We use a unique data set from a Teledyne Webb Slocum autonomous underwater glider and process-focused numerical simulations with the Regional Ocean Modeling System (ROMS). Understanding these processes will be critical to improving and building confidence in short-term forecasts of storm intensity as storms cross continental shelves and approach increasingly vulnerable population centers [*Miller et al*., 2009; *Kossin et al*., 2014].

2. Methods

Ocean observing systems have developed into critical networks of instruments capable of sampling the coastal ocean in three dimensions before, during, and after storm events [*Kohut et al*., 2006; *Miles et al*., 2013, 2015; *Domingues et al*., 2015; *Glenn et al*., 2016]. Hurricane Sandy made landfall after crossing through the Mid Atlantic Regional Association Coastal Ocean Observing System (MARACOOS), a certified Regional Information Coordination Entity (RICE) of the U.S. Integrated Ocean Observing System (IOOS) [*Briscoe et al*., 2008]. These systems typically include a range of technologies such as satellite observations, high frequency (HF) Radars, met-ocean buoys, autonomous underwater gliders, among many others and support regional ocean data products and forecasts through data assimilation and model validation. Technologies used in this study and described below include autonomous underwater gliders, HF Radar, and numerical model technologies that were developed and supported through MARACOOS over the past decade.

2.1. Gliders

Autonomous underwater gliders have become reliable technologies for sampling the ocean in extreme weather conditions [*Glenn et al*., 2008, 2016; *Ruiz et al*., 2012; *Miles et al*., 2013, 2015; *Domingues et al*., 2015; *Swart et al*., 2015; *Nicholson et al*., 2016; *du Plessis et al*., 2017]. The ability of Teledyne Webb Research manufactured Slocum gliders to access shallow ($<$100 m) continental shelves and their modular science bay design make them uniquely suited for rapid deployment to sample coastal storm events. Slocum gliders move vertically through the water column by using a pump in the fore section to change volume and shifting ballast to alter pitch to dive and climb at $\sim$15–20 cm s^{-1}. The glider body shape, wings, and nominal pitch angle of $\pm$26.5° result in forward motion of $\sim$20 km d^{-1} relative to the moving water column. Integrated sensors typically collect data at 0.5 Hz and send data back to shore in near real-time through an Iridium Satellite cellphone in the tail section. Rutgers University glider RU23 data were used in this study to investigate the evolution of the thermal structure and water column velocities on the continental shelf during Hurricane Sandy storm conditions. Previously these data were also used to investigate sediment resuspension and transport in Sandy by *Miles et al*. [2015]. RU23 was programmed to surface at 2 h intervals in order to provide high temporal resolution data during the storm. This glider was equipped with an unpumped Seabird glider conductivity, temperature, and depth (CTD) sensor; two Wetlabs, Inc. Eco Triplets with two channels measuring chlorophyll fluorescence, colored dissolved organic matter, and four channels of optical backscatter; and an externally mounted internally logging 2 MHz transducer Nortek Aquadopp current profiler.

Thermal inertia of the conductivity cell has remained a challenge for calculating high-quality salinity and density parameters with unpumped glider CTDs in regions with large temperature gradients such as those found on the MAB. Attempts at thermal lag correction to conductivity and subsequent salinity and density calculations following the *Garau et al*. [2011] minimization technique were unsuccessful. This is likely due to the exceptionally large thermal stratification, which exceeds what was successfully tested in that study, as well as the difficulty in finding consistent time offsets with the unpumped glider CTD. To address this issue, we calculate density by removing salinity data after large temperature changes in each profile (e.g., below the thermocline on glider dives and above the thermocline on the subsequent climb) and utilize the nearest-bottom salinity on dives and nearest-surface salinity on climbs to represent that layer's salinity for density calculations. While crude, this approach maintains water column stability. Further, the MAB density structure is dominated by temperature rather than salinity, so there is a limited impact on final density calculations. Temperature and corrected salinity and density fields were binned into 2 m bins. With the glider fall velocity of $\sim$15–20 cm s^{-1} and CTD sample rate at 0.5 Hz this resulted in over 10 points per bin. These binned data were used to estimate buoyancy frequency as:

$$N^2 = \frac{g}{\rho_o} \frac{\partial \sigma_\theta}{\partial z} \quad (1)$$

where N is the buoyancy frequency, g is gravity, ρ_o is a reference density of 1025 kg m^{-3}, σ_θ is potential density anomaly, and z is depth.

The Nortek Aquadopp current profiler was an externally mounted and independently logging three-beam 2 MHz instrument. It was mounted in an upward looking orientation for practical deployment and recovery purposes and to not block downward looking optical sensors. The transducer head was custom made to be oriented vertically at a glider pitch angle of 26.5°. Data collection was configured with 10 1 m bins and a 0.2 m blanking distance, and samples in beam coordinates were collected at 1 Hz. To rotate beam coordinates into east, north, and up (ENU) pitch and roll were used from the Nortek Aquadopps internal sensor, while heading information after timestamp alignment was interpolated from the glider compass. This was done to minimize magnetic interference from the moving battery pack and pump system in the fore section of the glider, which was closer to the mounting location of the Aquadopp than the aft mounted glider compass. To estimate realistic water column velocities a method typically used for lowered acoustic Doppler current profilers [*Visbeck*, 2002], and which has been adapted for use on Spray [*Todd et al*., 2011a, 2011b] and Slocum [*Miles et al*., 2015] gliders was used. This method uses the Aquadopp to determine water column vertical shear during a glider segment (glider dive and surfacing) and constrains these shear velocities with the glider dead-reckoned depth averaged current [*Davis et al*., 2002] to determine the absolute water column velocity. The time resolution of these currents is dependent on the length of time between each glider surfacing, which can vary. In this case, the glider surfaced approximately every 2 h as stated above in an effort to resolve tidal variability as well as the rapidly changing currents induced by Sandy.

2.2. HF Radar

The MAB has one of the largest continuous networks of CODAR HF Radar stations globally, ranging from North Carolina to Massachusetts. HF Radar uses the Doppler shift of backscattered radio frequencies from surface waves to measure the radial component of ocean surface currents, i.e. toward or away from each station [*Barrick*, 1971a,1971b; *Teague*, 1971]. Radial data are collected continuously and overlapping radials are combined via an optimal interpolation method to produce hourly total surface current maps hourly [e.g., *Kohut et al*., 2012]. The network in the MAB, managed through MARACOOS, consists of nested 5, 13, and 25 MHz networks [*Roarty et al*., 2010]. The 5 MHz network used in this study is capable of measuring surface currents out to the shelf-break, approximately 150 km offshore in ideal wave conditions and has a nominal spatial resolution of 6 km. The MARACOOS HF Radar network was operating at full capacity during Sandy's approach, but storm surges destroyed numerous stations reducing data coverage and quality starting at 3:00 GMT on 31 October 2012.

2.3. Atmospheric Model

The atmospheric model used in this study was the RUCOOL implementation of the Weather Research and Forecasting Advanced Research WRF (WRF-ARW) model developed at NCAR [*Skamarock et al*., 2008]. The forcing was previously used in *Miles et al*. [2015] and is configured with 6 km horizontal resolution, 35 vertical levels, horizontal boundary conditions from the Global Forecasting System (GFS) 0.5° operational configuration at the time, and a coldest-pixel composite SST bottom boundary condition from the Advanced Very High Resolution Radiometer (AVHRR) and NASA SPoRT [*Glenn et al*., 2016]. The SST bottom boundary condition is held static within each 36 h hindcast cycle, since there were very few new datapoints to add to each composite interval due to Sandy's extensive cloud cover. This static bottom boundary is appropriate based on the limited impact of air-sea coupling affecting Sandy's wind field [*Zambon et al*., 2014]. This WRF product is similar to the one used in previous studies [*Georgas et al*., 2014; *Glenn et al*., 2016; *Seroka*, 2016] and covers the entire MAB (Figure 1). Data were output hourly from a series of six 36 h forecast runs reinitialized at 00:00 GMT daily starting on 25 October. We combined hourly output from hour 7 to 30 and removed hours 0 to 6 to minimize the impact of model spin-up time on the final continuous hourly forcing. Please see *Miles et al*. [2015] for further details of the WRF atmospheric model configuration used in this study.

The WRF model output used in this study was previously compared with buoys 44009 and 44025 in *Miles et al*. [2015]. This comparison showed that simulated winds and pressure compared qualitatively well with

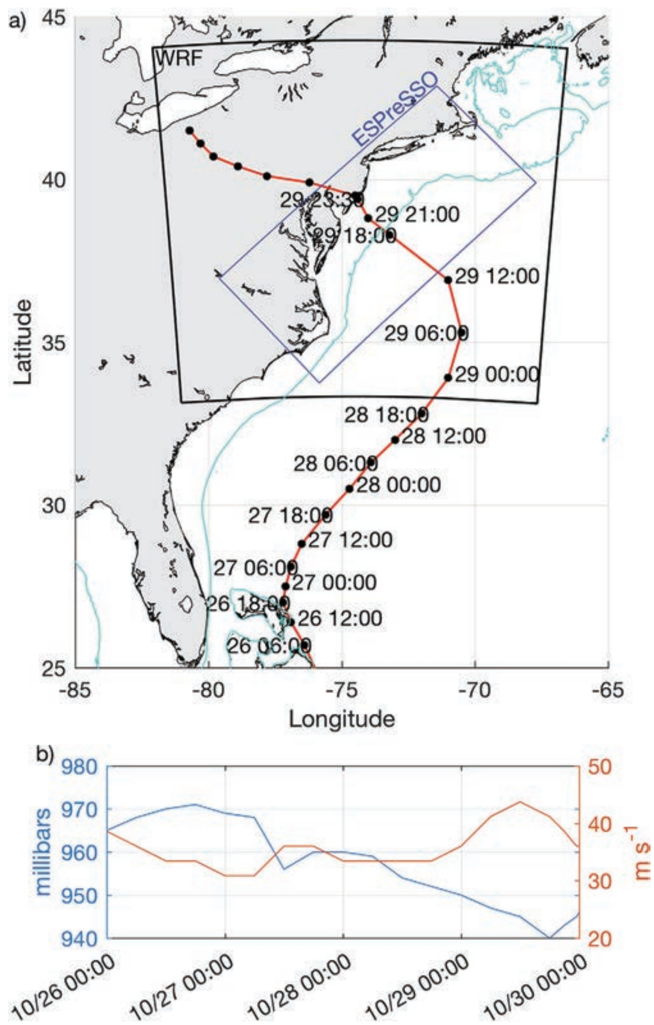

Figure 1. A map (a) of the WRF model domain (black box), ROMS ESPreSSO model domain (blue box), NHC best track positions (red line) and times (dd HH:MM in black), and the 100 m isobath (teal line). A time series (b) of the NHC best track pressure (blue) and maximum wind speed (orange).

observations and had correlation coefficients of 0.87 and 0.90 with winds at 44009 and 44025, respectively, and 0.99 with pressure at both buoys. Sandy track comparisons between modeled minimum pressure and the NHC best track estimates as the eye transited across the continental shelf (Figure 2) show the modeled track staying slightly north of the NHC best track until the final hour before landfall. The maximum separation between the two tracks during this time period is less than 35 km and was less than 10 km at landfall, well within the NHC best track estimate uncertainties of 80 to 30 km for tropical depressions and category 4 to 5 hurricanes, respectively, in the Atlantic Basin [*Torn and Snyder*, 2012].

2.4. Hydrodynamic Model

We performed numerical model simulations of the coastal ocean response to Sandy using the Regional Ocean Modeling System (ROMS) [*Shchepetkin and McWilliams*, 2005, 2009a, 2009b; *Haidvogel et al*., 2008] with the Experimental System for Predicting Shelf and Slope Optics (ESPreSSO) domain [*Cahill et al*., 2008; *Haidvogel et al*., 2008; *Hofmann et al*., 2008; *Zhang et al*., 2009; *Xu et al*., 2013]. ROMS is a free surface, sigma-coordinate, primitive equation numerical ocean model that has been used extensively to investigate regional ocean processes globally. The ESPreSSO domain (Figure 1) includes the entire MAB from within bays out past the shelf-break with 5 km horizontal resolution and 36 vertical levels. ESPreSSO uses

Four-dimensional variational (4D-Var) data assimilation to obtain the best state estimate of the coastal ocean in near real-time [*Moore et al*., 2011] and has been running nearly continuously since 2006. The standard ESPreSSO configuration uses boundary conditions from the Hybrid Coordinate Ocean Model (HYCOM) Navy Coupled Ocean Data Assimilation (NCODA) forecast system (http://hycom.org/), tides from the Advanced CIRCulation (ADCIRC) tidal model (http://adcirc.org/), and river discharge from the United States Geological Survey (USGS). Surface fluxes derived from the WRF-ARW simulation mentioned above were calculated using the COARE bulk formulae [*Fairall et al*., 2003]. The generic length scale k-kl vertical mixing scheme was used for water column turbulent mixing parameterization [*Umlauf and Burchard*, 2003; *Warner et al*., 2005]. The Sandy hindcast simulation was initialized at 00:00 GMT on 25 October 2012 and run forward until 31 October 2012 07:00 GMT with hourly output. *Miles et al*. [2015] previously used this model configuration and setup to investigate sediment resuspension and transport processes during Sandy on the MAB.

Depth-average momentum balance terms were extracted from standard ROMS output and are represented by the following equations:

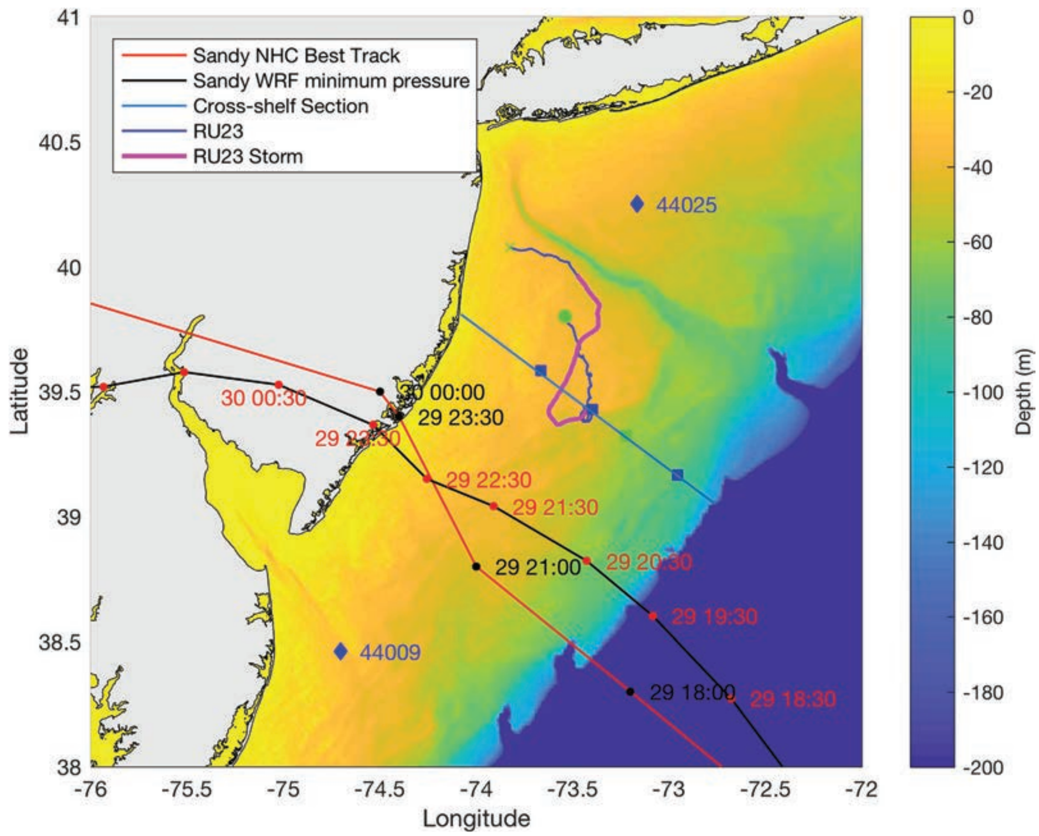

Figure 2. A zoomed in map of the New Jersey continental shelf and bathymetry with the NHC best track positions (red line) and times (dd HH:MM in black), and the WRF modeled track (black line) and times (dd HH:MM in red). The full glider RU23 track (blue) is plotted with the start location (green x) and recovery location (green circle) and the storm sampling period of 00:00 GMT on 28 October to 00:00 GMT on 31 October 2012 (magenta). NDBC buoys 44025 and 44009 are plotted with blue diamonds. The cross-shelf section used for Figures 7–12 is plotted in blue and the points for data extraction used in Figure 11 are plotted as blue squares. The third farthest extraction point from land at the 60 m isobath (green square) is used for Figure 6.

$$\underbrace{\frac{\partial u}{\partial t}}_{acceleration} = \underbrace{-\frac{\partial (uu)}{\partial x} - \frac{\partial (vu)}{\partial y}}_{horizontal\ \ advection} - \underbrace{\frac{1}{\rho_o}\frac{\partial P}{\partial x}}_{pressure\ \ gradient} + \left(\underbrace{\frac{\tau_s^x}{h\rho_o}}_{\substack{surface\\stress}} - \underbrace{\frac{\tau_b^x}{h\rho_o}}_{\substack{bottom\\stress}}\right) + \underbrace{fv}_{Coriolis} \tag{2}$$

$$\underbrace{\frac{\partial v}{\partial t}}_{acceleration} = \underbrace{-\frac{\partial (uv)}{\partial x} - \frac{\partial (vv)}{\partial y}}_{horizontal\ \ advection} - \underbrace{\frac{1}{\rho_o}\frac{\partial P}{\partial y}}_{pressure\ \ gradient} + \left(\underbrace{\frac{\tau_b^x}{h\rho_o}}_{\substack{surface\\stress}} - \underbrace{\frac{\tau_b^y}{h\rho_o}}_{\substack{bottom\\stress}}\right) - \underbrace{fu}_{Coriolis} \tag{3}$$

where t is time u and v are depth-averaged velocity in the x and y direction rotated into along-shelf and cross-shelf, P is pressure, ρ_o is a reference density of 1025 kg m^{-3}, τ_s^x and τ_s^y are wind stress, τ_b^x and τ_b^y are bottom stress, f is the Coriolis frequency. The horizontal viscosity terms were small in both the along and cross-shelf directions and were not included in equation (2) or (3). The temperature change rate equation was used to investigate the relative impact of mixing and advection on thermal changes throughout the water column as Sandy crossed the MAB shelf. Direct output from ROMS was used and is represented by:

$$\frac{\partial T}{\partial t} = -\frac{\partial (uT)}{\partial x} - \frac{\partial (vT)}{\partial y} - \frac{\partial (wT)}{\partial z} + \frac{\partial A_{kt}\frac{\partial T}{\partial z}}{\partial z} + D_T + F_T \tag{4}$$

with surface and bottom boundary conditions of:

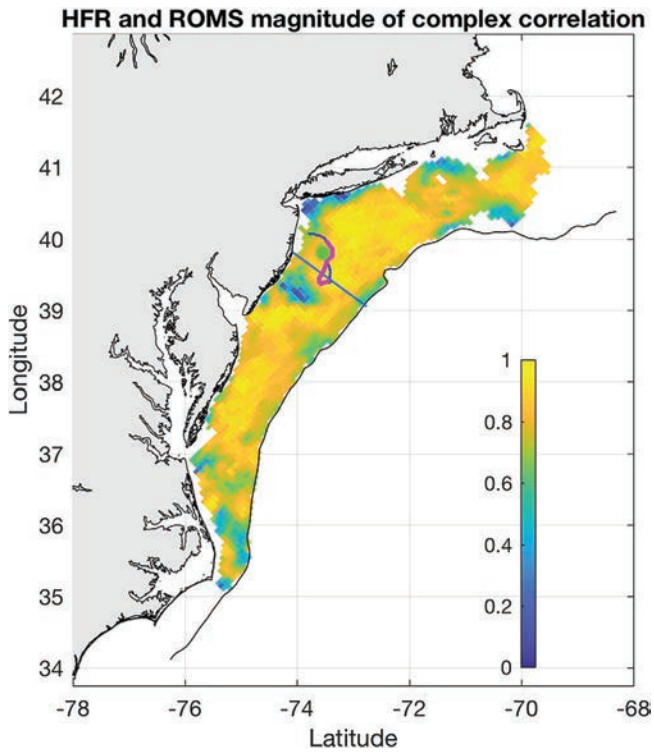

Figure 3. A map of the magnitude of the complex correlation between HF Radar hourly center-averaged surface currents and ROMS surface currents after interpolation to the nearest HF Radar grid point within the 150 m isobath (black contour). Correlation coefficients were made from model initialization at 00:00 GMT on 25 October to 00:00 GMT on 29 October 2012. The cross-shelf section used for Figures 7–12 is plotted in blue. The full glider RU23 track (blue) is plotted with the start location (green x) and recovery location (green circle) and the storm sampling period of 00:00 GMT on 28 October to 00:00 GMT on 31 October 2012 (magenta)

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=0}=\frac{Q_{net}}{\rho_o C_P} \tag{5}$$

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=-h}=0 \tag{6}$$

where, variables are as above in (2) and (3) in addition to T as temperature, D_T as the horizontal diffusion term, F_T is friction, A_{kt} is the vertical eddy diffusivity, h is depth, Q_{net} is the surface net heat flux, and C_p is the specific heat capacity of seawater as 3985 J (kg C)$^{-1}$.

The ROMS-ESPreSSO model output has been extensively validated and performed well compared to numerous other regional models [*Wilkin and Hunter*, 2013]. A portion of the results section is dedicated to comparisons between the model output and water column glider data at a single location. Here we also include additional verification using hourly averaged HF Radar output starting at model initialization time of 00:00 GMT on 25 October to 00:00 GMT 29 October 2012 prior to station loss as Sandy made landfall. For this comparison, complex correlation coefficients were calculated between hourly time series of each ROMS-ESPreSSO grid point and nearest HF Radar grid point on the continental shelf (onshore of the 150 m isobath). Complex correlation coefficients showed that the ROMS model simulated surface currents well throughout the majority of the domain (Figure 3) while HF Radar data were available. In particular, the ROMS model simulated surface currents well in the vicinity of the deployed glider and cross-shelf transect used for analysis in Figures 7–12.

3. Results

3.1. Storm Conditions

NHC best track estimates show Hurricane Sandy moved along the southeastern coast of the United States on 26 October 2012 in a relatively weak state with a minimum pressure of 970 m bar and maximum sustained wind speeds of 35 m s^{-1} (Figure 1). Sandy moved parallel to the US East Coast through the 27th and 28th with pressure gradually falling and maximum sustained wind speeds staying near 35 m s^{-1}. Just before midnight on 28 October and into the 29, wind speeds began to increase rapidly and Sandy began to make a northwestward turn toward the MAB. Wind speeds continued to increase, reaching a peak over 40 m s^{-1} at approximately 12:00 GMT on 29 October and a minimum pressure of 940 mbar a few hours later. Maximum sustained wind speeds decreased back to 35 m s^{-1} just before landfall in southern NJ at 23:30 GMT on 29 October Sandy's eye entered the WRF model domain (Figure 4) on 29 October just after midnight GMT. Modeled 10 m winds were directed alongshore toward the southwest along the MAB coastline at over 20 m s^{-1}. Winds continued in the alongshore direction toward the southwest on the NJ shelf until landfall, while in the southern MAB winds were directed offshore toward the south and southeast. At landfall in southern NJ winds rapidly shifted offshore over Delaware, alongshore toward the northeast on the NJ continental shelf, and onshore toward Long Island, NY farther north. As Sandy crossed the MAB

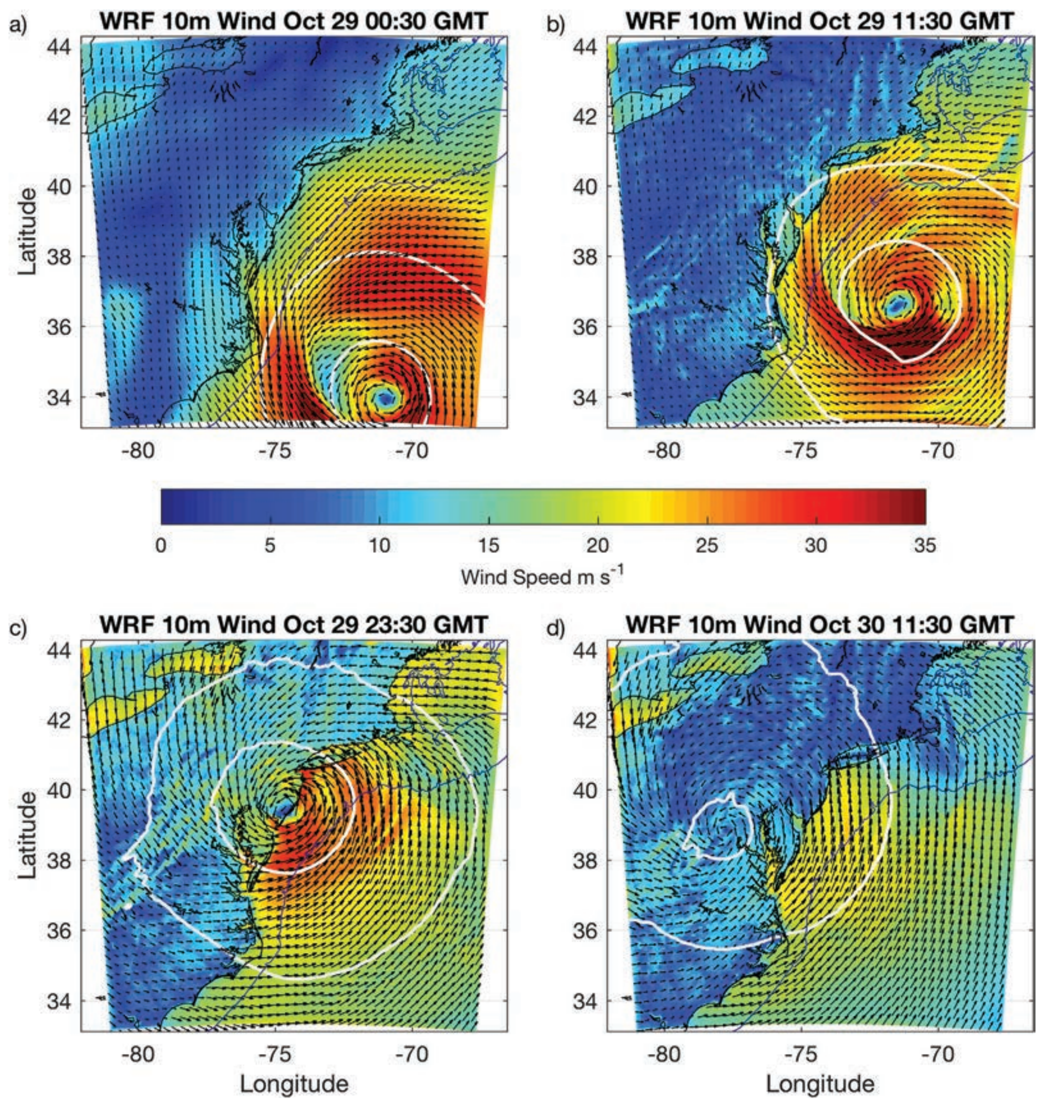

Figure 4. Maps of the WRF 10 m wind speed (colors) and direction (arrows) with the 990 (outer white contour) and 970 (inner white contour) millibar surface pressures at (a) 00:30 GMT, (b) 11:30 GMT, (c) 23:30 GMT on 29 October, and 11:30 GMT on 30 October.

continental shelf (Figure 2) it made its closest approach to the south of glider RU23 at 21:00 GMT on 29 October while also passing between the two NOAA NDBC buoys 44025 to the north and 44009 to the south.

3.2. Glider Water Column Observations

Glider RU23 was deployed on 25 October just south of the Hudson Shelf Valley off the northern NJ coastline (Figure 2). It was piloted offshore out to the 40 m isobath prior to the storm in order to avoid being forced by strong currents into the coastline. During the storm forcing period the glider was pushed toward the southwest over 60 km. Regardless of this alongshore advection the glider stayed near the 40 m isobaths, and on the northern side of the storm track. With the shelf-wide scale of storm forcing we interpret RU23 glider output as a time series of vertical profiles (Figure 5), though alongshore variability in water column properties may exist. These time series show four distinct time periods. The initial stratified period between 00:00 and 12:00 GMT on 28 October showed warm surface temperatures of over 17°C in the upper 30 m and 10°C temperatures below the thermocline, uniform to the bottom. Glider mounted Aquadopp derived cross-shelf currents were mostly vertically uniform and reflected the barotropic tide, with a slight bottom intensification in the offshore direction. Along-shelf flow was vertically uniform and southwestward at near

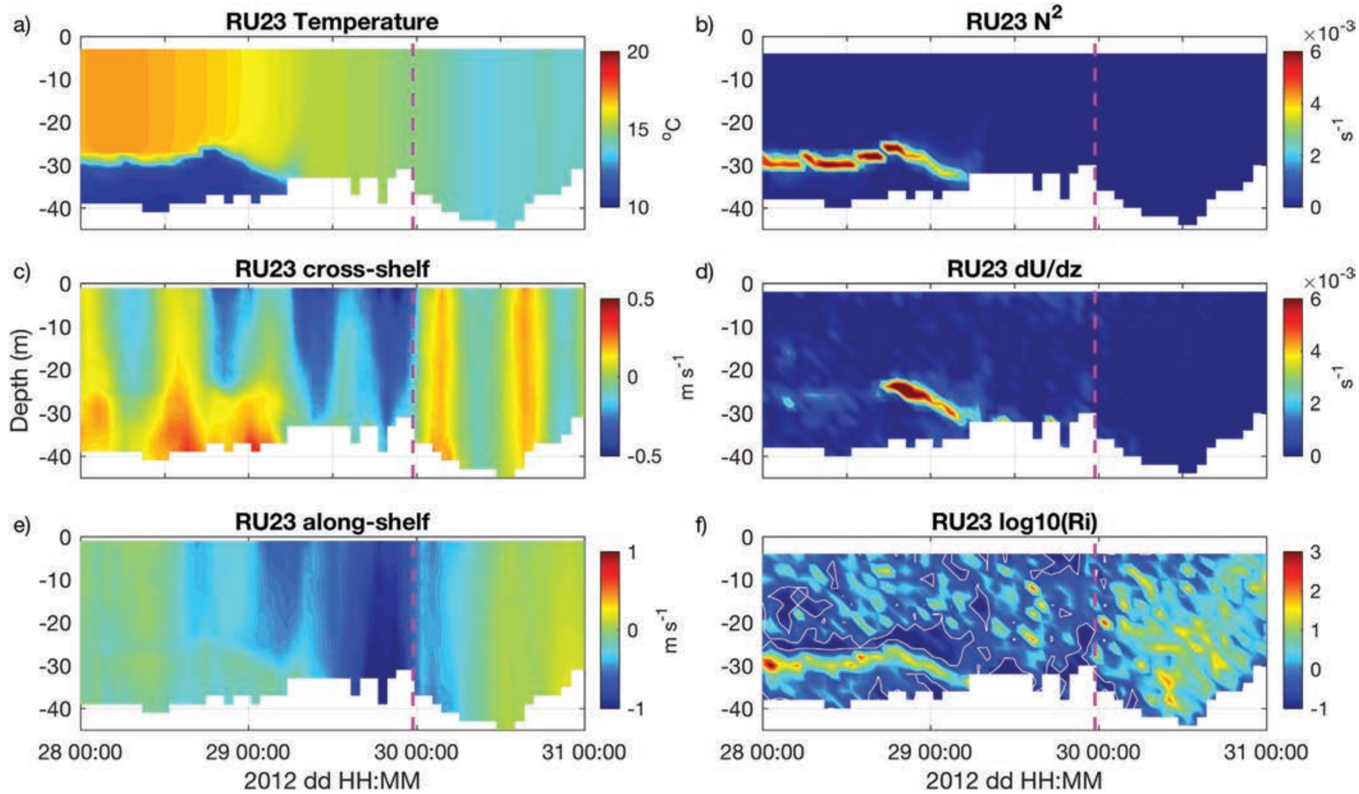

Figure 5. RU23 glider time series of vertical profiles extracted during the storm forcing period (track on magenta line shown in Figure 2). The vertical magenta line indicates Sandy landfall time. Variables plotted include (a) temperature, (c) cross-shelf velocity, (e) along-shelf velocity, (b) buoyancy frequency, (d) vertical shear of the horizontal velocity, and (f) the log10 of the Richardson number with Richardson number of 0.25 plotted with white contours. Velocity color bars are different in Figures 5c and 5e to highlight larger along-shelf magnitudes.

0.1 m s^{-1}. The sharp thermal stratification (>5°C m^{-1}) resulted in a stable pycnocline and large buoyancy frequencies. There was little vertical shear and the Richardson numbers remained large at the thermocline.

During the second time period between 12:00 GMT on 28 October and 06:00 GMT on the 29, the thermocline initially rose and then deepened dramatically, reaching the bottom in 12 h. Along-shelf currents increased to nearly 0.5 m s^{-1} in the surface layer and remained low in the bottom layer similar to during the initial stratified period. In the cross-shelf direction currents were onshore in the surface over 0.2 m s^{-1} while in the lower layer currents were offshore and near 0.4 m s^{-1} at 00:00 GMT on 29 October. While the thermocline deepened, vertical shear increased significantly, yet Richardson numbers remained above 0.25, indicating stable stratification was maintained up until the system transitioned from a two-layer to one-layer system by 06:00 GMT. During these 12 h the glider was advected ~12 km southward and remained on the northern side of the storm track, which indicates that much of the observed variability was temporal rather than spatial.

Between 06:00 GMT on 29 October and landfall at 23:30 GMT the water column responded to wind stress as a single layer. As the two-layer to one-layer transition occurred, the full water column cooled to just over 15°C, cross-shelf and along-shelf currents became relatively vertically uniform with primarily onshore flow with peak values near 0.2 m s^{-1}. Along-shelf flow was directed toward the southwest and reached near 1 m s^{-1} in the direction of the wind forcing. With a vertically well-mixed water column and uniform flow both buoyancy frequency and vertical shear were low and gradient Richardson numbers were variable throughout the water column. Following landfall storm-driven cross-shelf currents rapidly slowed and reflected the barotropic tide, while along-shelf currents slowed rapidly.

3.3. Hydrodynamic Model Output

ROMS output was extracted from a single location at the 60 m isobath (Figure 2) for comparison to glider cross sections (Figure 6). The model did not adequately represent the Cold Pool at the 40 m isobath where the glider was piloted but rather had a more defined Cold Pool farther offshore near the 60 m isobath.

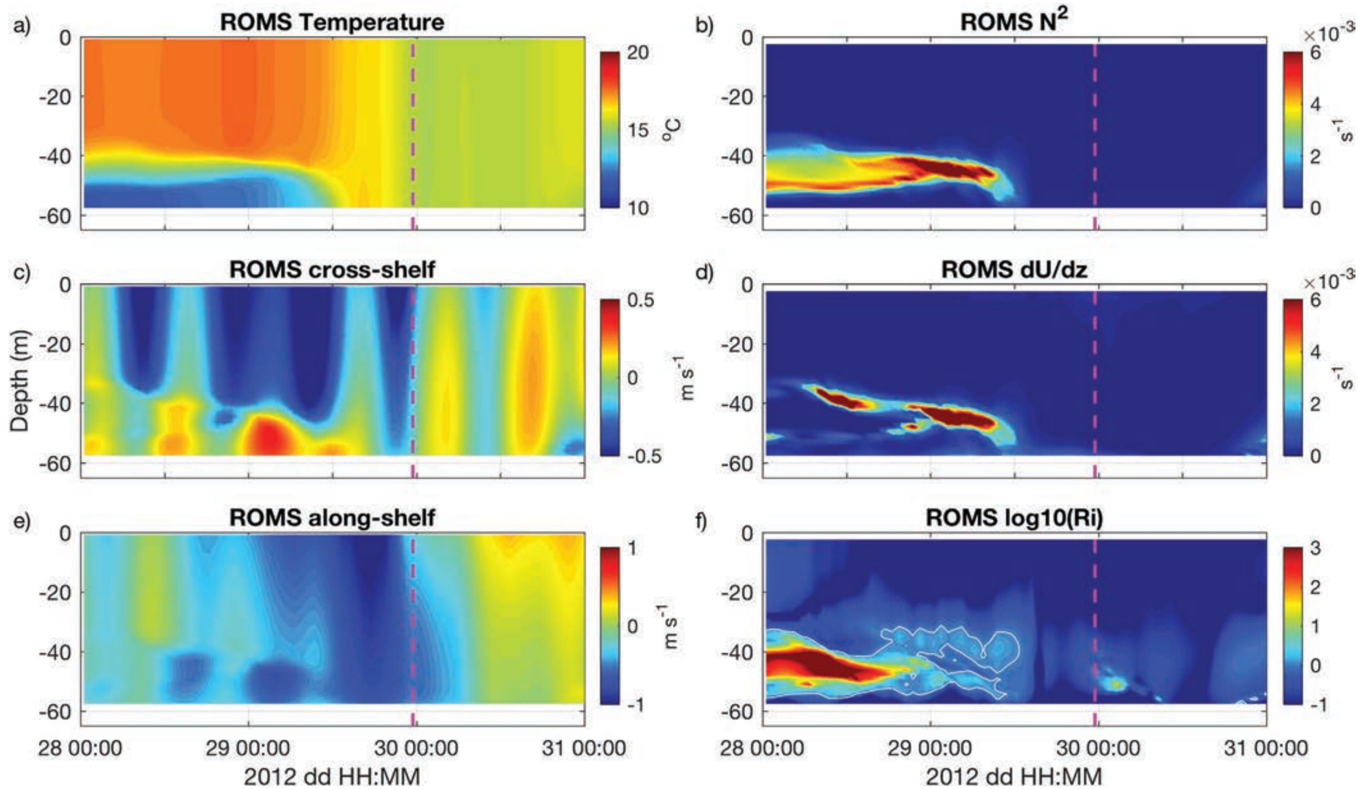

Figure 6. ROMS time series of vertical profiles extracted during the storm forcing period (green square plotted at the 60 m isobath shown in Figure 2). The vertical magenta line indicates Sandy landfall time. Variables plotted include (a) temperature, (c) cross-shelf velocity, (e) along-shelf velocity, (b) buoyancy frequency, (d) vertical shear of the horizontal velocity, and (f) the $\log_{10}$ of the Richardson number with Richardson number of 0.25 plotted with white contours. Velocity color bars are different in Figures 6c and 6e to highlight larger along-shelf magnitudes.

During the initial stratified period from 00:00 GMT and 12:00 GMT on 28 October modeled surface temperatures were only slightly warmer than observations, near 18°C while bottom temperatures were warmer than observations at11.5°C with a total difference of 6.5°C compared to 7°C observed by the glider. Currents were similar to glider sampled velocities with bottom intensified offshore flow in the cross-shelf direction and weak and variable along-shelf flow. At this farther offshore location stratification persisted until 12:00 GMT on 29 October, 6 h later than at the glider location. While the surface and bottom temperatures were similar to observations the thermocline was much thicker and weaker with a vertical temperature gradient of $\sim$0.3°C m^{-1} resulting in lower buoyancy frequencies than those observed by the glider over a broader vertical area, yet Richardson numbers remained above 0.25 throughout the storm forcing period. As stratification persisted longer in the model at this location flow was two-layer during the main storm forcing period with strong onshore flow near 0.5 m s^{-1} in the surface layer and offshore flow near 0.2 m s^{-1} near the bottom. Along-shelf southwestward flow did not reach its peak until after stratification eroded at 12:00 GMT on 29 October. While the thermocline deepened, N^2 remained elevated despite increasing vertical shear and, while Richardson numbers in the thermocline were reduced, they continued to remain above 0.25 until the system transitioned from two-layers to one. Despite differences between the glider observations and model output the observed water column features and transition from a two-layers to one-layer circulation are well represented.

Cross-shelf sections of the model simulated temperature and velocity were extracted along the transect shown in Figure 2 for three times, 12:30 GMT on 28 October, 00:30 GMT on 29 October, and 12:30 GMT on 29 October (Figure 7). At 12:30 GMT on 28 October a thin-layer of partially mixed Cold Pool water was present inshore up to the 20 m isobath with core Cold Pool water extending over a thicker bottom layer out to the shelf-break. Cross-shelf currents were directed offshore within the bottom Cold Pool layer and onshore in the surface layer. Along-shelf velocities were low throughout the water column at this time. Vertical velocities show downwelling at the inshore edge of the Cold Pool and over the deep ocean with upwelling

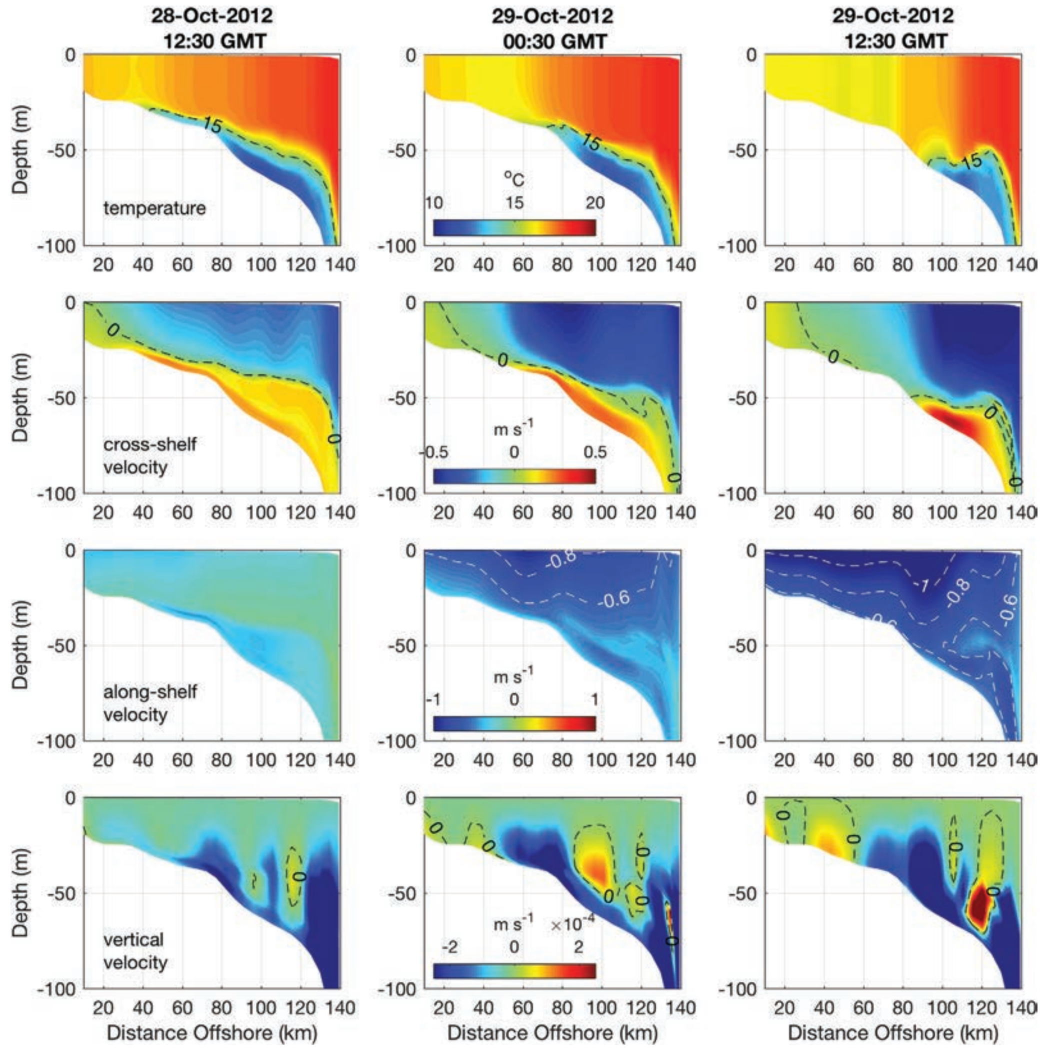

Figure 7. Cross-shelf sections of temperature (row 1), cross-shelf velocity (row 2), along-shelf velocity (row 3), and vertical velocity (row 4) extracted from the cross-shelf section shown in Figure 2. Times extracted include 12:30 GMT on 28 October, 00:30 GMT on 29 October, and 12:30 GMT on 29 October. Contours are used to show the approximate Cold Pool extent (row 1), to provide 0 crossing reference for velocities in rows 2 and 4, and to highlight the along-shelf southwestward velocities of 1, 0.8, and 0.6 m s^{-1} (row 3). Velocity color bars are different in rows 2–4.

within the core Cold Pool offshore. Over the next 24 h, a clear frontal region developed with vertically uniform temperatures that expanded across the innershelf. Cross-shelf velocities were onshore in the surface layer over the stratified region and slowed as they approached the unstratified innershelf. Bottom intensified offshore flow was evident within the Cold Pool and downwelling offshore flow occurred throughout the entire Cold Pool. Over the innershelf along-shelf velocities were toward the southwest throughout the entire water column, and were enhanced in an along-shelf jet toward the southwest at the downwelling front just above the innershelf edge of the Cold Pool at 12:30 GMT on 29 October.

Hovmöller diagrams of temperature and velocity were plotted along the same cross-shelf section to continuously track the temporal evolution of the surface and bottom layers (Figure 8). At 00:00 GMT on the 28th surface (Figure 8a) and bottom (Figure 8b) temperatures are similar out to 25 km offshore representing the well-mixed region inshore of the Cold Pool shown in Figure 7. The inshore edge of the Cold Poolis hereafter referred to as the Cold Pool Front and is defined by the cross-shelf temperature gradient in the bottom layer. The Cold Pool extended across the shelf between approximately 40 km and over 130 km offshore. Over the next 48 h until landfall the Cold Pool Front moved offshore by over 70 km. Within the innershelf bottom temperatures remained near 16°C throughout the duration of the storm while surface temperatures

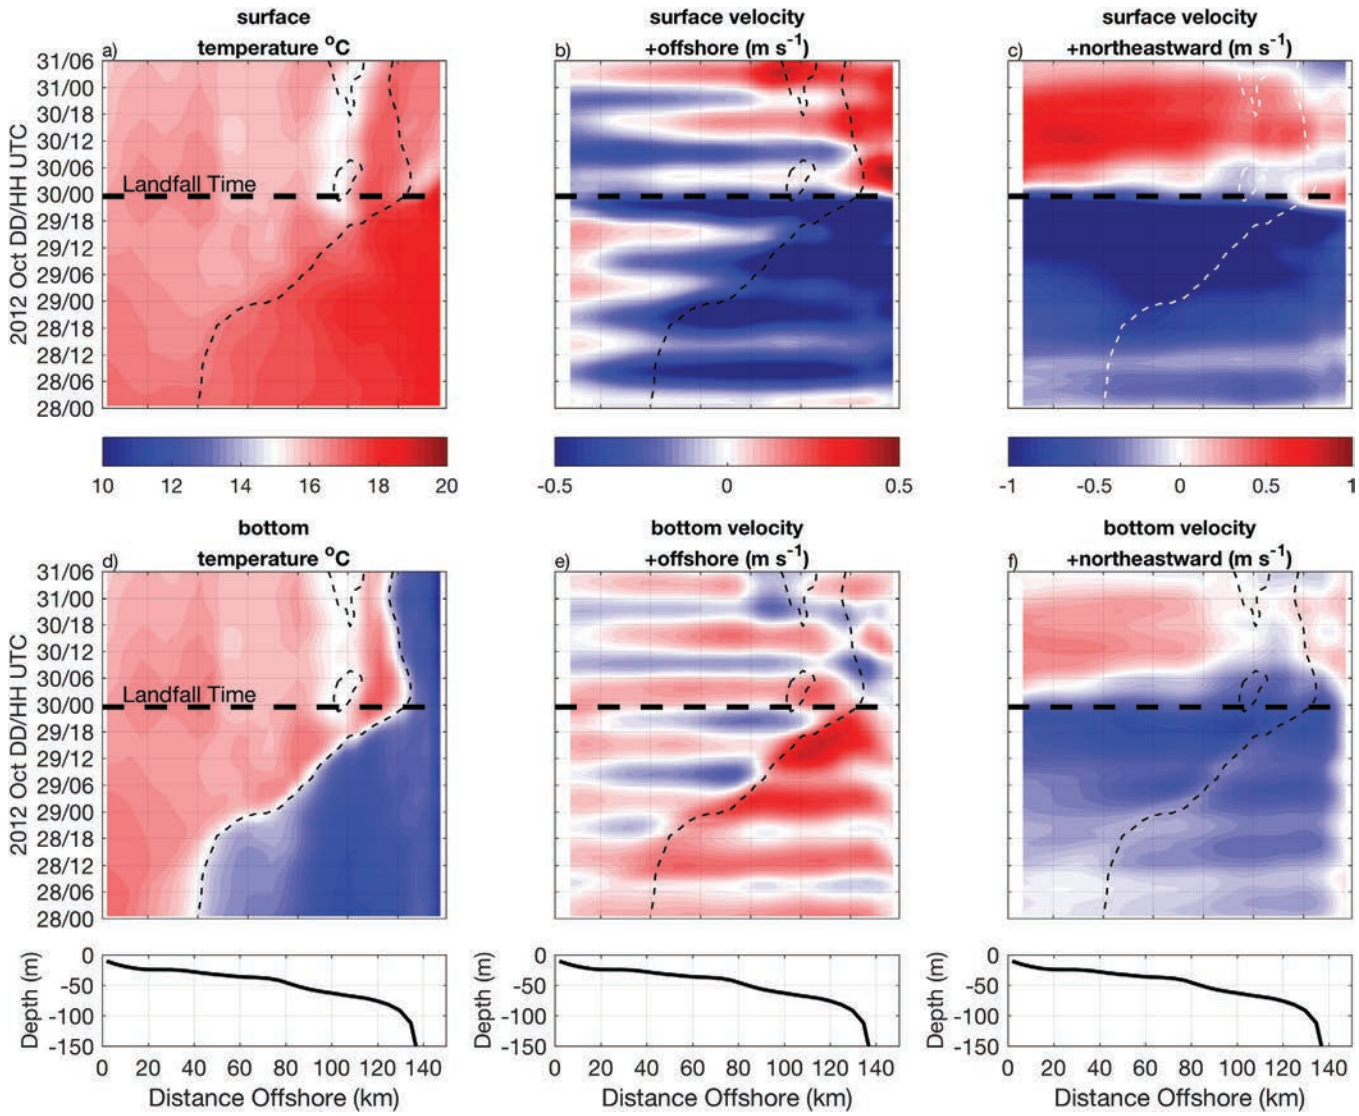

Figure 8. Hovmöller diagrams of hourly ROMS output extracted from the cross-shelf section shown in Figure 2. Extracted variables include (a) surface temperature, (b) surface cross-shelf velocity, (c) surface along-shelf velocity, (d) bottom temperature, (e) bottom cross-shelf velocity, and (f) bottom along-shelf velocity. Cross-shelf and along-shelf velocities are positive in the offshore and northeastward directions. Black dashed contours represent the 15°C bottom temperature or the approximate position of the Cold Pool Front. Horizontal dashed lines represent Sandy's landfall time. The bottom three plots are the bathymetry and distance offshore extracted from the cross-shelf line.

cooled by approximately 1°C out to 100 km offshore on the landward side of the Cold Pool Front. Enhanced cooling (warming) of the surface (bottom) occurred at landfall time 100 km offshore down (up) to 14.5°C. Landward of the Cold PoolFront, cross-shelf surface velocities were directed offshore. Seaward of the Cold Pool Front surface currents were directed onshore indicating a surface convergence zone and downwelling at the Cold Pool Front consistent with Figure 7. In the bottom layer, cross-shelf currents landward of the Cold Pool front were weak and directed onshore, while cross-shelf currents seaward of the Cold Pool front were strong and directed offshore indicating a region of divergence and offshore Cold Pool advection. Along-shelf currents during the ahead-of-eye period were consistently in the southwestward direction and were $\sim$1 m s^{-1} in the surface layer. Along-shelf bottom currents were in the same direction as surface currents but weaker until the main storm forcing period between 06:00 GMT on 29 October and just after landfall at 03:00 GMT on 30 October.

To further investigate the processes responsible for the observed and simulated coastal ocean response to Sandy, a time series of depth-averaged momentum balance terms are shown in Figures 9 and 10, with each term defined in equation (2) and (3) for cross-shelf and along-shelf directions respectively. The horizontal

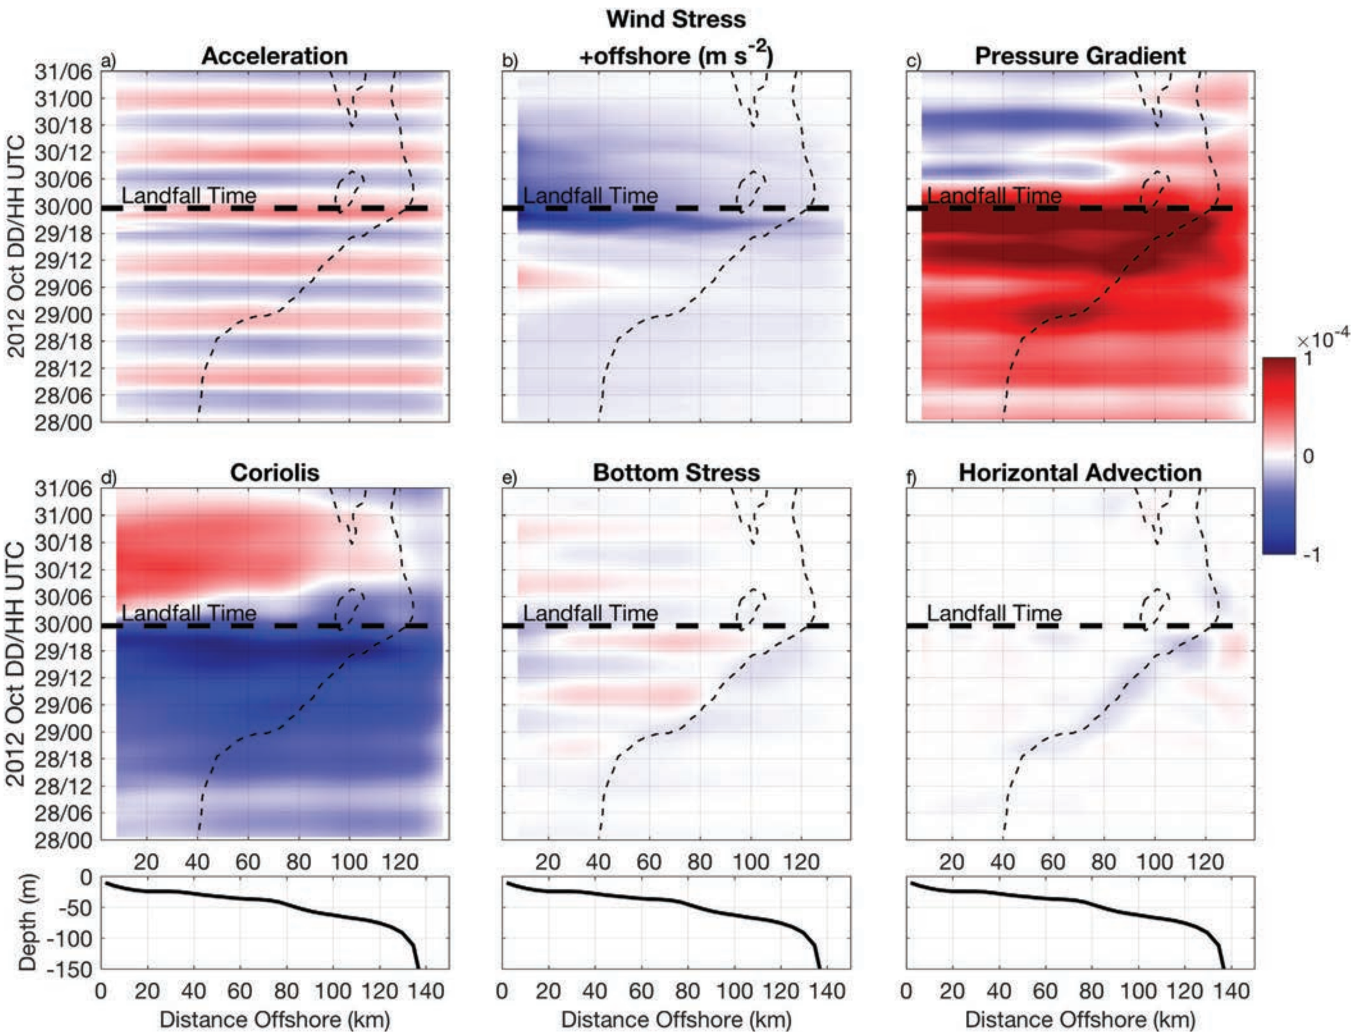

Figure 9. Hovmöller diagrams of hourly ROMS output of the depth-averaged cross-shelf momentum balance terms (equation (2)) extracted from the cross-shelf section shown in Figure 2. Extracted variables include (a) acceleration, (b) wind stress, (c) pressure gradient, (d) Coriolis, (e) bottom stress, and (f) horizontal advection. Positive is in the offshore directions Black dashed contours represent the 15°C bottom temperature or the approximate position of the Cold Pool Front. Horizontal dashed lines represent Sandy's landfall time. The bottom three plots are the bathymetry and distance offshore extracted from the cross-shelf line.

viscosity term was negligible and was not included. In both the cross-shelf and along-shelf directions the acceleration is tidally dominated with enhanced northeastward acceleration as Sandy made landfall. Wind stress was consistent with observed wind fields (Figure 4) alongshore toward the southwest and slightly offshore prior to landfall and rotated to northeastward and slightly onshore after landfall. The pressure gradient term was one of the dominant cross-shelf terms prior to landfall and was positive indicating an offshore directed sea-surface slope, or sea-surface setup along the coastline. This cross-shelf pressure gradient was balanced by a negative Coriolis term prior to landfall indicating that the coastal ocean over much of the shelf was nearly in geostrophic balance prior to Sandy making landfall. On the landward side of the Cold Pool Front, where the water column was vertically uniform, bottom stress was large and northeastward ahead of landfall, opposing the southwestward bottom currents. Depth-averaged horizontal advection terms in both the cross-shelf and along-shelf directions were small.

To quantitatively assess the impact of mixing and advection on the destratification of the continental shelf water column, we plotted time series profiles (Figure 11) of the temperature rate of change, combined temperature horizontal and vertical advection, and temperature vertical diffusion terms from equation (4). Data were extracted from four points on the cross-shelf transect shown in Figure 2 representing the approximate 20, 40, 60, and 80 m isobaths with the 60 m point aligning with the data extracted from ROMS in Figure 6. Tidal influences can be seen at all four locations in the total temperature rate and advection terms,

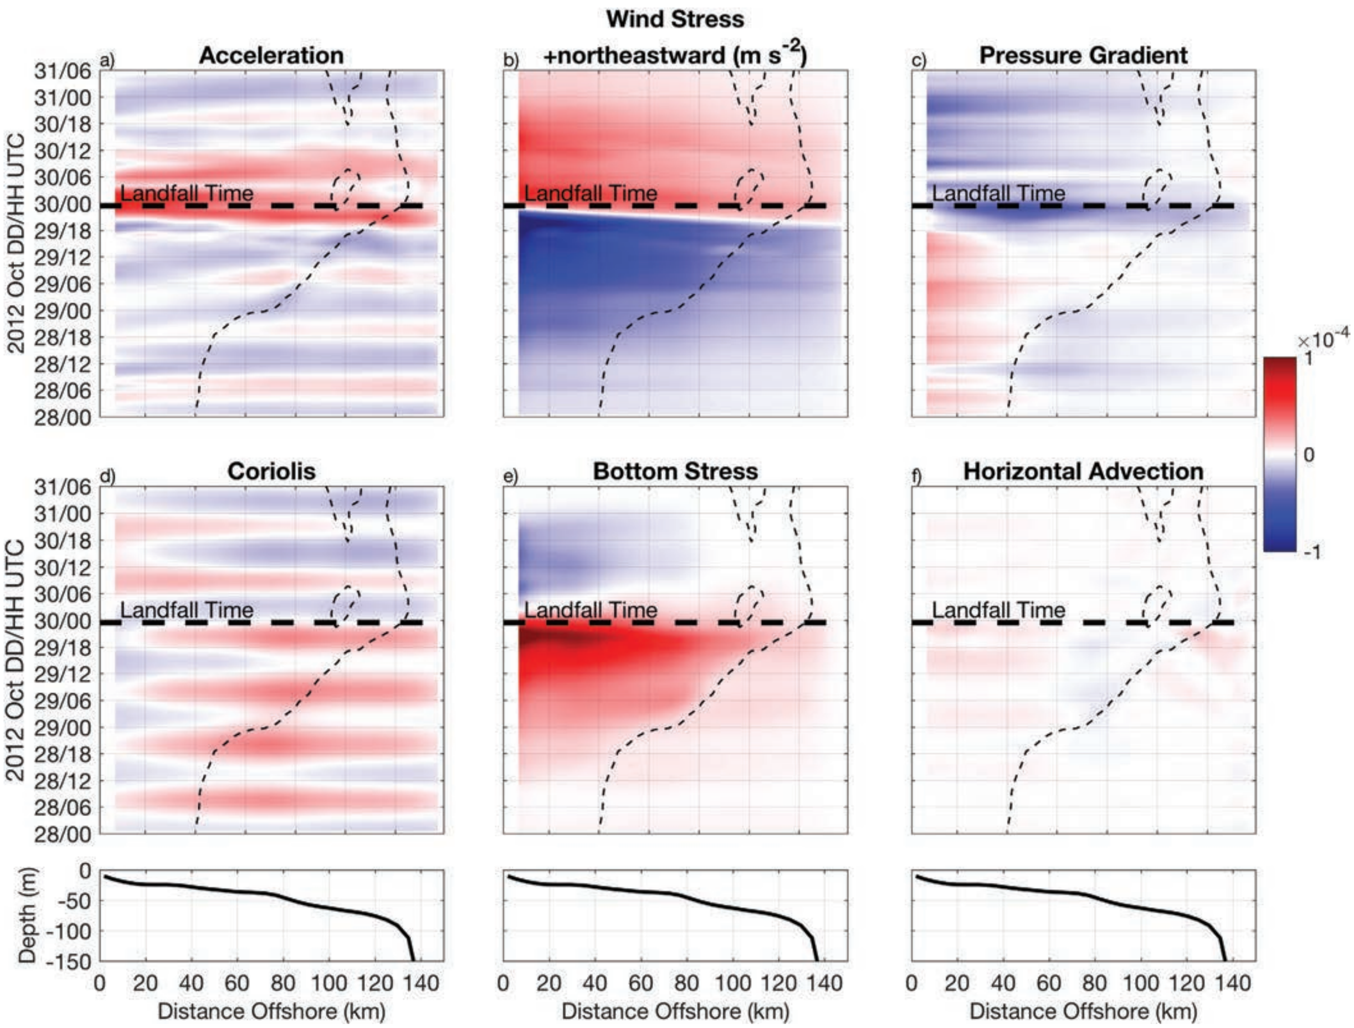

Figure 10. Hovmöller diagrams of hourly ROMS output of the depth-averaged along-shelf momentum balance terms (equation (3)) extracted from the cross-shelf section shown in Figure 2. Extracted variables include (a) acceleration, (b) wind stress, (c) pressure gradient, (d) Coriolis, (e) bottom stress, and (f) horizontal advection. Positive is in the southwestward direction. Black dashed contours represent the 15°C bottom temperature or the approximate position of the Cold Pool Front. Horizontal dashed lines represent Sandy's landfall time. The bottom three plots are the bathymetry and distance offshore extracted from the cross-shelf line.

particularly in the surface layer but not in vertical diffusion terms. While these tidal features are ubiquitous they are small relative to the large storm-driven advective terms and only represent changes on the order of 0.1°C at each given location. Aside from the tidally driven advection the inner shelf point exhibits little change throughout the storm forcing period and no vertical diffusion of temperature as temperature is vertically uniform. At the 40 m isobath cooling is evident at 00:00 GMT on the 29th in the surface layer and warming near the bottom. Cooling in the surface layer was driven by vertical diffusion of Cold Pool water while warming near the bottom was a combination of both advection and vertical diffusion. At the 60 m isobath a similar and more obvious pattern is evident with cooling in the surface layer and warming and deepening of the bottom layer between 00:00 GMT and landfall at 23:30 GMT on 29 October. Negative vertical diffusion of temperature is evident throughout the surface layer while positive vertical diffusion is only evident at the top of Cold Pool waters indicating erosion of the top of the Cold Pool into the surface layer. Within the Cold Pool, temperature advection was positive and dominated the temperature rate of change indicating that Cold Pool water was exported consistent with offshore flow observed in the near bottom layer in Figures 5 (glider time series), 6 (model time series), 7 model cross-shelf section), and 8 (model Hovmöller). At the offshore location there is a distinct periodic warming and cooling at the top of the Cold Pool by temperature advection, potentially linked with internal wave dynamics, though the period of the signal is unclear due to the short duration of the response. A distinct positive advective signal was again evident

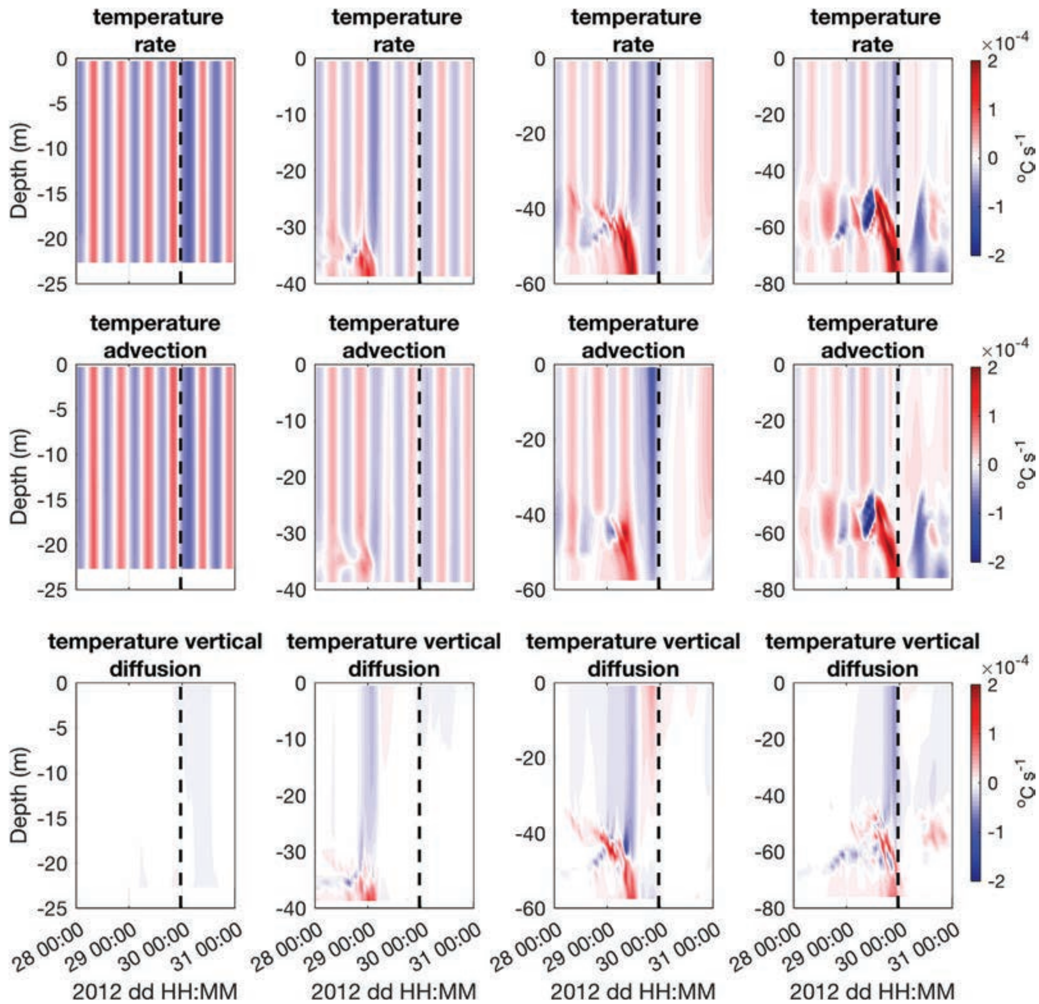

Figure 11. Time series of vertical profiles of the temperature diagnostic terms (equation (4)) extracted from the 4 cross-shelf points shown in Figure 2. Variables include the temperature rate of change (row 1), combined horizontal and vertical advection terms (row 2), and temperature vertical diffusion terms (row 3). The dashed vertical black line is Sandy's landfall time at 23:30 GMT on 29 October 2012.

near bottom at, and just after, landfall consistent with offshore advection of the Cold Pool seen at the shallower 60 m location. Vertical diffusion of temperature is limited and irregular pre-landfall while cooling is seen in the sea-surface after landfall when winds and currents reverse direction.

4. Discussion

The observed and modeled offshore bottom velocities, stable water column, momentum balance terms, and temperature diagnostics indicate that mixing processes alone were not sufficient for the seaward progression of the Cold Pool Front ~70 km offshore ahead of Sandy's landfall in New Jersey. The observed ahead-of-eye-center surface cooling was similar to previous studies of tropical cyclones that impacted the MAB during the stratified season such as Irene [*Glenn et al.*, 2016; *Seroka et al.*, 2016] and Barry [*Seroka*, 2017]. However, unlike these previous storms Sandy induced an extreme coastal ocean response to a tropical cyclone with the offshore advection of the Cold Pool Front. Three features of Sandy contributed to this coastal ocean response. (1) Sandy's cross-shelf track: typically tropical cyclones enter the stratified MAB from the south and travel alongshore toward the northeast [*Hall and Yonekura*, 2013] leading to initially onshore leading edge winds that rotate into alongshore southward or northward as a storm passes depending on its inshore or offshore track. Synthetic tropical cyclones that followed a similar cross-shelf track to Sandy was found to have a return rate of greater than 700 years for the MAB region [*Hall and Sobel*, 2013], and only five storms of tropical storm strength or greater have crossed nearly perpendicular to the NJ shelf since 1889 (https://coast.noaa.gov/hurricanes/). (2) Sandy was an exceptionally large storm: After exiting the Caribbean and passing the Bahamas, Sandy's radius of maximum winds increased to over 185 km, a large size it maintained until landfall [*Blake et al.*, 2013]. This large size is nearly 4 times the average radius of maximum wind for typical U.S. landfalling storms [*Hsu and Yan*, 1998]. 3) Sandy was a slow moving storm: Typical storms within the MAB region have translation speeds of approximately 40 km h^{-1} [*Landsea et al.*, 2015], while Sandy had an average translation speed between 00:00 GMT on 28 October to 23:30 GMT on 29 October of 27 km h^{-1} [*Blake et al.*, 2013].

The above three factors combined to produce a prolonged exposure of the stratified coastal ocean to alongshore southwestward downwelling favorable wind stress for nearly 48 h, or over 2.5 inertial periods, which are approximately 18 hours on the central MAB. The idealized two-dimensional downwelling response of a stratified coastal ocean to alongshore wind stress has been described for the Oregon [*Allen and Newberger*, 1996] and Mid Atlantic [*Austin and Lentz*, 2002] continental shelves. In *Austin and Lentz* [2002], they used an idealized version of the Princeton Ocean Model to represent a gently sloping continental shelf with a highly stratified water column typical of the Northeastern U.S. in summer. Downwelling favorable winds of $\sim$8 m s^{-1} were ramped up over one inertial period and held constant for nearly 2 weeks. They simulated onshore Ekman transport in the surface that deepened the pycnocline in the nearshore region until it intersected the bottom and was advected offshore. In their simulation they found that over the first inertial period alongshore wind stress resulted in onshore Ekman transport in the surface layer and led to a barotropic response that advected the bottom downwelling front seaward. For two-dimensional cross-shelf circulation they assumed that the vertically integrated transport was zero and could be divided into the surface Ekman transport, the barotropic interior, and the bottom Ekman transport. In the initial forcing period when the bottom Ekman layer is not spun up the cross-shelf balance is between the surface Ekman transport and the barotropic interior flow [*Dever*, 1997]. From *Austin and Lentz* [2002], the offshore displacement of the front for the barotropic response scaled with:

$$x_{baro}(t)= \sqrt{\int_0^t \frac{2U^s}{\alpha}dt+X_0^2} \tag{7}$$

where x_{baro} is the cross-shelf displacement, t is time, α is the slope of the shelf, X_0 is the initial front position, and U^s is the surface Ekman transport such that $U^s=\tau/\rho f$ where τ is the alongshore wind stress, ρ is a reference density, and f is the Coriolis frequency. The limited along-shelf bottom stress, elevated alongshelf wind stress, and elevated cross-shelf pressure gradient components of the momentum balance (Figure 9 and 10) during the first inertial period starting at 00:00 GMT on 28 October 2012 support this. In *Austin and Lentz* [2002], after the first inertial period the bottom Ekman layer develops and the bottom Ekman transport approximately equals the surface Ekman transport and the offshore displacement of the front scaled with:

$$x_{ek}(t)= X_0+\sqrt{\int_0^t \frac{2U^s}{\alpha}dt} \tag{8}$$

which is also supported by the increased along-shelf bottom stress matching the along-shelf wind stress at 06:00 GMT on 29 October 2012 (Figure 10).

To determine if the Cold Pool Front displacement in Sandy fits with the theoretical scaling in *Austin and Lentz* [2002] we used constants of $\alpha = 0.00055$, $X_0 = 40$ km, $f = 10^{-4}$ s^{-1}, $\rho = 1025$ kg m^{-3}. The alongshore wind stress from WRF was averaged along the cross-shelf section in Figure 2 hourly. The winds between 00:00 to 18:00 GMT 28 October were used with equation (7) and during the remaining time period until landfall 18:00 GMT on 28 October to 23:30 GMT on 29 October with equation (8). The frontal displacement from concatenating the results from equations (7) and (8) is shown in Figure 12 along with the offshore displacement of the 15°C isotherm which was previously shown in Figures 8–10 to represent the Cold Pool Front. The 15°C isotherm position and estimated frontal displacement were in good agreement with a barotropic displacement of $\sim$10 km in the first inertial period and an Ekman driven offshore displacement of $\sim$60 km in the remaining 1.5 inertial periods until landfall at the top of Figure 12. Key assumptions necessary for the *Austin and Lentz* [2002] scaling to be valid include (1) that conservation of mass is a strong constraint on the flow, (2) along-shelf variability in the flow is small compared to the cross-shelf variability, or

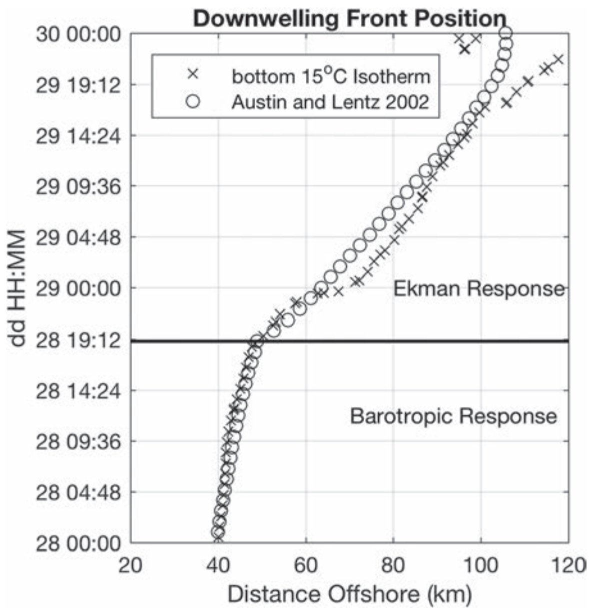

Figure 12. A Hovmöller diagram showing the offshore position of the 15°C bottom contour (x's) extracted from the ROMS model to represent the approximate position of the Cold Pool Front, and the position estimated from [*Austin and Lentz*, 2002] using the barotropic response (Equation 7) for the first inertial period and the Ekman response (equation (8)) for the remainder of Sandy's storm forcing period (o's). The solid horizontal line indicates the end of the first inertial period.

that the flow is approximately two-dimensional, (3) Ekman transport in the surface layer is well established and independent of turbulent closure schemes; and (4) deepening of the mixed-layer is limited.

This coastal ocean response to a tropical cyclone in the stratified MAB is unique to Hurricane Sandy. Alongshore winds measured at buoy 44025 (Figure 2) for Sandy showed that winds steadily increased from 5 to over 20 m s^{-1} and persisted for over 48 h ahead of landfall. An analysis of along-shelf wind speed from buoy 44025 from 1985 to present, which included the 11 storms that impacted the MAB during the stratified season highlighted in *Glenn et al*. [2016] show that no tropical cyclones resulted in alongshore wind stress that exceeded 18 h, thus none were capable of inducing the offshore Ekman response observed on the shelf during Sandy. While cross-shelf tracking storms are not typical over the MAB, NOAA storm track maps (coast.noaa.gov/hurricanes) show the southeastern coast of China and the Yellow Sea, regions with highly stratified water columns in summer [*Chen et al*., 1994; *Li et al*., 2012], are frequently impacted by cross-shelf tracking storms that may induce significant alongshore wind stress prior to landfall. A sediment resuspension and transport study on Typhoon Morakot in 2009 [*Li et al*., 2012] shows seaward displacement of cold bottom waters offshore. While not explicitly tested, the offshore advection of the Cold Pool ahead-of-eye-center may have been a contributing factor to the limited deintensification observed in Hurricane Sandy and more research on the coastal ocean response to tropical cyclones is needed.

In addition to the impacts on the water column structure, the observed and modeled offshore advection of the downwelling front ahead-of-eye-center also had implications for sediment resuspension and transport. Sandy had a large impact on coastal sediment resuspension and transport throughout the MAB [*Trembanis et al*., 2013; *Miles et al*., 2015; *Warner et al*., 2017]. The 70 km cross-shelf advection of the Cold Pool reduced water column stability on the innershelf and allowed for significant sediment resuspension and transport. On the offshore side of the downwelling front, where the water column was stratified, bottom stress was limited and subsequently sediment resuspension and transport along with cross-shelf currents was limited. On the inshore side of the downwelling front bottom stress was enhanced, sediment was resuspended throughout the full water column, and along-shelf flow transported sediment from the northern portion of the NJ Shelf near the Hudson Shelf Valley to the southern portion of the NJ Shelf near Delaware bay [*Miles et al*., 2015]. This rapid resuspension and resorting of shelf sediments in a few hours, which was on the scale of trawling and dredging impacts, has potential implications for benthic habitats [*Fanning et al*., 1982; *Thrush and Dayton*, 2002] and for prediction of the fate and effects of pollutants introduced at the coastline [*Biscaye et al*., 1988]. In addition to changes in sediment character, downwelling circulation on the NJ shelf has previously also been found to redistribute surfclam larvae across the shelf and may have implications for their settlement and recruitment among other macrofaunal communities [*Grassle et al*., 2006]. Also, rapid temperature changes with the passage of a warm downwelling front may have negative physiological impacts on benthic organisms [*Thiyagarajan et al*., 2000].

5. Conclusions

In this study we use an integrated ocean observing system that consists of an HF Radar network, Teledyne-Webb Slocum gliders, buoys, and regional ocean and atmospheric modeling to detail the coastal ocean response to Hurricane Sandy. Many studies have detailed the impact of tropical cyclones on the upper ocean, particularly while these storms transit over the deep sea [*Price*, 1981; *Price et al.*, 1994; *Zedler et al.*, 2002; *D'Asaro*, 2003; *Jaimes and Shay*, 2009; *Jaimes et al.*, 2011; *Sanford et al.*, 2011]. While many of these studies have focused on shear-driven vertical mixing, a study by *Yablonsky and Ginis* [2009] showed that modeling three-dimensional upwelling processes is necessary to accurately represent sea surface cooling induced by tropical cyclones over the deep ocean. More recent studies [*Glenn et al.*, 2016; *Seroka et al.* 2017; *Seroka et al.*, 2016] have shown three-dimensional coastal ocean processes can contribute to rapid sea-surface cooling through enhanced vertical shear ahead-of-eye center. This paper adds to that growing knowledge by detailing an additional case-study where ahead-of-eye-center downwelling circulation can advect the Cold Pool offshore and reduce stratification on the shallow inner shelf before eye-passage. While to-date this is a unique process observed during hurricane Sandy there is evidence that oceanographic conditions and storm tracks off of Southeastern China may result in similar dynamics. The results of this study continue to highlight the need for combined ocean observing systems and regional modeling in order to further understand the range of coastal ocean responses to tropical cyclones and potential feedbacks on storm intensity.

Acknowledgments
Glider data used in this study are available through the U.S. IOOS glider DAC https://data.ioos.us/gliders/erddap/tabledap/ru23-20121025T1944.html. Regional Ocean Modeling System and WRF model output are available at ftp://boardwalk.marine.rutgers.edu/tnmiles/JGR_Sandy_2017/. Buoy data and HF Radar data are publicly available through http://www.ndbc.noaa.gov/andhttp://tds.marine.rutgers.edu/thredds/cool/catalog.html, respectively. Funding support was provided by the National Oceanic and Atmospheric Administration (NOAA) led Integrated Ocean Observing System (IOOS) through the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS, NA11NOS0120038), the New Jersey Board of Public Utilities (2010RU-COOL), and the NOAA Cooperative Institute for the North Atlantic Region (CINAR, NA13OAR4830233), Disaster Recovery Act. The authors thank Teledyne Webb Research and Rutgers University for student support, the NOAA National Centers for Environmental Prediction for student engagement. Additionally, we would like to thank the glider technicians and pilots of the Rutgers University Center for Ocean Observing Leadership; the help of John Wilkin and the research associates of the Rutgers Ocean Modeling group with help setting up the ocean model; and two anonymous reviewers for their helpful comments.

Special Section:
Oceanic Responses and Feedbacks to Tropical Cyclones

Key Points:
- Observations, models reveal similar processes governing stratified coastal ocean cooling response to Hurricane Irene, Tropical Storm Barry
- Robust shear-induced mixing produced rapid ahead-of-eye-center cooling in TCs on opposite ends of track and seasonal stratification envelope
- Coupled TC models capable of predicting processes leading to rapid cooling of stratified coastal oceans critical for populated coastlines

Abstract Large uncertainty in the predicted intensity of tropical cyclones (TCs) persists compared to the steadily improving skill in the predicted TC tracks. This intensity uncertainty has its most significant implications in the coastal zone, where TC impacts to populated shorelines are greatest. Recent studies have demonstrated that rapid ahead-of-eye-center cooling of a stratified coastal ocean can have a significant impact on hurricane intensity forecasts. Using observation-validated, high-resolution ocean modeling, the stratified coastal ocean cooling processes observed in two U.S. Mid-Atlantic hurricanes were investigated: Hurricane Irene (2011)—with an inshore Mid-Atlantic Bight (MAB) track during the late summer stratified coastal ocean season—and Tropical Storm Barry (2007)—with an offshore track during early summer. For both storms, the critical ahead-of-eye-center depth-averaged force balance across the entire MAB shelf included an onshore wind stress balanced by an offshore pressure gradient. This resulted in onshore surface currents opposing offshore bottom currents that enhanced surface to bottom current shear and turbulent mixing across the thermocline, resulting in the rapid cooling of the surface layer ahead-of-eye-center. Because the same baroclinic and mixing processes occurred for two storms on opposite ends of the track and seasonal stratification envelope, the response appears robust. It will be critical to forecast these processes and their implications for a wide range of future storms using realistic 3-D coupled atmosphere-ocean models to lower the uncertainty in predictions of TC intensities and impacts and enable coastal populations to better respond to increasing rapid intensification threats in an era of rising sea levels.

1. Introduction

Although substantial progress in the prediction of tropical cyclone (TC) tracks has been realized globally over the past few decades, TC intensity prediction skill has remained comparatively flat across all TC ocean basins [*DeMaria et al.*, 2014; *Sopko and Falvey*, 2014; *Cangialosi and Franklin*, 2016]. This intensity gap can be traced to high-resolution requirements for TC models, poor understanding and modeling of the atmospheric boundary layer, difficulty for many existing assimilation techniques to ingest observations of small but intense features, and—most importantly for this study—challenges in modeling the upper ocean response to TCs [*Emanuel*, 2017, and references therein]. Large uncertainty in predicting the strength of TCs thus remains, which has its most significant implications for landfalling TCs where impacts to life and property—via storm surge, wind damage, and inland flooding—are greatest. These storms must first traverse the shallow, coastal ocean before making landfall. The number of studies in the literature investigating shallow, coastal ocean TC responses, indeed, pales in comparison to the number examining deep, open ocean TC responses [*Seroka et al.*, 2016]. Further, the differences between the deep, open ocean processes and the coastal processes are stark due to the influence of the bottom boundary layer and coastal wall in shallow water [*Glenn et al.*, 2016; *Seroka et al.*, 2016]. It is critical to close this gap, with the goal of improving the simulation of coastal ocean physics in coupled TC intensity models [e.g., *Zambon et al.*, 2014; *Warner et al.*, 2017].

In the summer hurricane season, the shallow Mid-Atlantic Bight (MAB) off the U.S. East Coast is one of the most seasonally stratified regions in the world [*Schofield et al.*, 2008], characterized by a sun-heated warm (>25°C) and thin (10 m or less) surface layer and a cold (<10°C) bottom layer termed the "Cold Pool"

[*Houghton et al*., 1982]. When Hurricane Irene traversed the highly stratified, shallow MAB waters in August 2011 before making landfall in New Jersey, rapid surface cooling caused by mixing processes resulting from the two-layer baroclinic circulation in the MAB were observed by an underwater glider and several National Data Buoy Center (NDBC) buoys; these intense mixing processes and the surface cooling (up to 11°C) response in the MAB are described in detail in *Glenn et al*. [2016]. Because the magnitude of the cooling was so significant, it led to a reversal in the direction of air-sea latent and sensible heat fluxes—from the ocean providing heat to the storm when using a fixed prestorm warm sea surface temperature (SST) bottom boundary condition to the ocean acting as a heat sink when using the fixed poststorm cold SST condition [*Seroka et al*., 2016].

This cooling was also found to primarily occur ahead of Irene's eye center—critical for direct impact on storm intensity—as the storm traversed northeastward along the MAB coastline. The cascade of processes responsible were strong ahead-of-eye-center onshore winds and surface currents, coastal setup with water piling up along the coast, offshore bottom currents in response to the resulting offshore pressure gradient, and larger shear-driven turbulence, mixing, and entrainment of cold bottom water to the surface due to directly opposing onshore surface and offshore bottom currents.

The ahead-of-eye-center cooling signal that resulted from these baroclinic coastal ocean mixing processes was found to be present in the 10 additional storms since 1985 that traversed northeastward across the MAB in the summer stratified season, and also in Super Typhoon Muifa (2011) in the similarly highly stratified Yellow Sea between eastern China and Korea. Further, this ahead-of-eye-center cooling was found to have a large impact on Hurricane Irene's intensity, larger than any other Weather Research and Forecasting (WRF) parameter tested [*Seroka et al*., 2016].

Many questions remain. First, it is not known to what extent the ahead-of-eye-center cooling impacted the intensities of the other 10 MAB storms and Typhoon Muifa. Extensive sensitivity studies like the one performed by *Seroka et al*. [2016] would need to be conducted for each storm to investigate these intensity impacts.

Second, it is not known if the same or different cooling processes occurred in the other 10 MAB storms and in Typhoon Muifa. To improve understanding of TC coastal ocean response, the dominant momentum balances that occurred in these storms as well as mixing versus advective processes that led to the ahead-of-eye-center cooling signals should be investigated in detail. It is also critical to understand the spatial—cross-shelf and along-shelf, shallow and deep water—variability of the cooling processes, for a wider range of storms including Irene. Previous studies focused on these processes at the underwater glider location and not elsewhere on the MAB continental shelf [i.e., *Glenn et al*., 2016]. These research gaps will guide this paper's work.

Standard operational model annual performance metrics are based on the mean across all storms simulated during one or several hurricane seasons [e.g., *Kim et al*., 2014; *Tallapragada et al*., 2014; *Cangialosi and Franklin*, 2016]. While this method is effective in testing overall performance of a model, it tends to wash out any unique storm characteristics in both the atmosphere and the ocean. The full range of storm characteristics represents the full range of storm air-sea feedbacks that coupled models should capture and resolve. Therefore, it is critical to not only improve models incrementally based on the mean in an operational environment [e.g., *Kim et al*., 2014; *Tallapragada et al*., 2014; *Cangialosi and Franklin*, 2016] but also to investigate individual case studies and processes that models may or may not be correctly resolving [e.g., *D'Asaro et al*., 2007; *Lin et al*., 2009; *Jaimes and Shay*, 2015; *Glenn et al*., 2016; *Seroka et al*., 2016].

In order to better understand the baroclinic ocean response for different storms, further investigation was performed on Irene and Tropical Storm Barry (2007), 1 of the other 10 MAB storms listed in *Glenn et al*. [2016]. A map of National Hurricane Center (NHC) best tracks for Irene and Barry show both storms traversing northeastward over the MAB, with Irene traveling 600 km from eastern North Carolina (NC) to New York City in 19 h in late August 2011 (~32 km/h translation speed), and Barry traveling 700 km from eastern NC to just south of Montauk Point, NY in 18 h in early June 2007 (~39 km/h translation speed, Figure 1, left). Typical translation speeds at MAB latitudes are 29–36 km/h [*Mei et al*., 2012]. Intensity time series show Irene weakening throughout its MAB crossing using both wind and pressure intensity metrics and show Barry weakening—at a lesser rate than Irene—over its last 12 h across the MAB using both metrics (Figure 1, right). Both storms had a radius of maximum wind (RMW) reported in the Automated Tropical Cyclone Forecast (ATCF) [*Sampson and Schrader*, 2000] system database of ~74 km 30 h prior to storm presence

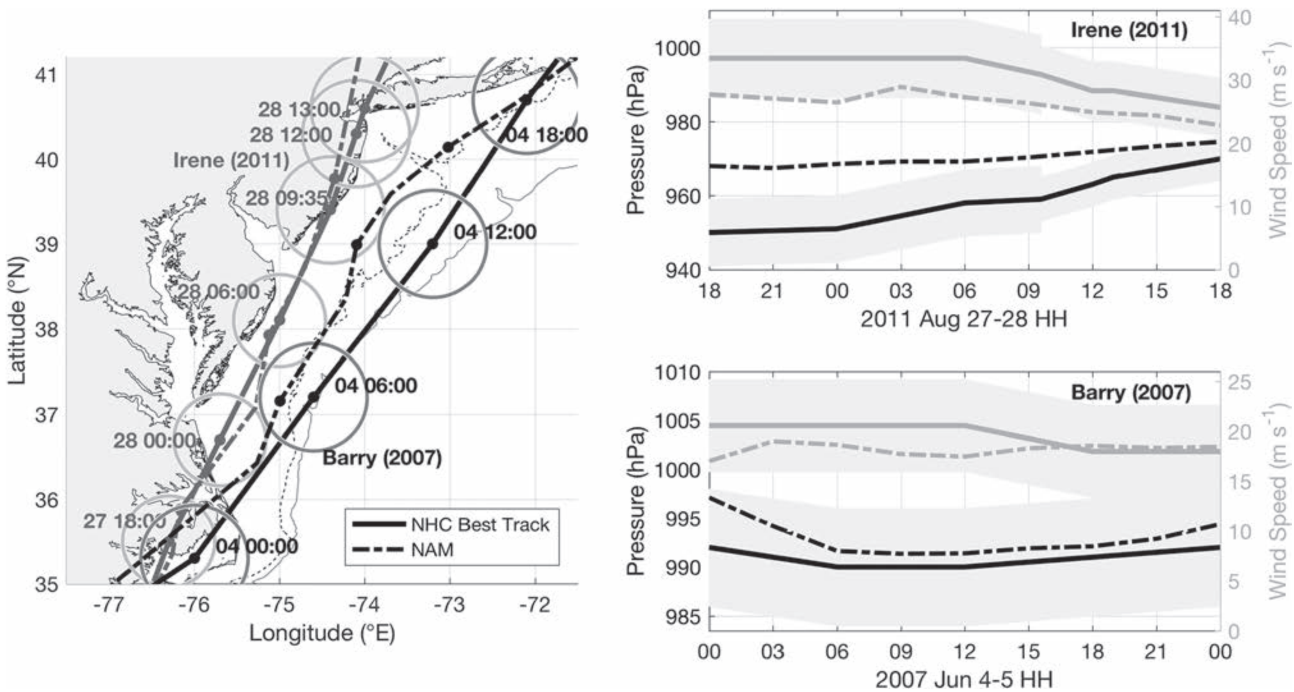

Figure 1. Irene and Barry. NHC best track spatial map (left) for Irene (gray solid line) and Barry (black solid line), with position uncertainty circles plotted at each NHC best track position for each storm. NAM in dash-dotted line for Irene (gray) and Barry (black). 50 and 200 m isobaths are in dotted contours. Date and time are in format 2011 MM HH:MM for Irene and 2007 MM HH:MM for Barry. NHC best track intensity time series for Irene (top right) and Barry (bottom right), with minimum central pressure (hPa) in solid black line and maximum sustained 10 m wind speeds (m s^{-1}) in solid gray line and intensity uncertainty in shaded gray. NAM in black dash-dotted lines for minimum central pressure and gray dash-dotted lines for maximum winds. NHC best track position and intensity uncertainties are from [*Torn and Snyder*, 2012] and depend on the intensity of the TC. All times are in UTC.

over eastern NC, with Irene's RMW increasing to 185 km 36 h later when the storm was over the MAB. For context, the average RMW for hurricanes making landfall in the U.S. from 1893 to 1979 was 47 km [*Hsu and Yan*, 1998].

For both of these storms, Rutgers University underwater gliders were deployed on the MAB continental shelf. Irene had a more inshore track northward through the MAB and Barry tracked farther offshore along the shelf break (Figure 1). Irene occurred in late August toward the end of the MAB summer stratified season, while Barry occurred in early June, during the beginning of the summer stratified season. However, the intent is not to perform direct comparisons between the two storms, as this would introduce several uncontrollable variables and not be a fully controlled experiment. Rather, the objective is to better understand the conditions in both the atmosphere and ocean that may lead to the baroclinic coastal ocean cooling processes, ahead-of-eye-center cooling, and impact on storm intensities for two extremes in the storm track—one nearshore and one well offshore—and two extremes in summer stratification—one near the end and one near the beginning of the season. This paper will investigate the details of and variability in the dominant baroclinic coastal ocean processes—in both the cross-shelf and along-shelf directions—for both Irene and Barry. By studying the spatiotemporal variability in these baroclinic coastal ocean cooling TC processes, the aim will be to improve the modeling of the full range of stratified coastal ocean TC responses.

2. Data and Methods

2.1. High Frequency (HF) Radar

Hourly surface ocean current data, 1 h center-averaged, from a network of CODAR Ocean Sensors SeaSonde HF Radar stations [*Roarty et al.*, 2010] along the MAB coast were used in this paper. Surface current map data have a nominal 6 km spatial resolution (Figure 1).

2.2. Gliders

Teledyne-Webb Research (TWR) Slocum gliders, autonomous underwater vehicles (AUVs), were used in this paper [*Schofield et al.*, 2007; *Glenn et al.*, 2008, 2016; *Ruiz et al.*, 2012; *Miles et al.*, 2013, 2015]. Rutgers

Figure 2.

University Gliders RU16 (Irene) and RU17 (Barry) data were analyzed. Both gliders were equipped with a Seabird unpumped conductivity, temperature, and depth (CTD) sensor.

Depth and time-averaged velocity calculations were performed using a dead-reckoning technique, a method typically used for underwater gliders [*Sherman et al*., 2001; *Davis et al*., 2002; *Schofield et al*., 2007]. To estimate bottom layer currents at the glider location, a combination of dead-reckoned depth-averaged glider currents and HF radar surface currents is used (Figure 2). This method assumes that the HF radar surface currents are representative of the currents in the surface mixed layer above the thermocline. See *Glenn et al*. [2016] for detailed methods and equations used to calculate bottom layer currents.

2.3. Bathymetry

U.S. Coastal Relief Model data from the NOAA National Centers for Environmental Information were used for water depth and coastlines throughout this paper [*NOAA National Centers for Environmental Prediction*, 2016].

2.4. Satellite SST

Advanced Very High Resolution Radiometer (AVHRR) data were used for ocean model SST verification. Techniques empirically derived for the MAB to remove bright cloud covered pixels and retain darker ocean pixels were used to decloud AVHRR data but preserve the rapid TC cooling signal, following *Glenn et al*. [2016].

2.5. Regional Ocean Modeling System (ROMS): ESPreSSO

Ocean model simulations were conducted using ROMS [*Haidvogel et al*., 2008], a free-surface, sigma coordinate, primitive equation ocean model (code available at http://www.myroms.org). ROMS has been used for a wide variety of coastal applications. Specifically, the ESPreSSO (Experimental System for Predicting Shelf and Slope Optics) model [*Wilkin and Hunter*, 2013], covering the MAB from Cape Cod to south of Cape Hatteras, and from the inland bays to beyond the shelf break, was used for simulations. In an assessment of skill of real-time ocean models over the MAB continental shelf for 2010–2011, ESPreSSO performed well as compared to global models and other regional models, indicating its usefulness for simulating coastal ocean circulations across a wide range of conditions, including Hurricane Irene which also occurred in 2011 [*Wilkin and Hunter*, 2013].

The ESPreSSO grid has a horizontal resolution of 5 km and 36 vertical levels in a terrain-following *s*-coordinate system. Initial conditions here were developed from an ESPreSSO grid ROMS reanalysis with strong constrained four-dimensional variational (4D-Var) data assimilation, including assimilation of sea surface height, SST, HF radar surface currents, and in situ temperature and salinity observations. For atmospheric forcing, North American Mesoscale (NAM) 12 km 3 hourly forecast data from its daily 00Z cycles were used. Only short-term forecast hours f03–f27 were used to limit any longer-term forecast error, with the f00 analysis skipped to allow for model spin-up. NAM surface air temperature, pressure, relative humidity, 10 m vector winds, precipitation, downward longwave radiation, and net shortwave radiation were used to specify the surface momentum and buoyancy fluxes based on the COARE bulk formulae [*Fairall et al*., 2003].

The NAM track map and intensity time series as assembled here for both Irene and Barry are compared to the NHC best track analyses (Figure 1). NHC best track uncertainty estimates depend on the intensity of the TC, with the uncertainty increasing as the intensity decreases [*Torn and Snyder*, 2012]. For both storms, the NAM tracks are all well within or just outside the best track uncertainties, and the NAM maximum wind intensities are within or at the best track uncertainties (Figure 1). For Barry, the minimum central pressure intensities are well within the uncertainties, and for Irene, they are at or just outside the uncertainties. The wind rather than central pressure intensities are most relevant for this study, as the winds provide the momentum fluxes forcing the TC ocean response. Overall, the NAM tracks properly represent the typical MAB track envelope, with Irene propagating along the inner shelf and Barry along the mid to outer shelf.

Figure 2. Irene and Barry. HF radar surface ocean current 1 h center-averaged maps for Irene and Barry before eye passage by RU16 (Irene, top left) and RU17 (Barry, top right). NHC best track in black, with large black arrow indicating general direction of surface currents. Location of RU16 and RU17 shown with red triangles. Time series at glider locations of temperature with thermocline depth in black contour, transition layer depth (see *Glenn et al*. [2016] for definitions) in magenta contour, and large white arrows indicating general direction of layer currents (second row from top); cross-shelf currents (third row from top); along-shelf currents (fourth row); and surface to bottom shear for Barry (bottom right). Currents and shear are smoothed using the MATLAB "smooth" function using a span of 8.

Boundary conditions were daily two-dimensional surface elevation and three-dimensional velocity, temperature, and salinity fields from the Hybrid Coordinate Ocean Model (HYCOM) Navy Coupled Ocean Data Assimilation (NCODA) forecast system. River inflows were from the seven largest rivers, using daily average U.S.G.S. discharge data. Tidal boundary conditions were from the ADvanced CIRCulation (ADCIRC) tidal model. Finally, vertical turbulence diffusivity was determined using the general length-scale method k-kl type vertical mixing scheme [*Umlauf and Burchard*, 2003; *Warner et al*., 2005].

For Barry, the ROMS ESPreSSO simulation was initialized at 1200 UTC on 29 May 2007 and ended at 1200 UTC on 8 June 2007, with storm eye passage by glider RU17 at 1700 UTC on 4 June 2007, just over 5 days into the simulation to allow for model spin-up. For Irene, the ROMS ESPreSSO simulation was initialized at 1200 UTC on 24 August 2011 and ended at 0000 UTC on 3 September 2011, with storm eye passage by glider RU16 at 1200 UTC on 28 August 2011, exactly 4 days into the simulation.

The depth-averaged momentum balance terms were direct output from the ROMS simulations, and the equations are as follows:

$$\underbrace{\frac{\partial u}{\partial t}}_{\text{acceleration}} = \underbrace{-\frac{\partial(uu)}{\partial x}-\frac{\partial(vu)}{\partial y}}_{\text{horizontal advection}} \underbrace{-\frac{1}{\rho_0}\frac{\partial P}{\partial x}}_{\text{pressure gradient}} + \left(\underbrace{\frac{\tau_s^x}{h\rho_0}}_{\text{surface stress}} - \underbrace{\frac{\tau_b^x}{h\rho_0}}_{\text{bottom stress}}\right) + \underbrace{fv}_{\text{Coriolis}}, \tag{1}$$

$$\underbrace{\frac{\partial v}{\partial t}}_{\text{acceleration}} = \underbrace{-\frac{\partial(uv)}{\partial x}-\frac{\partial(vv)}{\partial y}}_{\text{horizontal advection}} \underbrace{-\frac{1}{\rho_0}\frac{\partial P}{\partial y}}_{\text{pressure gradient}} + \left(\underbrace{\frac{\tau_s^y}{h\rho_0}}_{\text{surface stress}} - \underbrace{\frac{\tau_b^y}{h\rho_0}}_{\text{bottom stress}}\right) - \underbrace{fu}_{\text{Coriolis}}, \tag{2}$$

where u and v are the along-shelf and cross-shelf components of depth-averaged velocity, respectively, t is time, P is depth-averaged pressure, ρ_o is a reference density, τ_s and τ_b are surface (wind) and bottom stresses, h is water column depth, and f is the latitude-dependent Coriolis frequency. Horizontal diffusion was small and neglected here.

The temperature rate equation terms to diagnose advection versus mixing were also direct output from ROMS. The equation is as follows:

$$\frac{\partial T}{\partial t} = -\frac{\partial(uT)}{\partial x}-\frac{\partial(vT)}{\partial y}-\frac{\partial(wT)}{\partial z}+\frac{\partial A_{kt}\frac{\partial T}{\partial z}}{\partial z}+D_T+F_T, \tag{3}$$

with the following surface and bottom boundary conditions, respectively:

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=0} = \frac{Q_{net}}{\rho_0 C_p}, \tag{4}$$

$$\left(A_{kt}\frac{\partial T}{\partial z}\right)_{z=0} = 0. \tag{5}$$

Here T is the temperature, t is time, u, v, and w are the along-shelf, cross-shelf, and vertical components of velocity. A_{kt} is the vertical diffusivity coefficient, D_T is the horizontal diffusion term, and F_T is friction. Q_{net} is the surface net heat flux, $\rho_0 = 1025$ kg m^{-3} is a reference density, $C_p = 3985$ J (kg °C)$^{-1}$ is the specific heat capacity of seawater, and h is the water depth. Horizontal diffusion again was small and neglected here.

3. Results

3.1. Observations

Glenn et al. [2016] used HF radar and glider RU16 data to determine surface, depth-averaged, and bottom currents at the glider location during Irene. Part of the time series is repeated here in Figure 2 for ease of comparison to a similar analysis for Barry. At 0600 UTC on 28 August 2011, less than 4 h before Irene's NJ landfall and eye passage by glider RU16, surface ocean currents were directed onshore and upshelf, aligning close to the onshore winds ahead of Irene's eye (Figure 2, top left). Current magnitudes at this time approached 1 m s^{-1}. At 0200 UTC on 4 June 2007, a full 15 h before Barry's eye passage by glider RU17, surface ocean currents were in a very similar direction, onshore and upshelf.

Time series of temperature profiles at the glider locations below the surface current maps indicate initially very strong stratification and an eventual breakdown in stratification upon storm forcing. For Irene in late August, surface mixed-layer temperatures approached 25°C to ~10–15 m depth, and bottom MAB Cold Pool temperatures were less than 10°C. For Barry in early June, surface mixed-layer temperatures down to ~10–15 m depth were approaching 16°C with bottom MAB Cold Pool temperatures again less than 10°C, approaching 5°C. For Irene, the thermocline (black contour) deepened to ~30 m depth and surface mixed-layer temperatures cooled to ~17°C, with much (~5°C, or ~75%) of the cooling occurring ahead-of-eye-center. For Barry, the thermocline (black contour) deepened briefly to 25 m depth and surface mixed-layer temperatures cooled to nearly 14°C, with 100% of the cooling at RU17 occurring ahead-of-eye-center.

Cross-shelf and along-shelf surface (red), depth-averaged (green), and bottom (blue) current time series are depicted in the two figures below the temperature time series in Figure 2. For Irene, currents in Earth coordinates are rotated 31° clockwise from north to attain cross-shelf and along-shelf components. For Barry, currents in Earth coordinates are rotated 50° clockwise from north to attain cross-shelf and along-shelf components. For both Irene and Barry, red surface currents peaked onshore ahead-of-eye-center, and blue bottom currents peaked offshore at the same time yet with a bit of a lag in setup. For Irene, along-shelf currents were very small ahead-of-eye-center, but for Barry, along-shelf surface currents to the northeast peaked ahead-of-eye-center and bottom currents peaked just before. For both storms, observations indicate a two-layer circulation, with cross-shelf surface currents onshore and cross-shelf bottom currents offshore, enhancing the shear and resultant mixing and cooling. For Barry, a similar surface to bottom shear profile occurred in the along-shelf direction. Figure 2 (bottom right) shows a calculation of surface to bottom shear, combining both the along-shelf and cross-shelf components for Barry due to the large observed along-shelf component. Maximum shear occurred at the same time as maximum surface cooling and thermocline deepening, and well before eye passage.

3.2. Modeling

In order to investigate the details of the baroclinic processes and mixing that occurred in Irene and Barry, including momentum balance analysis and the temperature diagnostic equation for mixing versus advection comparisons, ROMS ESPreSSO simulations were performed as described in section 2.5 above.

3.2.1. ROMS Simulation Validation: Hurricane Irene (2011)

A prestorm map of SST over the MAB from AVHRR at 0742 UTC on 24 August 2011 (Figure 3, top left) shows coastal upwelling along the NJ, DE, and MD coastlines, with a warm tongue of SST through the southern MAB and extending offshore of the 50 m isobath and into the northern MAB north of the Hudson Canyon. The ROMS ESPreSSO rerun SST ~4 h later (Figure 3, top right) shows very good agreement with AVHRR, capturing the coastal upwelling, warm tongue, Gulf Stream, and colder waters south of Rhode Island and Nantucket.

A poststorm map of SST over the MAB from AVHRR at 0828 UTC on 29 August 2011 (Figure 3, middle left) shows a much different story, with cold <18°C SST from the mouth of the Hudson Canyon and northward, and a corridor of colder water at the 50 m isobath and offshore in the southern MAB. The ROMS ESPreSSO rerun SST (Figure 3, middle right) again shows very good agreement with AVHRR, with perhaps the only minor issue being not as cold water at the mouth of the Delaware Bay and in the southern MAB.

A difference map of poststorm minus prestorm AVHRR SST (Figure 3, bottom left) shows maximum cooling (approaching 11°C) at the mouth of the Hudson Canyon and across the MAB, with less cooling in the shallow regions of the shelf and offshore in the deep water. Again, ROMS (Figure 3, bottom right) agrees very well with the AVHRR cooling map, capturing the maximum in cooling at the Hudson Canyon mouth.

Finally, RU16 glider temperature profile time series (Figure 4, left) shows the same deepening of the thermocline and cooling of the surface layer as shown in Figure 2. ROMS (Figure 4, right) taken at the closest grid cell to the average position of RU16 during the storm period shows an initial thermocline ~10–15 m too deep but with correct surface mixed layer and bottom layer temperatures. Although the simulated

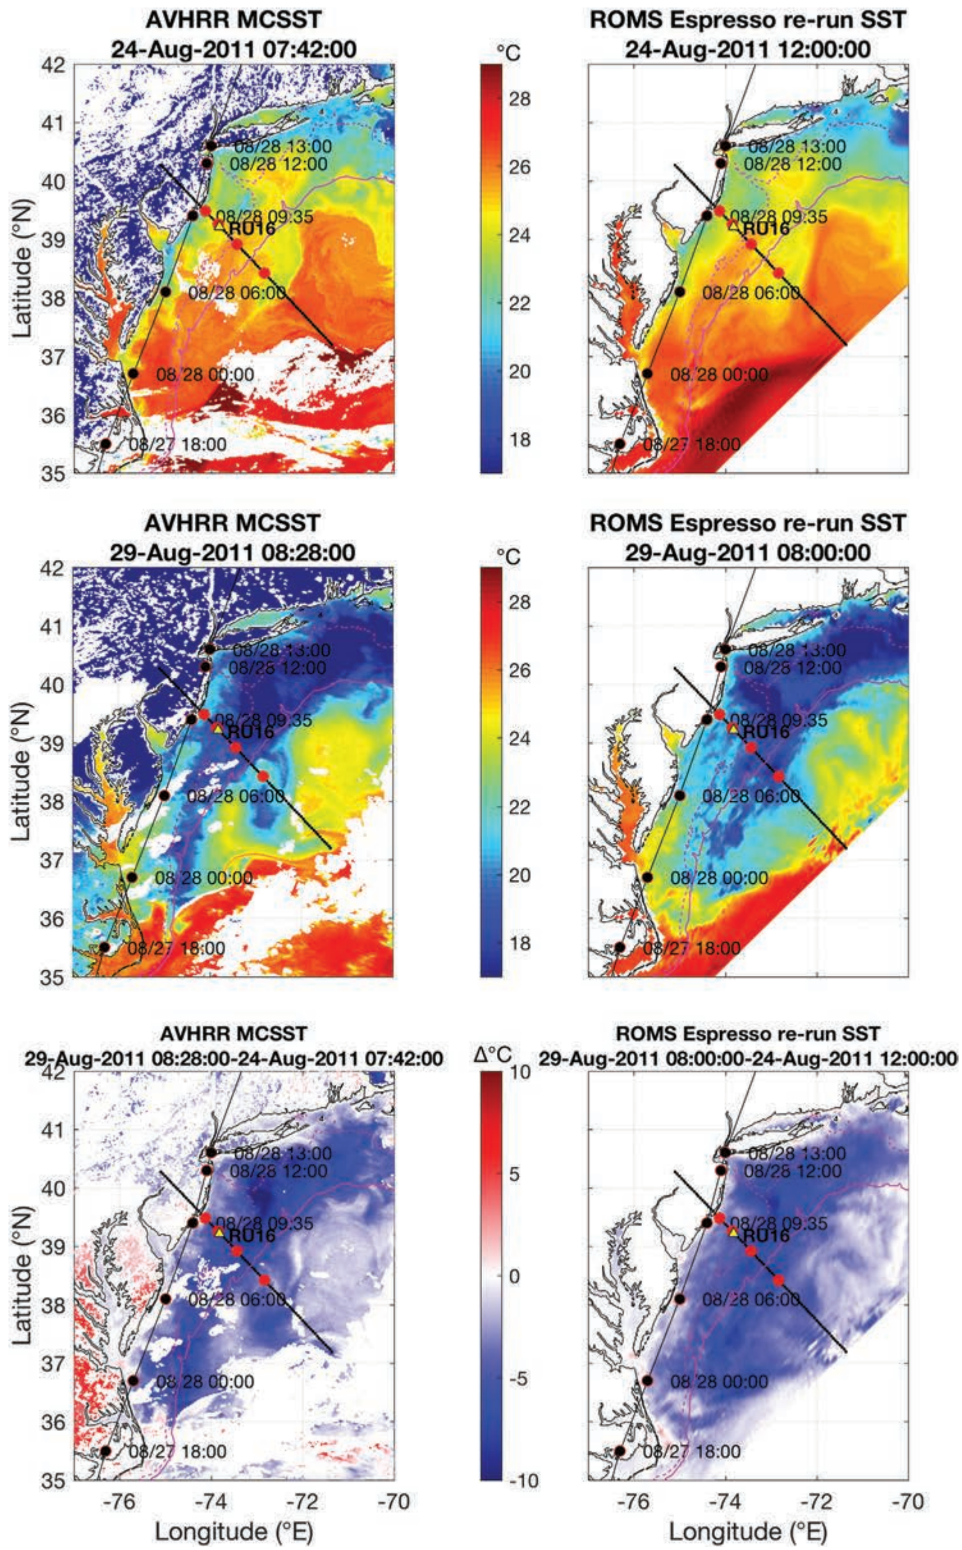

Figure 3. Irene. AVHRR Multi-Channel SST (MCSST) (top left) and ROMS ESPreSSO rerun SST (top right) prestorm for Irene; the same for poststorm in middle figures, and for poststorm minus prestorm in bottom figures. Dashed magenta contour is 50 m isobath, and solid magenta contour is 200 m isobath. RU16 location throughout the storm period plotted as yellow triangle, NHC best track for Irene in black with red outlined dots, small black dots in line northwest to southeast indicating cross-section location taken for Hövmoller figures below, and large red dots along this black line indicating profile locations taken for temperature diagnostic Figure 15.

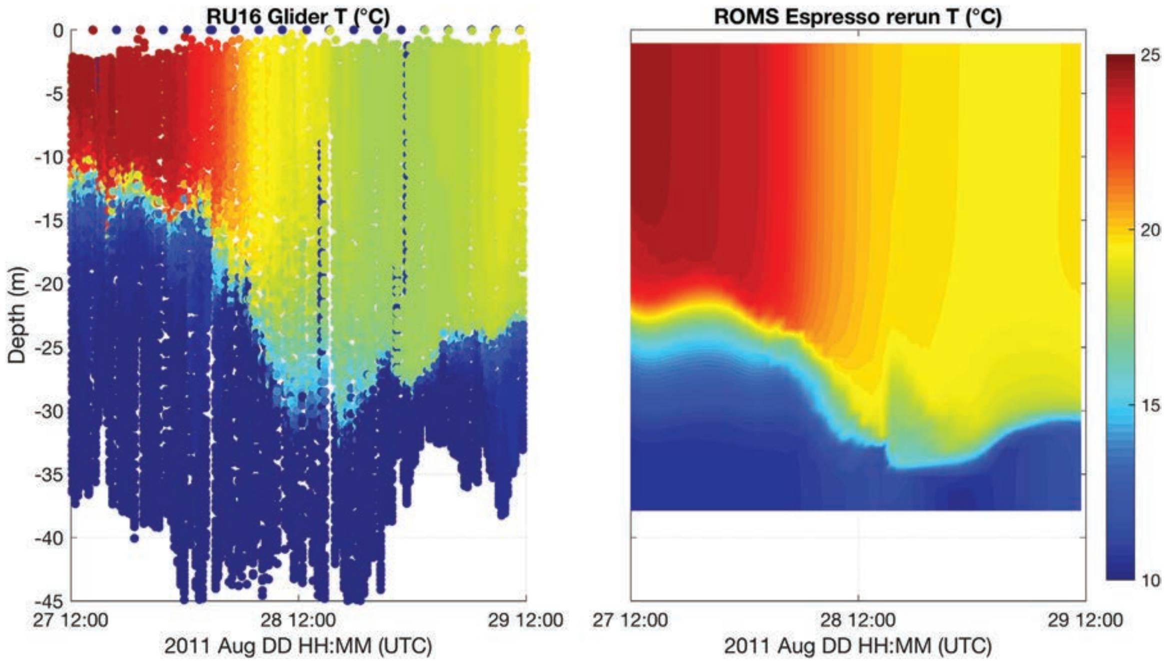

Figure 4. Irene. RU16 glider temperature (°C) (left) and ROMS ESPreSSO rerun temperature (°C) (right) at the closest ESPreSSO grid point to the average RU16 glider location during the storm.

thermocline is deeper than observed, the two-layer structure is present to support the relevant processes. Upon storm forcing, the ROMS thermocline deepens to the correct depth, but the surface does not sufficiently cool, likely due to the inadequate supply of cold bottom water at the start. Insufficient surface ocean cooling in model simulations due to an excessively thick surface layer has also been found to occur in other recent TC studies [e.g., *Zhang et al*., 2016], and is likely a common deficiency in numerical model simulations of TC ocean response. Despite deficiencies in the details, the overall storm response characteristics—two-layer structure at the start, deepening of the thermocline, and rapid and intense cooling of the surface mixed layer—are present and adequate for determining dominant force balances and diagnosing the causes of SST cooling.

3.2.2. ROMS Simulation Validation: Tropical Storm Barry (2007)

A prestorm map of SST over the MAB from AVHRR at 0559 UTC on 2 June 2007 (Figure 5, top left) is partially blocked by clouds but shows a warm Gulf Stream offshore, a couple Gulf Stream rings to the northwest in the slope water, a ribbon of colder water along the shelf break at 200 m, a ribbon of warmer water inshore of the 50 m isobath, and coastal upwelling east of Cape May, NJ, at the mouth of Delaware Bay, and along the Delmarva Peninsula. ROMS (Figure 5, top right) shows good agreement with AVHRR, with a warm Gulf Stream, cold water to the north, NJ and Delaware Bay coastal upwelling, warmer midshelf MAB waters, and a hint of the warm Gulf Stream filament approaching the 200 m isobath.

A poststorm map of SST over the MAB from AVHRR at 0207 UTC on 5 June 2007 (Figure 5, middle left) with the same color bar in Figure 5 (top) shows cooler water over the northern MAB, and ROMS at the same time (Figure 5, middle right) provides a similar picture. The difference maps of poststorm minus prestorm AVHRR SST (Figure 5, bottom left), ROMS rerun at the same time difference (Figure 5, bottom middle), and ROMS rerun to maximize cooling (Figure 5, bottom right) highlight the cooling and warming patterns across the MAB. Although clouds block parts of the map, AVHRR shows a pattern of warming in the southern MAB and offshore, and cooling in the northern MAB and offshore. Both ROMS rerun difference maps show more widespread cooling, with slight warming offshore NJ and off the Delmarva Peninsula, and where the Gulf Stream meanders moved through time.

Finally, the profile time series of temperature at the RU17 glider location (Figure 6, left) again shows surface mixed-layer cooling and deepening during the storm period, as in Figure 2. ROMS ESPreSSO rerun (Figure 6, right) shows a thermocline initially 15–20 m too deep, but surface and bottom temperatures overall correct.

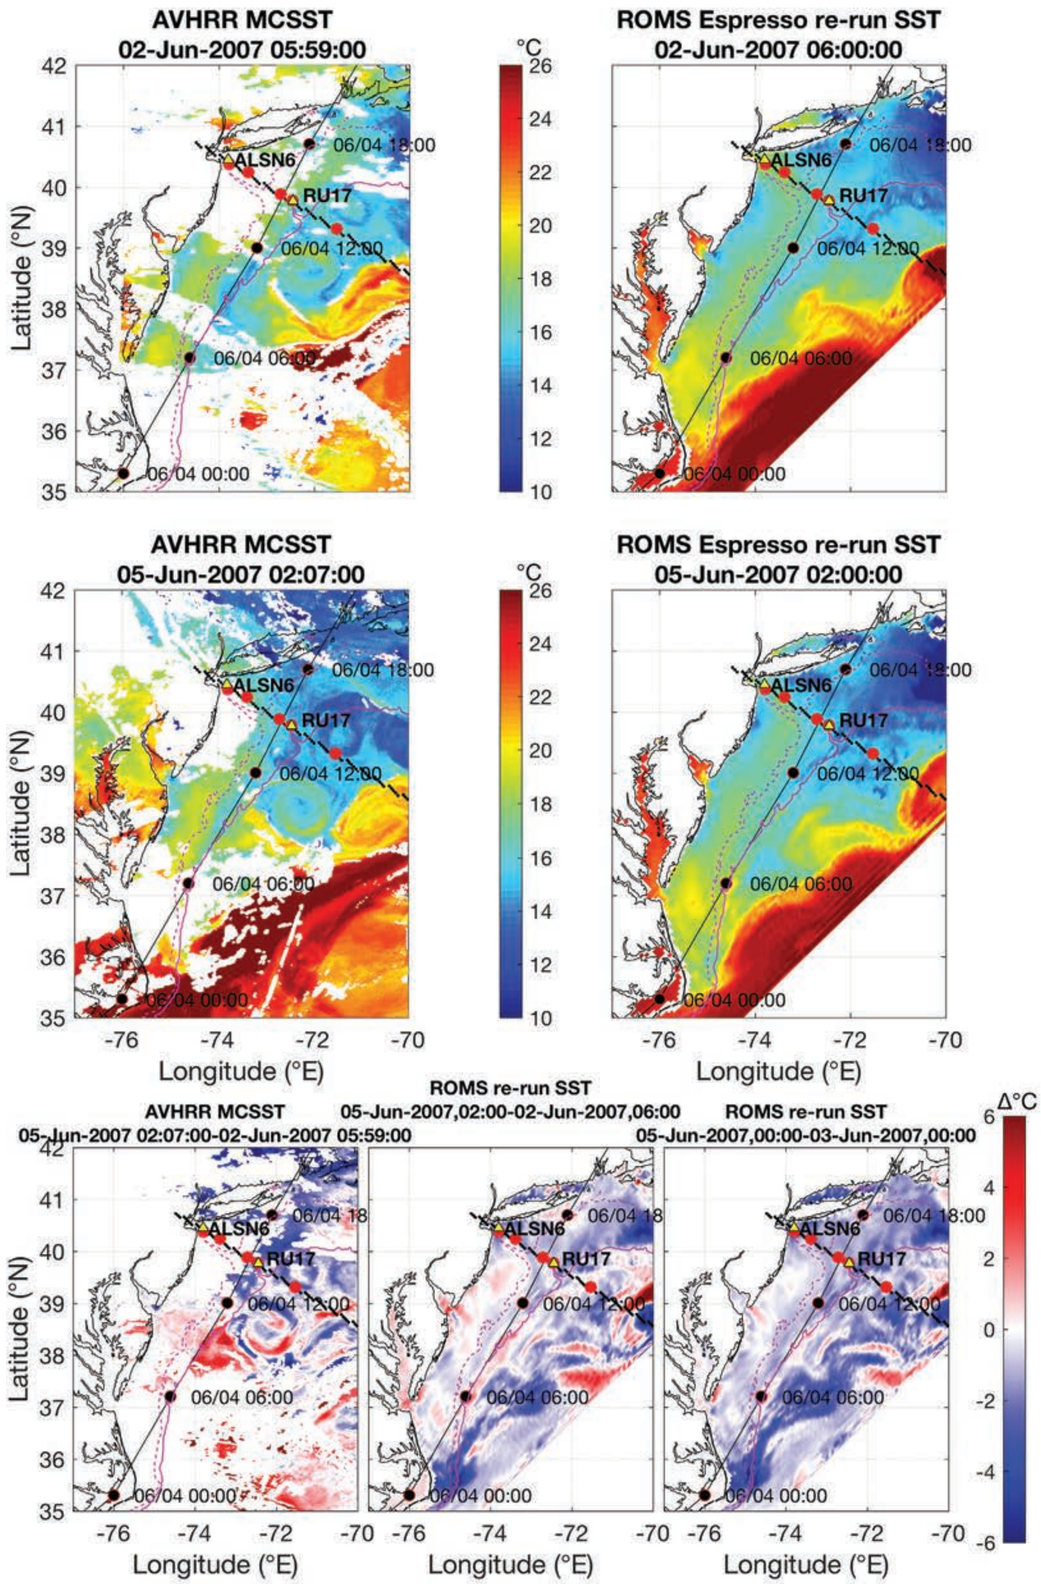

Figure 5. Barry. The same as Figure 3, but for Barry. NDBC station ALSN6 and RU17 glider locations indicated with yellow triangles. Northern cross-section location used for Barry plotted as west-northwest to east-southeast black dots just north of the Hudson Canyon, and large red dots along this black line indicating profile locations taken for temperature diagnostic Figure 16. A third figure on bottom (bottom right) is added for Barry with poststorm minus prestorm time difference chosen to maximize the cooling across the map in the ROMS ESPreSSO rerun.

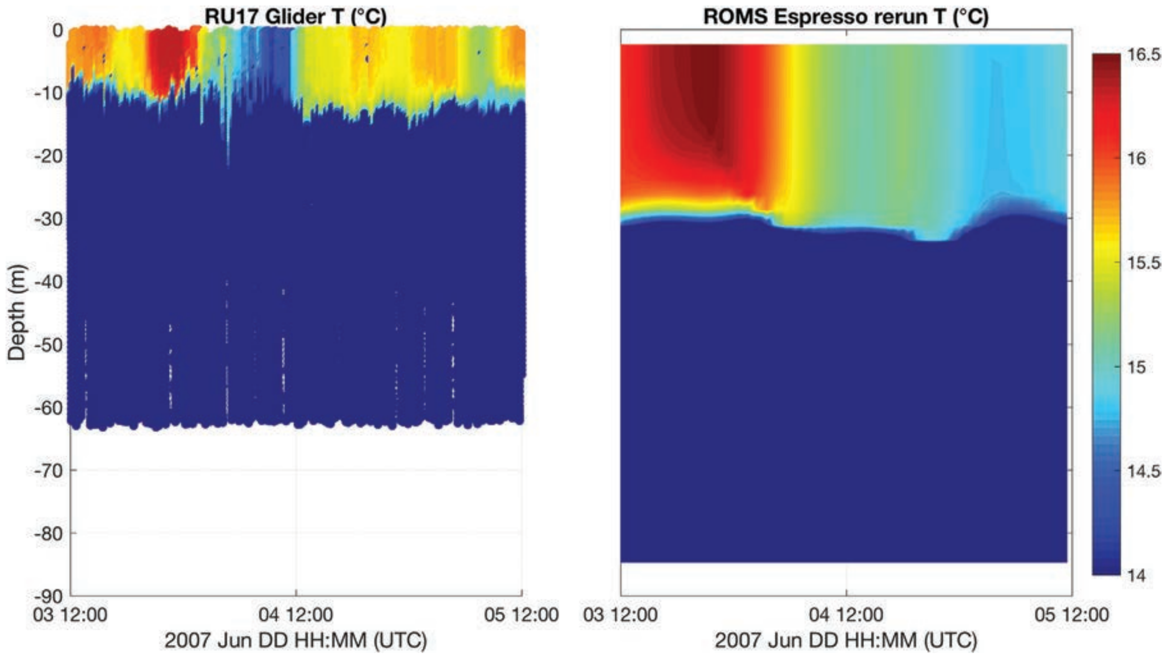

Figure 6. Barry. The same as Figure 4, but for RU17 glider in Barry. RU17 only sampled to ~60 m even though full water column depth was >80 m.

The resulting cooling of the surface layer occurs at about the correct time, but the surface layer warming poststorm does not occur.

3.2.3. Temperature, Current, Shear, and Momentum Balance Spatial Time Series: Irene

At the cross-section location near RU16 noted by the northwest to southeast black dots in Figure 3, Hövmoller diagrams of time (increasing up) versus distance offshore were produced. Surface temperature (Figure 7, top left) shows initially warm surface water stretching from the edge of the coastal upwelling to >200 km offshore. Then, SST rapidly cools across the shelf and in deep water, so that any cooling after eye passage (from NAM—two hours later than observed) is minimal. No SST cooling occurred within the nearshore coastal upwelling region. Bottom temperature (Figure 7, bottom left) shows a warm downwelling bulge during the storm, starting at the coastline and extending to close to 50 km offshore. The core of the MAB Cold Pool can be seen around 100 km offshore. Four sample locations are noted with the vertical solid lines labeled (1) in the upwelling region, (2) near RU16, (3) in the core of the Cold Pool, and (4) in deep water. These four locations will be used in the temperature diagnostic analysis (section 3.2.5).

A Hövmoller of cross-shelf surface currents (Figure 7, top middle) show onshore currents increasing at about 0000 UTC on 28 August, from about 50 km offshore across the shelf and into some of the deeper water. For Irene model results, currents in Earth coordinates are again rotated 31° clockwise from north to attain cross-shelf and along-shelf components. The onshore surface currents peak at around 0300 UTC and then decrease a few hours before eye passage. Bottom currents (Figure 7, bottom middle) are opposing offshore across the shelf and weaker than the onshore surface currents. The bottom onshore currents begin again at about 0000 UTC on 28 August and last until eye passage. After eye passage, surface currents switch to offshore, with the switch nearshore occurring a few hours after eye passage likely due to tidal influence (not shown). Bottom currents switch to onshore after eye passage almost immediately. Maximum shear from this plot occurred roughly from 0000 to 1200 UTC on 28 August and reversed from 1500 UTC on 28 August to 0000 UTC on 29 August.

The along-shelf surface current Hövmoller (Figure 7, top right) shows northeastward currents ahead of and after eye passage, with southwestward surface currents after eye passage in deeper water. Bottom currents (Figure 7, bottom right) are southwestward ahead of eye passage and immediately after, then northeastward later at 0000 UTC on 29 August. Maximum shear from this plot occurred roughly from 0600 to 1500 UTC on 28 August.

A bulk surface to bottom shear Hövmoller diagram, comprised the cross-shelf and along-shelf components, is shown in Figure 8 (left). This bulk shear Hövmoller shows a symmetric ~50% ahead and 50% behind eye

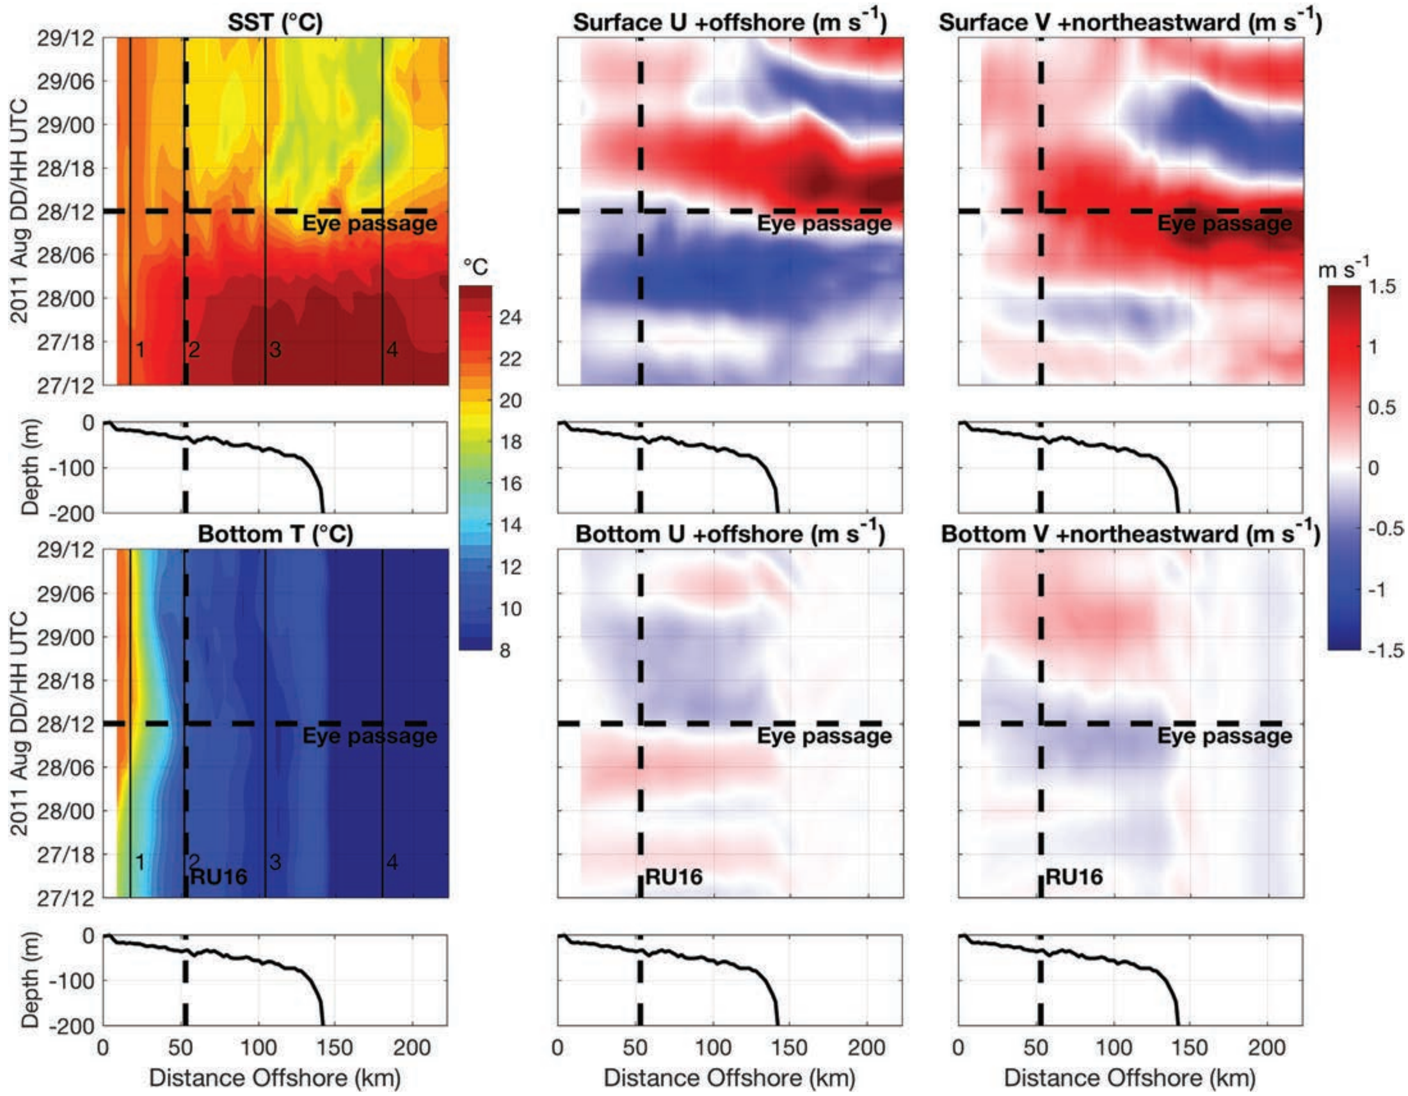

Figure 7. Irene. Hövmollers of ROMS ESPreSSO rerun SST (°C, top left), surface cross-shelf currents (m s^{-1}, top middle), and surface along-shelf currents (m s^{-1}, top right), with positive reds offshore/northeastward and negative blues onshore/southwestward for cross-shelf/along-shelf currents. Bottom row the same as top row but for the bottom of the water column. Eye passage in NAM atmospheric forcing marked with the horizontal dashed line, and RU16 glider location marked with the vertical dashed line. Vertical solid lines in left figure labeled 1 (upwelling), 2 (near RU16), 3 (in Cold Pool core), and 4 (in deep water) are locations where temperature diagnostics are performed in Figure 15. Water depth (m) along the cross section is plotted in the figures below the Hövmoller figures.

shear pattern in deep water, consistent with *Price* [1981]. In the shallow water over the continental shelf, shear is skewed ahead-of-eye-center. Because in deep water the bottom layer is quiescent and in shallow water the bottom layer is moving, only qualitative comparisons between deep and shallow water can be made. Additionally, bottom currents in shallow water are affected by opposing bottom stress, restricting any quantitative comparisons between deep and shallow water. By changing bottom currents to 0, a more evenly distributed shear pattern between ahead of and behind eye passage results (Figure 8, right), showing that the opposing bottom currents in the two-layer circulation has an influence on the shear pattern.

The ahead-of-eye-center cooling due to this shear is greater than behind-eye cooling (Figure 7, top left), potentially because (1) behind the eye center the water column is already mixed, and the surface layer is already deeper, (2) there are weaker backside offshore winds than frontside onshore winds due to frictional land effects—supported by observations at NDBC buoys 44014, 44009, and 44065, and at a WeatherFlow Inc. coastal land station at Tuckerton, NJ, and (3) the frontside of Irene cools the SST, the eye moves over the cooler water and weakens the storm, and the backside is weaker (Figure 1). As will be shown in the following momentum balance Hövmollers, the dominant cross-shelf momentum terms are onshore wind

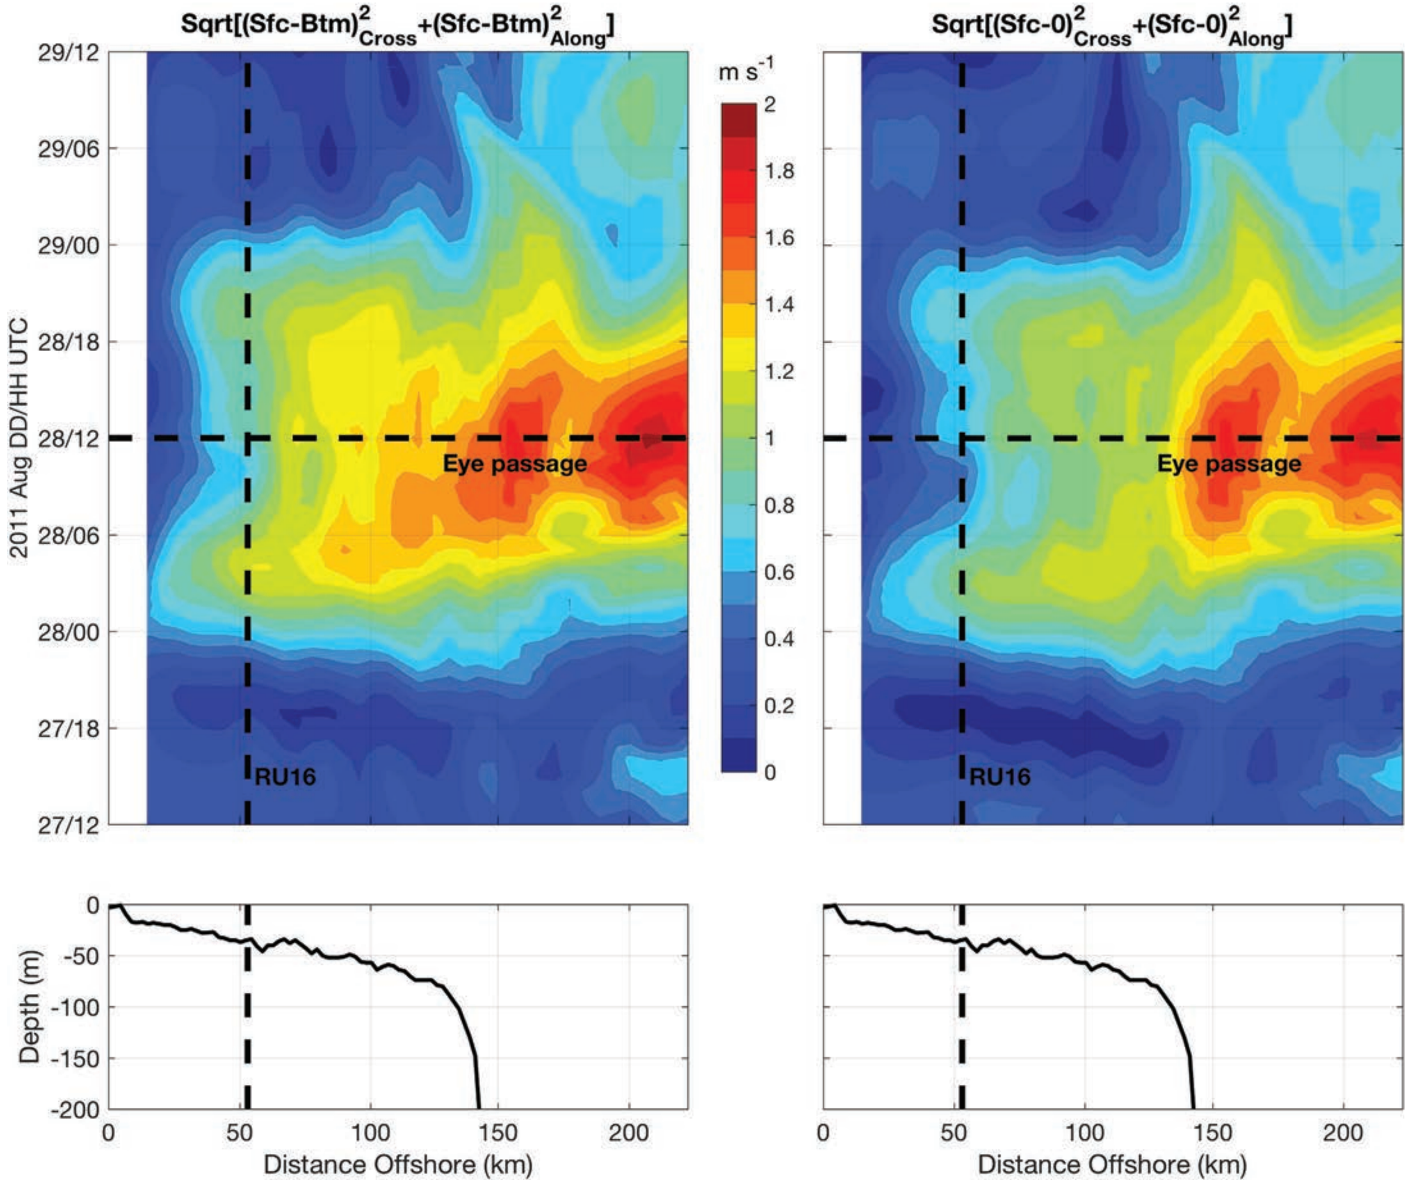

Figure 8. Irene. Same formatted Hövmoller as in Figure 7, but for bulk surface to bottom cross- and along-shelf shear (left, m s^{-1}). This bulk shear is calculated according to the equation in the header: square root of the sum of the squares of the surface to bottom cross-shelf and along-shelf shears. Right figure is the same as left but for 0 substituted for bottom currents.

stress balanced by offshore pressure gradient force ahead-of-eye-center, and offshore wind stress balanced by onshore pressure gradient force behind-eye-center. This balance is likely due to the presence of the coastline and shallow bottom, in which onshore surface winds ahead-of-eye-center pile water at the coast and result in the offshore bottom current, and offshore surface winds behind-eye-center push water away from the coast and result in the onshore bottom current. In both cases—ahead-of-eye-center and behind-eye-center—a two-layer circulation occurs due to the presence of the coastline, shallow bottom, and stratified water column.

The depth-averaged cross-shelf momentum balance time series (Figure 9) depicts all terms except for horizontal viscosity, which was very small. Acceleration shows a strongly tidal signal, with less onshore acceleration just before eye passage. Wind stress is strongly onshore ahead-of-eye passage, and switches to offshore after. Pressure gradient force is offshore ahead-of-eye-center from the coast all the way to the shelf break, and then switches to onshore midshelf first and then both nearshore and near the shelf break second; this pressure gradient pattern is due to coastal setup ahead-of-eye and coastal set down behind-eye.

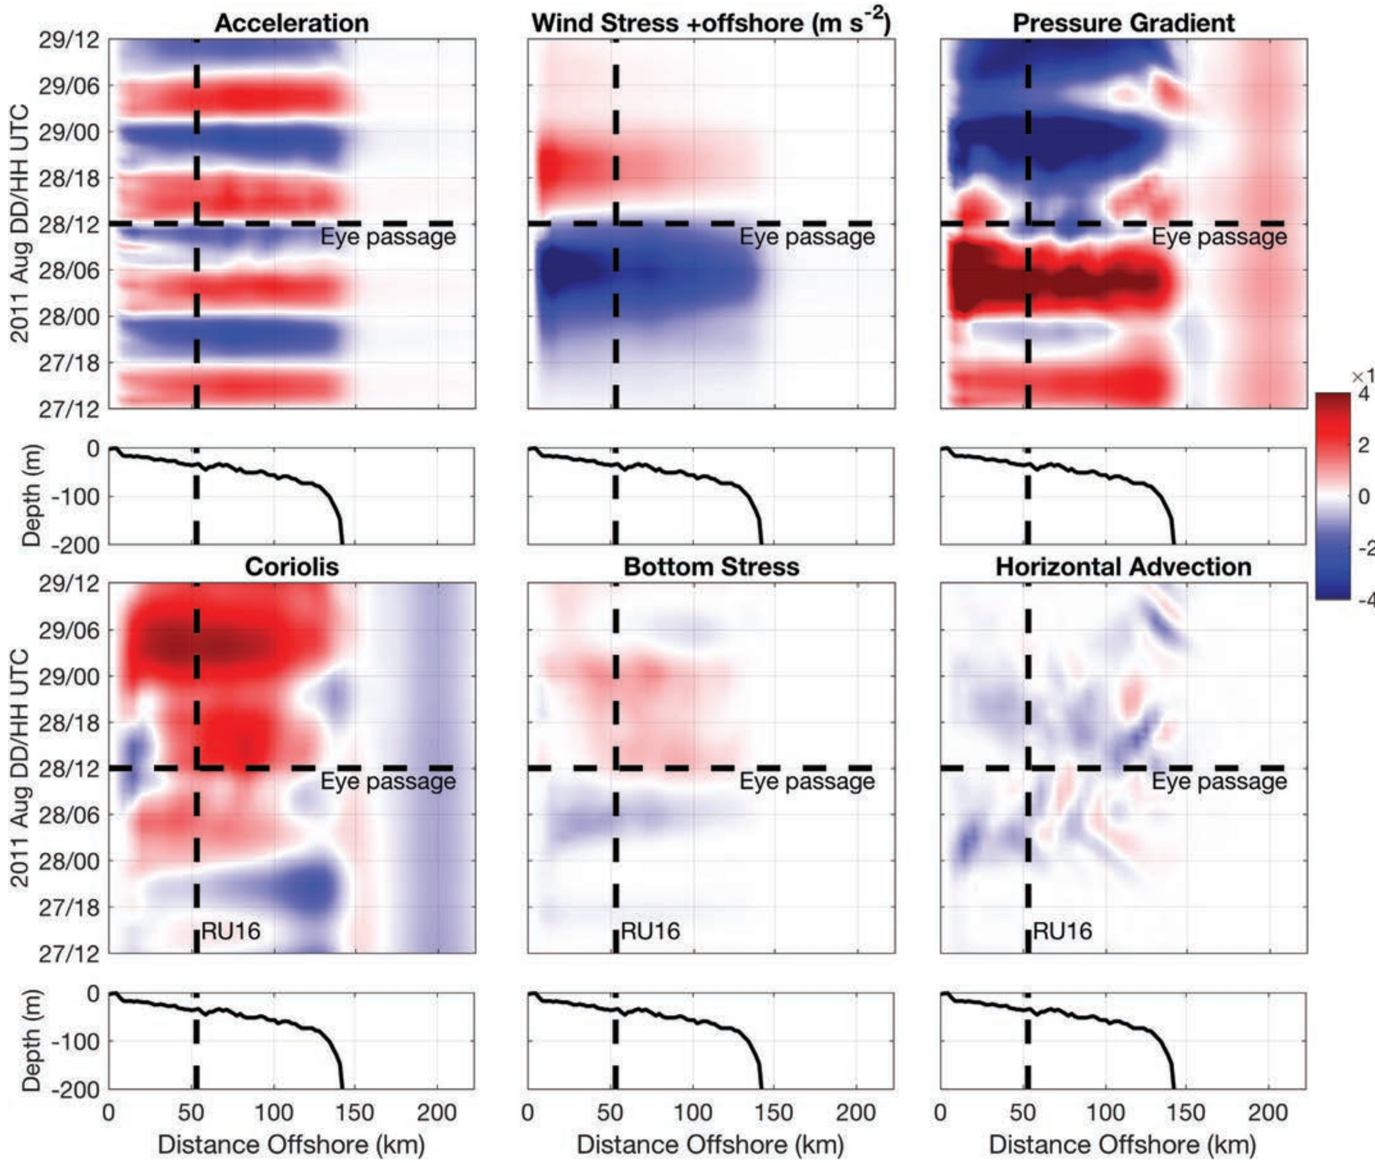

Figure 9. Irene. Hövmollers of the cross-shelf depth-averaged momentum balance terms (m s^{-2}), with positive reds offshore and negative blues onshore. Horizontal diffusion was small and thus not plotted.

Coriolis is offshore, increasing after the eye. Bottom stress is onshore opposing the offshore bottom currents ahead-of-eye, and then switches sign after eye. Finally, advection is small and noisy, with a response near the inertial period especially near the shelf break. The dominant cross-shelf force balance progresses from onshore wind stress balanced by offshore pressure gradient ahead-of-eye-center, to offshore wind stress and Coriolis balanced by onshore pressure gradient after eye passage until 0000 UTC on 29 August, and finally to a geostrophic balance of offshore Coriolis balanced by onshore pressure gradient.

In the along-shelf direction, depth-averaged momentum balance terms (Figure 10) are generally smaller than the cross-shelf terms. Again, acceleration has a tidal signal, but so does Coriolis. The dominant along-shelf force balance progresses from southwestward wind stress balanced by northeastward pressure gradient and Coriolis, to northeastward wind stress balanced by southwestward pressure gradient and Coriolis, and finally to alternating southwestward and northeastward pressure gradient balanced by Coriolis (tidal periodicity).

3.2.4. Temperature, Current, Shear, and Momentum Balance Spatial Time Series: Barry

The time series of SST for Barry (Figure 11, top left) was taken at the northern WNW to ESE cross-section location just north of the Hudson Canyon as indicated by the black dots in Figure 5. This northern location

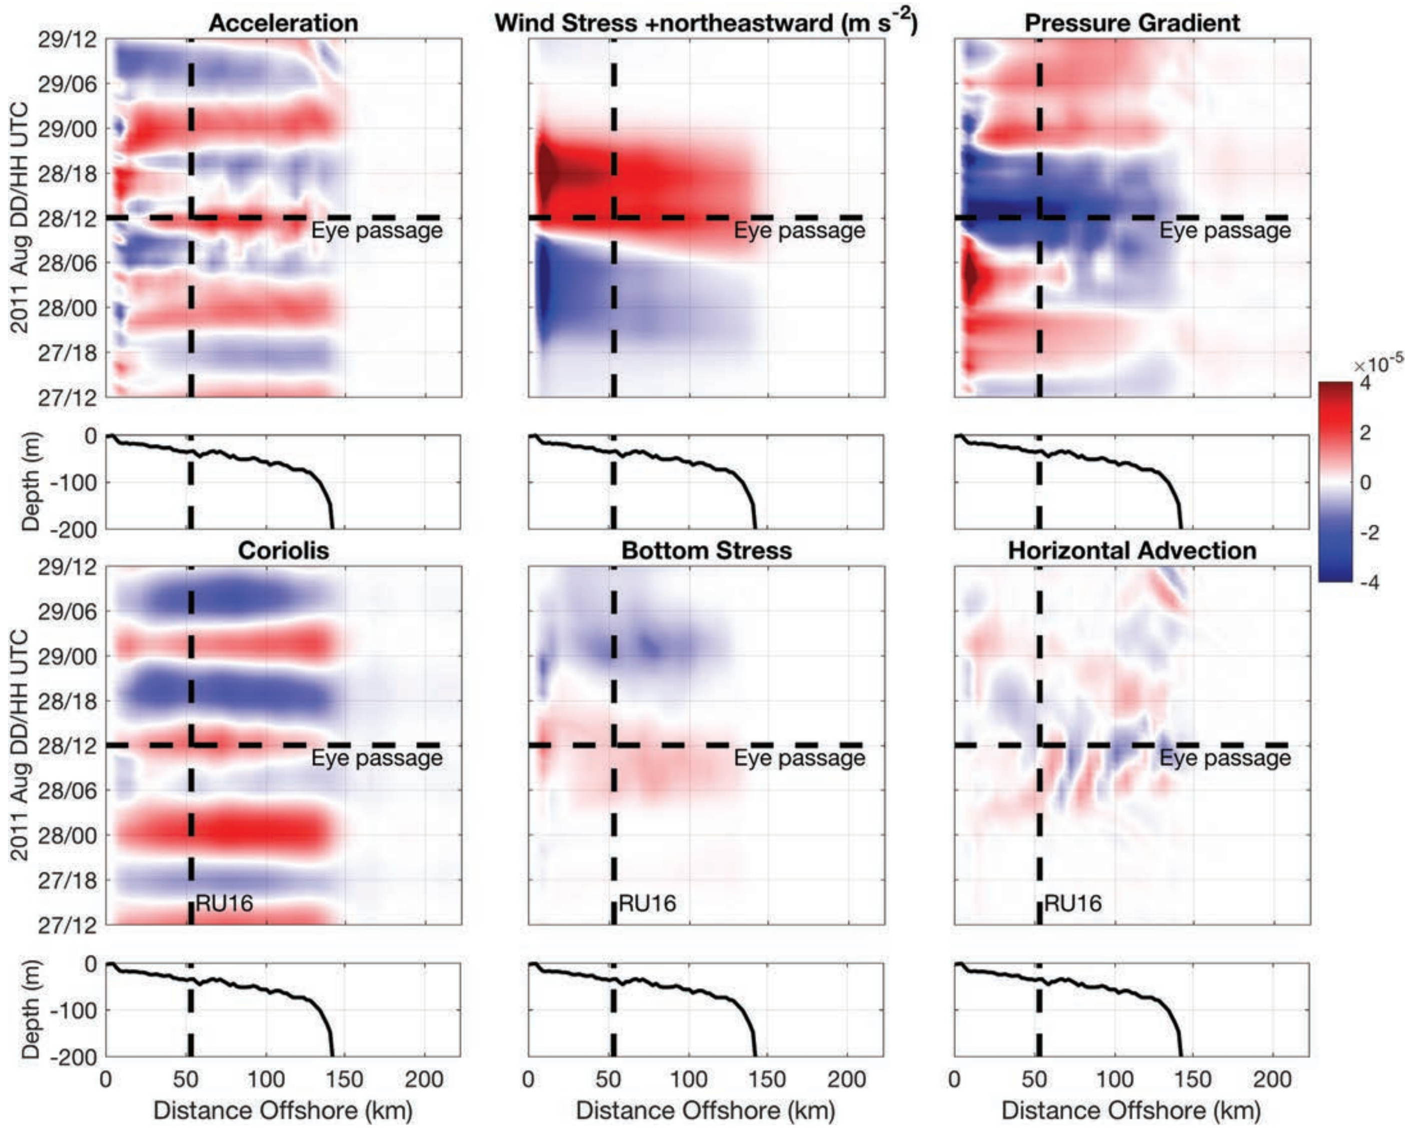

Figure 10. Irene. Same as Figure 9 but for along-shelf depth-averaged momentum balance terms (m s^{-2}), with positive reds northeastward and negative blues southwestward.

was chosen to target the greatest SST cooling in Barry. A similar cooling signal is apparent across the shelf and even in deep water. At National Data Buoy Center (NDBC) station ALSN6, the Barry station used by *Glenn et al*. [2016] for the ahead-of-eye-center cooling signal, cooling (~3.5°C) was greatest. At the warm strip of water indicated by the vertical line labeled "2," and in the deep water, total cooling was less than 1°C. The bottom temperature spatial time series (Figure 11, bottom left) shows a similar but more subtle downwelling bulge from the coast as was evident in Irene. Five sample locations are noted with the vertical solid lines labeled (1) in the nearshore maximum cooling and near ALSN6, (2) in the warm strip of water, (3) in the core of the Cold Pool, (4) near RU17, and (5) in deep water. These five locations will be used in the temperature diagnostic analysis (section 3.2.6).

The cross-shelf surface current time series (Figure 11, top middle) shows onshore surface currents peaking 12–18 h prior to eye passage, but remaining weakly onshore until eye passage. For Barry model results, currents in Earth coordinates are again rotated 51° clockwise from north to attain cross-shelf and along-shelf components. Bottom currents (Figure 11, bottom middle) show a primarily tidal signal, with alternative offshore and onshore bottom currents. Maximum shear was roughly 0600 to 1200 UTC on 4 June. This maximum shear occurs when the bottom offshore currents (mainly tidal) oppose the onshore surface currents. Because the storm forcing is weaker than in Irene, the tidal signal dominates the bottom current forcing.

 10.1002/2017JC012756

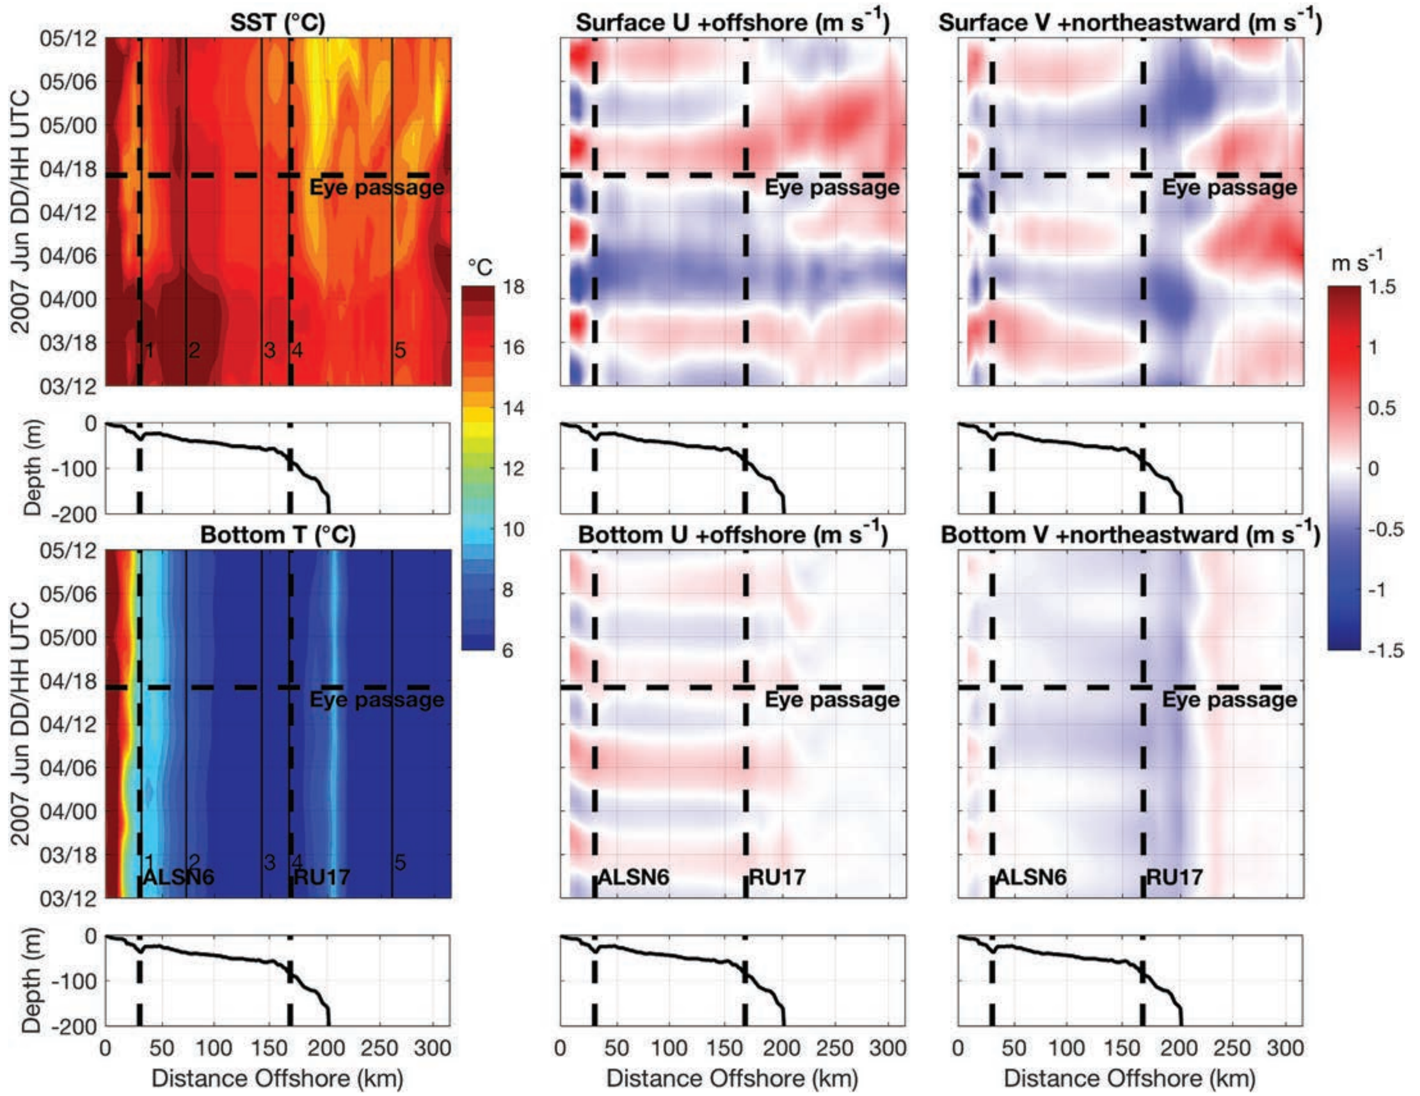

Figure 11. Barry. Same as Figure 7 but for Barry, with ALSN6 and RU17 locations plotted as vertical dashed lines. Vertical solid lines in left figures labeled 2 (near ALSN6), 2 (in warm strip), 3 (in Cold Pool core), 4 (near RU17), and 5 (in deep water) are locations where temperature diagnostics are performed in Figure 16.

This is consistent with the findings of *Keen and Glenn* [1995], who found that during a storm crossing the MAB in October 1990, the tidal signal dominated the bottom current forcing, and storm sedimentation was directly related to the tidal flow.

In the along-shelf direction, surface currents were northeastward before eye passage and southwestward after (Figure 11, top right). Bottom currents were southwestward the entire storm period, both before and after eye passage. A similar analysis just south of the Hudson Canyon may help answer why this occurred. One potential reason is that the Hudson Canyon acted as a barrier, blocking bottom currents from crossing the large bathymetric gradients.

The bulk surface to bottom shear Hövmoller for Barry, comprised the cross-shelf and along-shelf shears, is shown in Figure 12 (left). This bulk shear Hövmoller again shows a roughly symmetric ~50% ahead and 50% behind eye shear pattern in deep water if the time period of 0000 UTC on 4 June to 0600 UTC on 5 June is used. Again, like for Irene, shear is skewed ahead-of-eye passage in the shallow water, and by substituting 0 for bottom currents, a more (but not quite fully) symmetric shear pattern in shallow water results (Figure 12, right).

The Hövmoller cross-shelf depth-averaged momentum balance terms (Figure 13) show a strongly tidal signal in the acceleration, pressure gradient, and Coriolis terms across the shelf, and in the bottom stress and

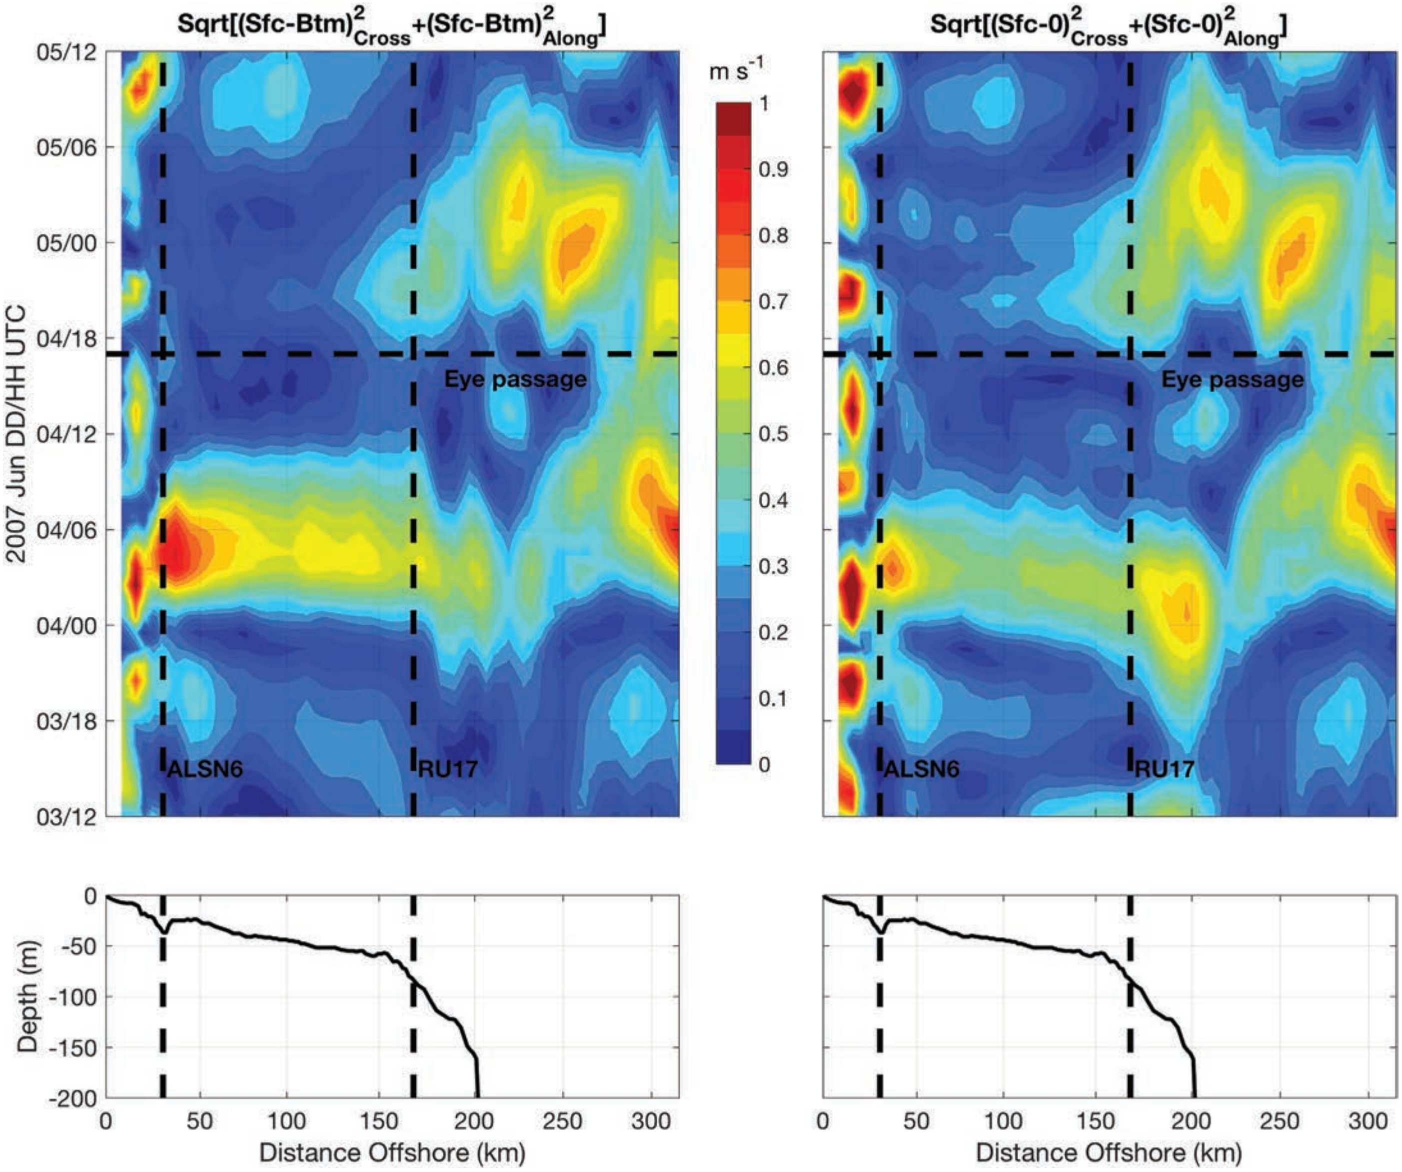

Figure 12. Barry. Same as Figure 8 (bulk surface to bottom shear analysis), but for Barry.

horizontal advection terms very near shore. Wind stress was directed onshore ahead of eye passage and weakly offshore after. Pressure gradient was primarily tidal, with more positive offshore values along the shelf break just ahead of eye passage as compared to after eye passage. Coriolis was largely tidal and onshore, with the maximum again at the shelf break. Bottom stress was mostly tidal, but mostly negative opposing the offshore bottom currents at about 0600 UTC on 4 June ahead of eye, when the downwelling circulation aligned with the tidal signal. Finally, horizontal advection was mostly small. The dominant depth-averaged cross-shelf force balance progressed from onshore wind stress balanced by offshore pressure gradient ahead of eye passage, to offshore wind stress balanced by alternating onshore/offshore Coriolis and pressure gradient (tidal periodicity) just after eye passage, to quasi-geostrophic balance with alternating onshore/offshore Coriolis balanced by pressure gradient (again tidal).

The Hövmoller along-shelf depth-averaged momentum balance terms (Figure 14) show a mostly tidally forced signature. Acceleration was mostly tidal, with slightly more negative onshore (or less positive offshore) acceleration ahead of eye passage from 0000 to ~0900 UTC on 4 June. Wind stress was southwestward ahead of eye passage and northeastward after. Pressure gradient and Coriolis terms were primarily

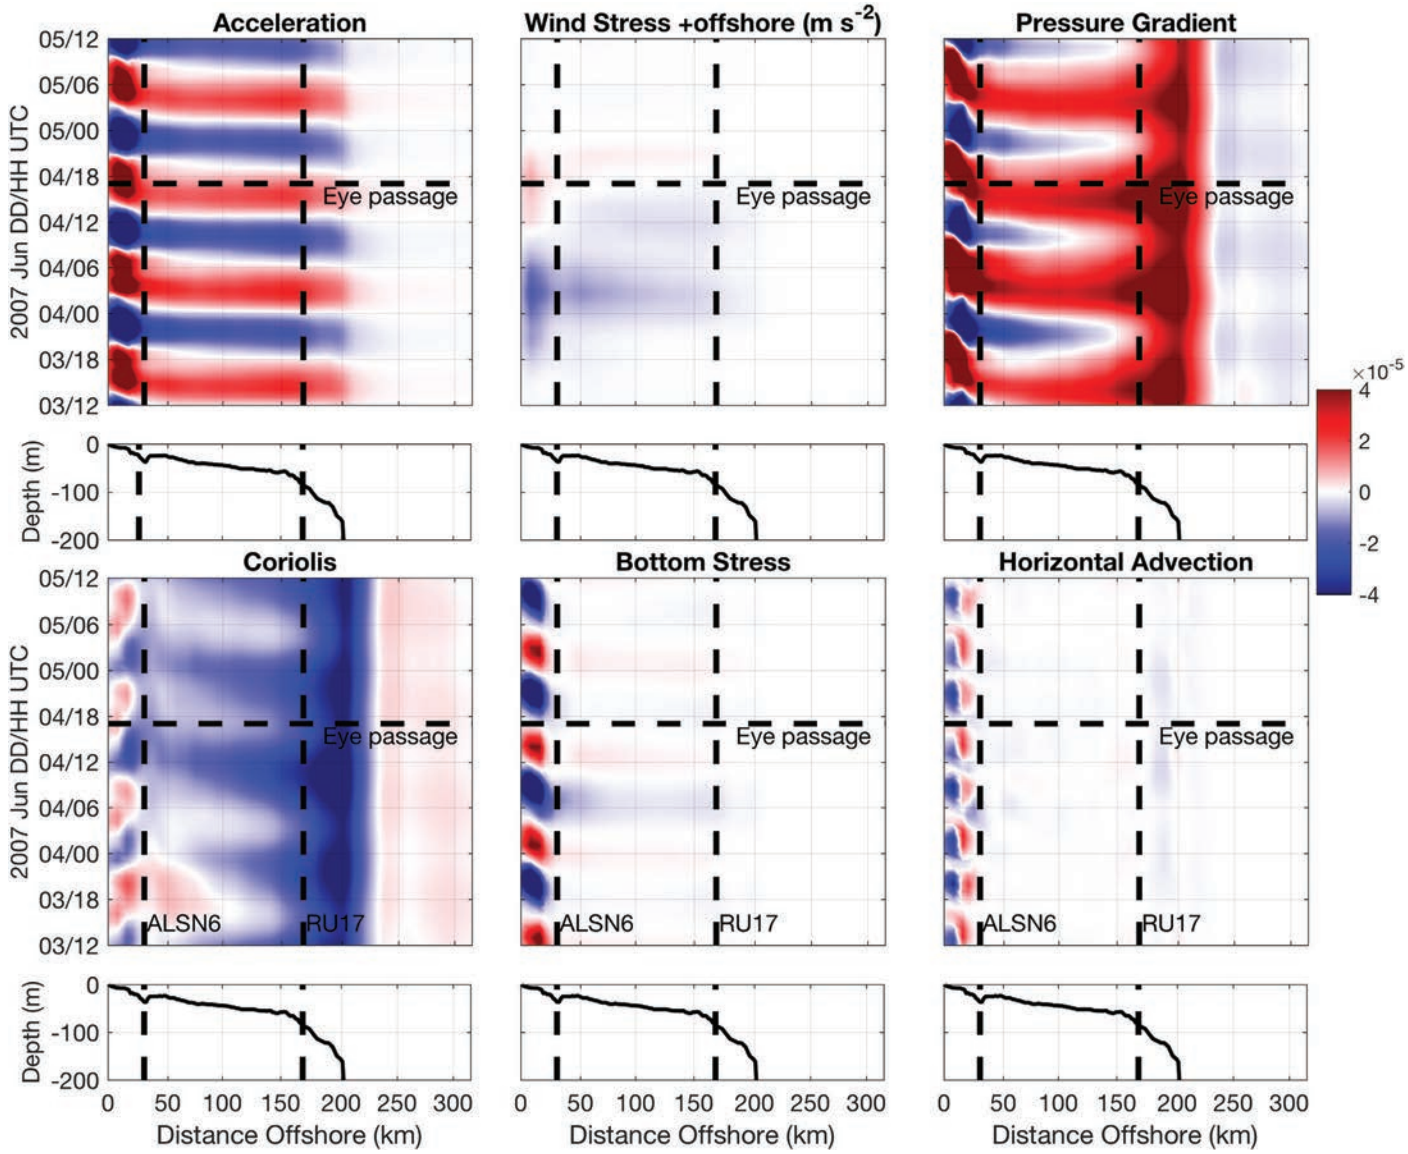

Figure 13. Barry. Same as Figure 9 (Hövmoller cross-shelf depth-averaged momentum balance terms), but for Barry.

tidal, bottom stress was always northeastward opposing the southwestward bottom currents, and horizontal advection was small. The dominant along-shelf depth-averaged momentum balance progressed from southwestward wind stress balanced by northeastward bottom stress and a residual in the alternating northeastward/southwestward pressure gradient term and Coriolis term ahead of eye passage, to northeastward wind stress balanced by alternating northeastward/southwestward Coriolis and pressure gradient behind eye passage.

The shelf break maxima in the pressure gradient and Coriolis terms could be due to the presence of a warm core ring starting prestorm just north of the Hudson Canyon and the northern cross-section location (Figure 5, top left) and moving southeastward by poststorm (Figure 5, middle left). This ring, moving along the shelf break and beginning to impinge onto the shelf, forces a geostrophic circulation at the shelf break front [*Zhang and Gawarkiewicz*, 2015], which is evident at the shelf break in both the cross-shelf and along-shelf momentum balance Hövmollers (Figures 12 and 13).

3.2.5. Advection Versus Mixing Temperature Response: Irene

The temperature diagnostic equation terms were plotted for Irene (Figure 15) at the points indicated by the large red dots in Figure 3 and by the vertical solid black lines in Figure 7 (left) to determine the primary

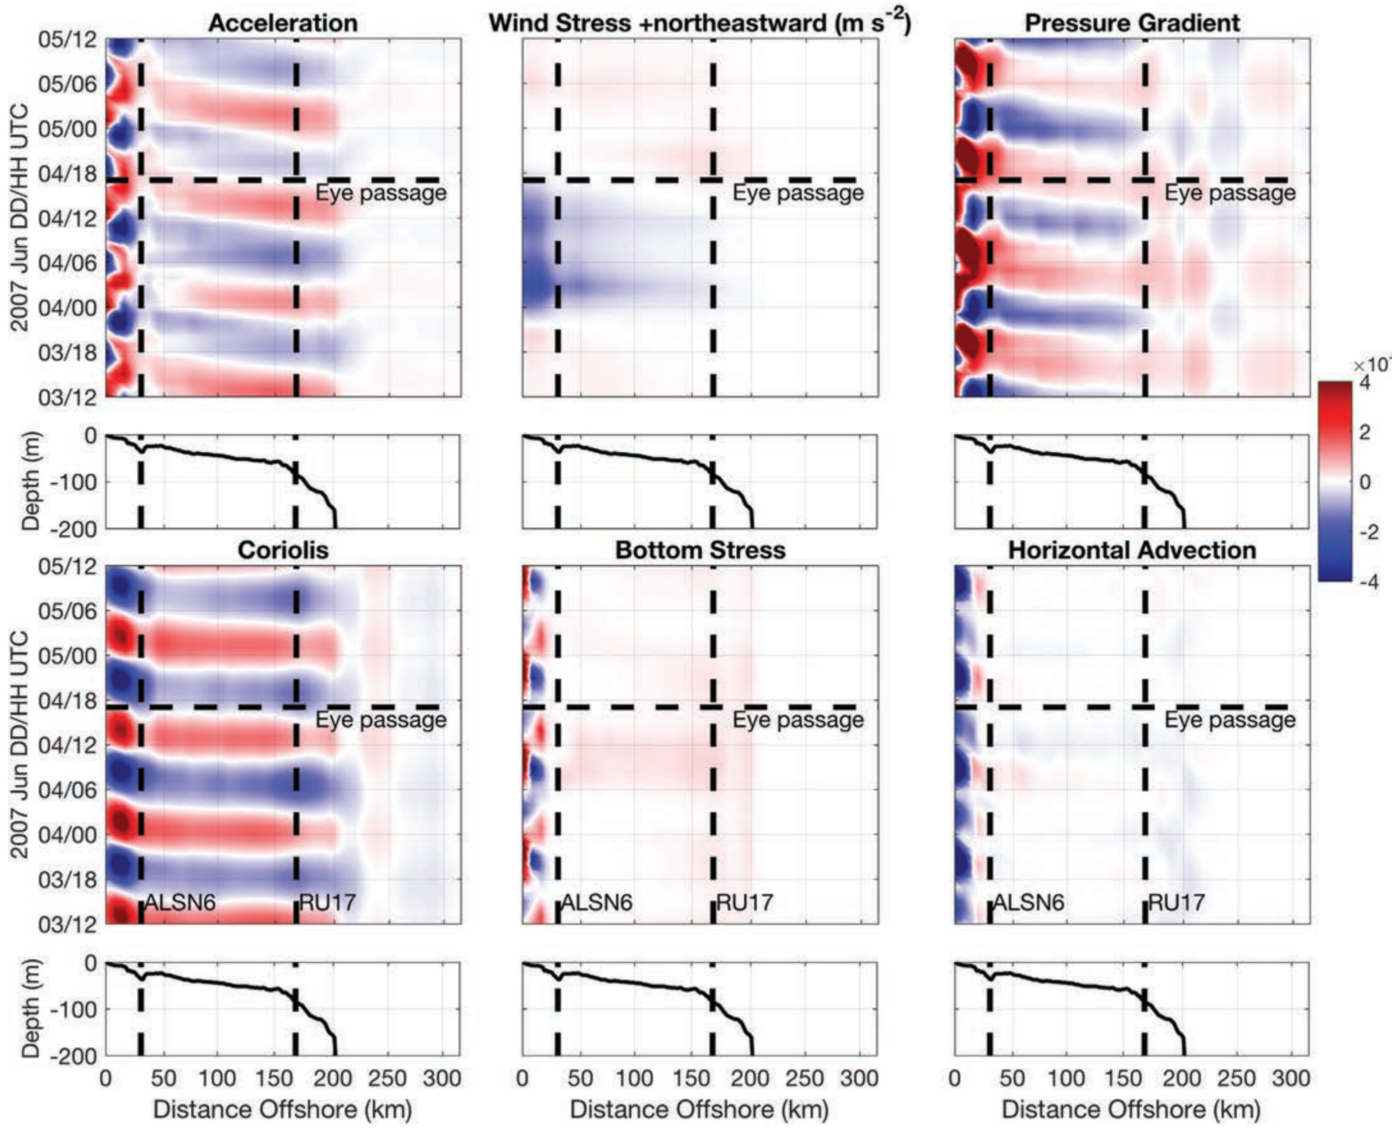

Figure 14. Barry. Same as Figure 10 (Hövmoller along-shelf depth-averaged momentum balance terms), but for Barry.

cause of cooling. The left figure is within the upwelling region, the second is at RU16, the third is in the MAB Cold Pool core, and the fourth is in deep water. At the top is the full temperature rate term, in the middle is the vertical diffusion term, and at the bottom are the vertical plus horizontal advection terms. Horizontal diffusion was not plotted, as it was very small. First, a general tidal signal is apparent in the full temperature rate term, primarily due to advection at all four locations. Cooling in the mixed layer was due to vertical diffusion at all four points, with ahead-of-eye-center cooling occurring at points 1–3. At point 1 within the upwelling, surface mixed-layer cooling stopped once the thermocline reached the bottom of the water column, as the source of cold water was removed (Figure 15, left middle). At point 2 near RU16, ahead-of-eye-center cooling was caused by vertical diffusion cooling being skewed ahead-of-eye-center. At point 3 in the Cold Pool core, vertical diffusion cooling was also skewed ahead-of-eye-center, with advection warming after eye passage. Finally, at point 4 in the deep water, a deep, cold quiescent bottom allowed for some cold water to entrain into the thick ~200 m surface mixed-layer ahead-of-eye passage, with an advective signal dominating after eye passage.

3.2.6. Advection Versus Mixing Temperature Response: Barry

The temperature diagnostic equation terms plotted for Irene at four locations in Figure 15 were also plotted for Barry at five locations in Figure 16. These five locations are indicated by the large red dots in Figure 5
