
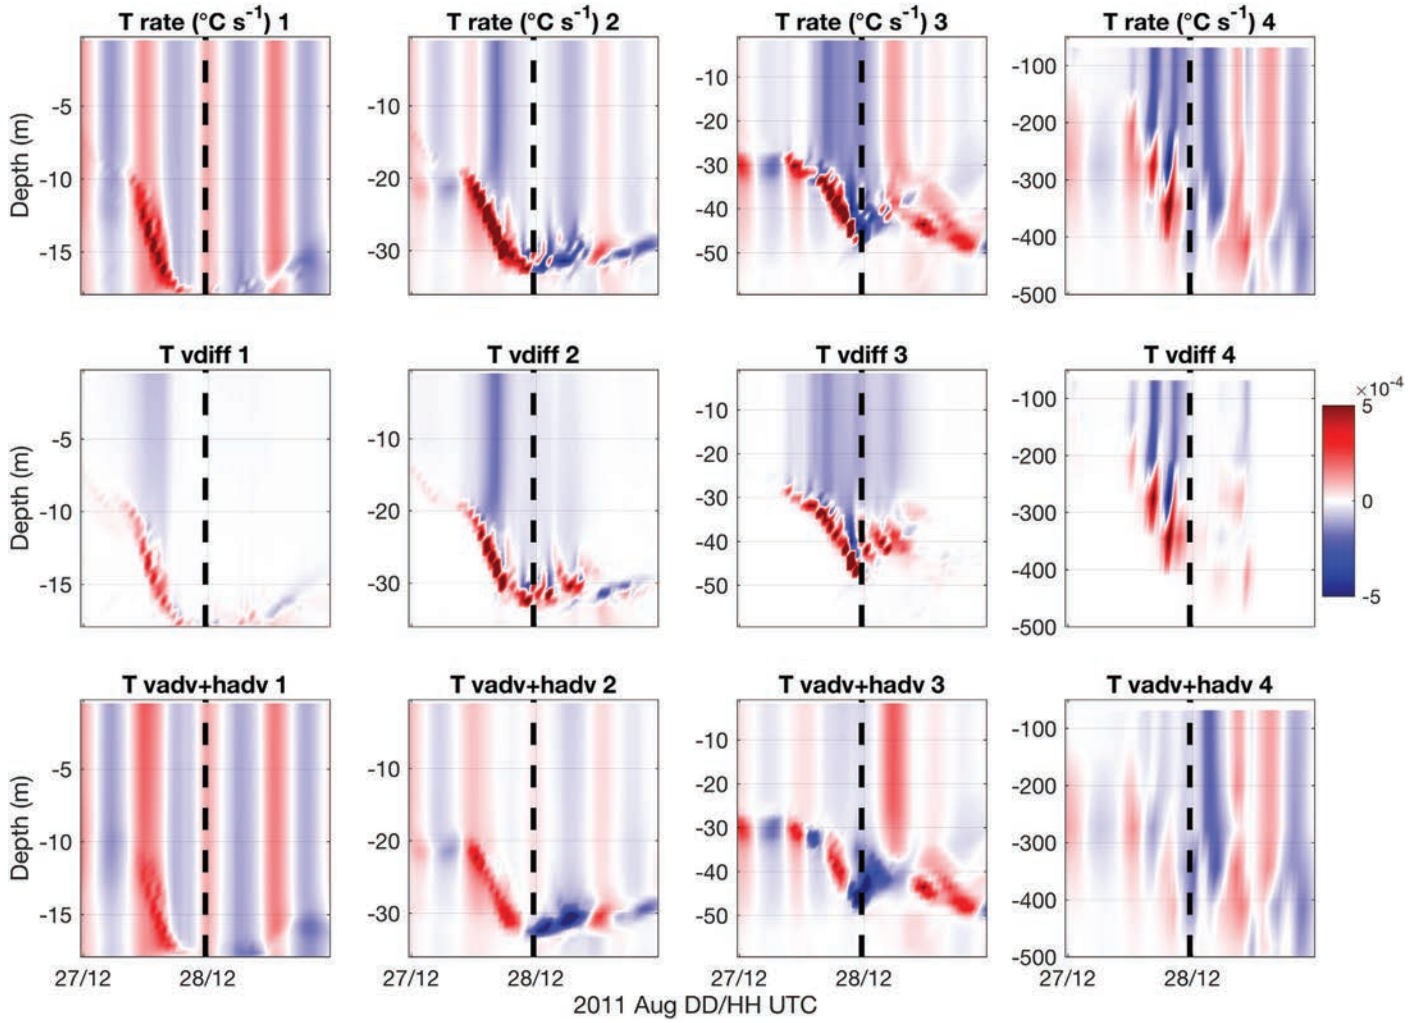

Figure 15. Irene. Temperature diagnostic equation terms at points 1–4 marked in Figure 3 red dots ordered 1–4 northwest to southeast, and in Figure 7 (left), with full temperature rate term at top, vertical diffusion in middle, and vertical + horizontal advection at bottom (°C s^{-1}). Horizontal diffusion is small and thus not plotted. Eye passage marked with vertical dashed line. At point 4, only the top 500 m of the water column is plotted.

and the vertical solid black lines in Figure 11 (left). For Barry, Figure 16 (left) is near ALSN6, the second figure is within the warm strip of water, the third figure is within the Cold Pool core, the fourth is near RU17, and the fifth is in deep water. Again, a tidal advection signal is apparent, with vertical diffusion not exhibiting any tidal cooling/warming signal. Vertical diffusion again caused cooling in the mixed layer except at point 5 in the deep water. Point 5 looks primarily advective with a deep quiescent bottom. At points 1–4 the tidal advection cooling/warming periodicity was modulated by the vertical diffusion cooling, which looks to be skewed ahead-of-eye passage during the greatest shear period (Figure 12, left).

4. Summary

Baroclinic coastal ocean cooling processes were investigated in detail for Hurricane Irene (2011) and Tropical Storm Barry (2007), two summer TCs, both with rapid ahead-of-eye-center cooling, but with different tracks and occurring at different times in the summer season. Cross-shelf variability in the depth-averaged momentum balance terms demonstrated that the dominant force balance driving the baroclinic circulation was the same across the entire MAB shelf. Cross-shelf variability in the temperature diagnostic equations showed that the resultant ahead-of-eye-center cooling of the surface layer in both storms was dominated by mixing rather than advection.

For Irene, it was previously found that cross-shelf two-layer surface to bottom opposing current shear was large and along-shelf surface to bottom shear was small at the RU16 glider location [*Glenn et al.*, 2016]. Here

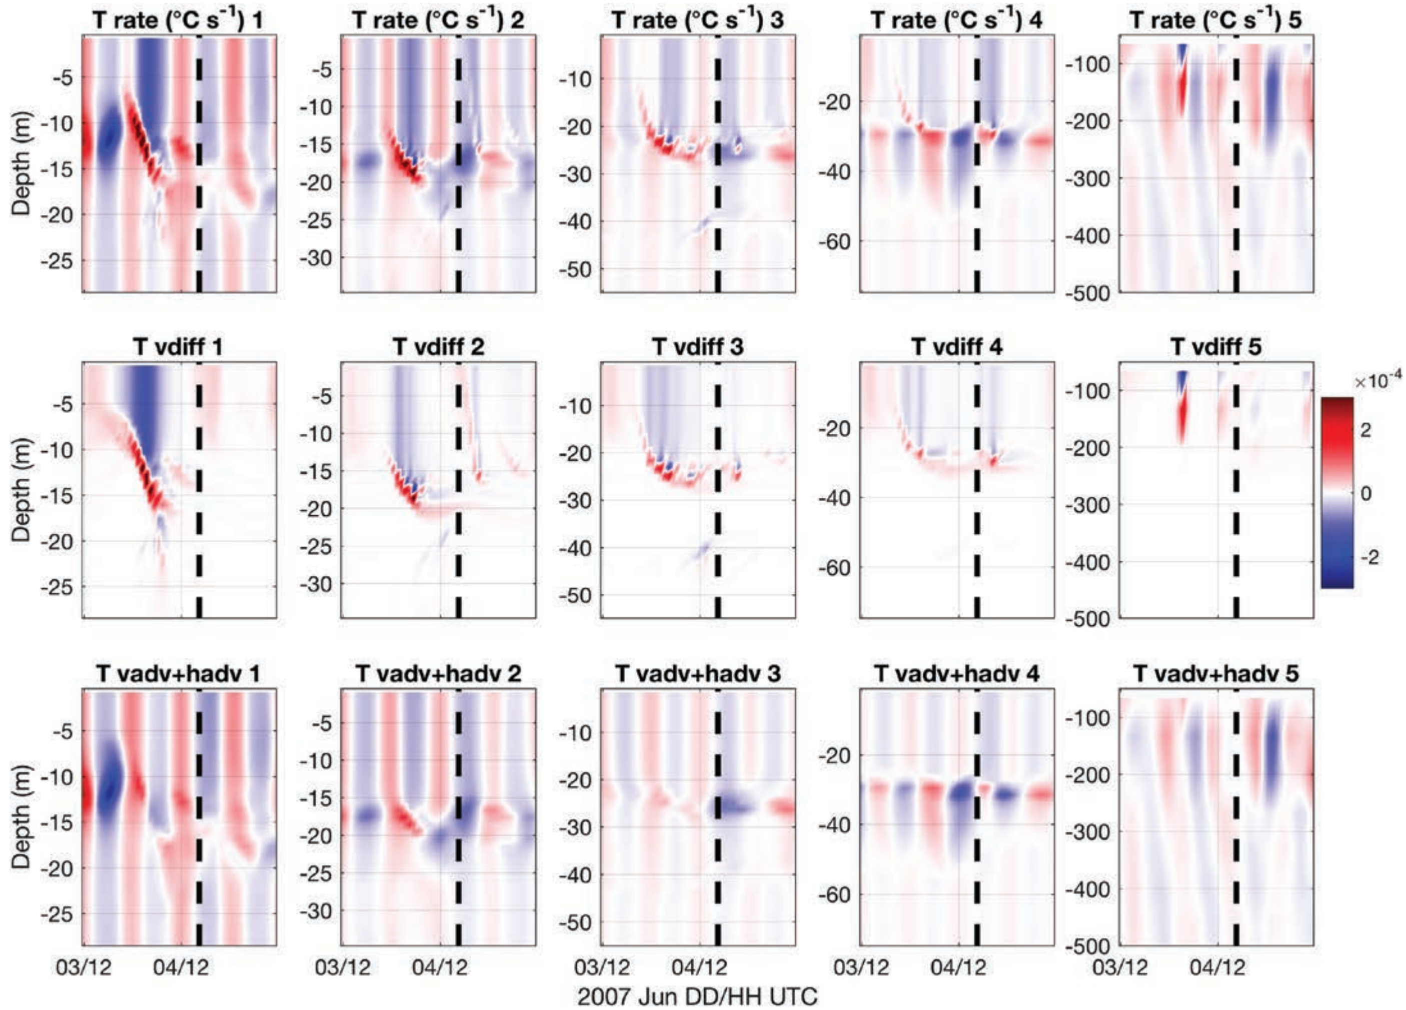

Figure 16. Barry. Same as Figure 15 (temperature diagnostic equation terms) but for Barry. Points 1–5 are marked in Figure 5 red dots ordered 1–5 west-northwest to east-southeast, and in Figure 11 (left).

for Barry, it was found that both the cross-shelf and along-shelf components of the surface to bottom opposing current shear contributed to the mixing and cooling observed at the RU17 glider location. For both storms, analysis of bulk shear (including both cross-shelf and along-shelf shear components) indicated a symmetric 50% ahead and 50% behind eye shear pattern in deep water, but with maximum shear skewed ahead-of-eye-center in the shallow water over the continental shelf. This ahead-of-eye-center skewing of the vertical shear was found to occur not only due to opposing bottom currents over the shelf before the eye, but also due to weaker winds and a deeper surface layer after the eye.

For Irene, the dominant force balance ahead of eye passage was onshore wind stress balanced by offshore pressure gradient, and the large offshore pressure gradient term stretched across the entire shelf. The wind stress and pressure gradient terms switched directions right after eye passage and eventually the force balance evolved to geostrophic long after the storm. For Barry, the dominant force balance on the shelf ahead of eye passage was modulated by the tides but also had the onshore wind stress term balanced by offshore pressure gradient, and again the large offshore pressure gradient term extended all the way across the shelf. The along-shelf force balance also played a role for Barry, potentially due to the location of the cross section relative to the changing slopes of the bathymetry just north of the Hudson Canyon. In both the cross-shelf and along-shelf directions, independent of the wind forcing, there was a maximum in the pressure gradient and Coriolis terms near the shelf break, which coincided with a warm eddy moving southwestward along the shelf slope front with a geostrophic circulation.

Finally, cross-shelf variability in the temperature change diagnostic terms was investigated. For both storms in the shallow water on the shelf, vertical diffusion was the main cause of the mostly ahead-of-eye-center cooling in the surface mixed layer. Tidal periodicity of cooling/warming was apparent in the combined vertical and horizontal advection terms. Cooling in the surface layer due to vertical diffusion did occur within the coastal upwelling during Irene, and the cooling stopped once the thermocline hit the bottom of the water column as the bottom cold water was also removed. In deep water, vertical diffusion and advection were important drivers of mixed-layer cooling for Irene, whereas for Barry in deep water, advection was the main driver in the periodic and alternating warming/cooling near the surface.

The drivers for the major differences in coastal ocean response between Irene and Barry were storm track, structure, intensity, and time of year. Irene had a more inshore MAB track during the late summer stratified season, whereas Barry was weaker with a farther offshore track during the early summer stratified season. Due to the offshore track, MAB surface winds for Barry had a more along-shelf component than the primarily cross-shelf winds during Irene, leading to both cross-shelf and along-shelf components playing a larger role in the coastal ocean response for Barry, and a primarily cross-shelf response for Irene.

5. Discussion

Glenn et al. [2016] identified 11 summer storms that traversed northeastward across the MAB and that exhibited a range of ahead-of-eye-center cooling. Here we selected two extreme cases—both with an underwater glider deployed—from this envelope: one with an offshore track and the other with an inshore one. One was near the beginning of the summer stratified season and the other near the end. Indeed, differences in the details exist between the two storm extremes—from the along-shore component playing a larger role in Barry's force balance, to the alternating warming/cooling advective tidal signal playing a larger role in Barry's temperature response. Nevertheless, both storms exhibited a two-layer baroclinic circulation, forced by an offshore pressure gradient opposing the onshore wind stress ahead-of-eye-center and extending across the entire MAB shelf. Cooling in both storms was mostly ahead-of-eye-center and dominated by vertical shear-induced mixing. These commonalities across the two storm extremes indicate that the process is robust and can be expected on stratified continental shelves over a wide range of TC scenarios.

Because this process is robust across these two extreme cases drawn from the 30 year envelope of MAB summer cyclones, it will be critical to resolve and forecast the same process for future storms, with the goal of lowering the uncertainty in predictions of TC impacts. Realistic 3-D coupled models that assimilate coastal observatory data and that are capable of predicting the ahead-of-eye-center stratified coastal ocean cooling processes will be critical [e.g., *Zambon et al.*, 2014; *Warner et al.*, 2017]. The increasingly populated [*Peduzzi et al.*, 2012] at-risk coastlines—the Northeast U.S. and northeastern China and Korea—adjacent to the two most stratified seas in the world—the MAB and Yellow Sea—will be increasingly vulnerable to TCs as sea levels rise [*Hansen et al.*, 2016], as TCs more frequently and severely undergo rapid intensification just before landfall [*Emanuel*, 2017], and if maximum TC intensities continue to migrate poleward [*Kossin et al.*, 2014]. By lowering uncertainty in coastal TC intensity forecasts through models that resolve these stratified coastal ocean cooling processes, these populations can better prepare for and respond to these rising threats.

Acknowledgments
HF Radar, glider, and satellite SST data used in this study are available through the MARACOOS assets page http://maracoos.org/data, https://rucool.marine.rutgers.edu/data, and http://marine.rutgers.edu/cool/auvs/index.php?did=369 with more detailed data sets available upon request to gregory.seroka@noaa.gov. ***Abstract*—The global need for sustainable development has never been greater. Solutions to provide food, water, energy and economic security to a growing global population that is increasingly coastal will necessarily involve the ocean. Every coastal country should be able to monitor their own waters, share their data as appropriate, and respond to actionable forecasts and information that supports a sustainable and resilient blue economy. This will require a new workforce trained in the operation of new ocean observing technologies capable of widespread distribution that can broaden participation by all nations. Towards this end, Rutgers University has developed a new Operational Masters in Integrated Ocean Observing to bridge the training gap between Ph.D. scientists and efforts to develop an ocean-literate public. The 15-month program begins with a summer software bootcamp to spin-up a common toolkit for data access. The fall and spring semesters feature 2-semester course sequences in (a) Integrated Ocean Observatories, (b) an Ocean Observing Field and Laboratory course, and (c) an Ocean Observing Cyber Lab. The capstone is an operational Masters thesis that leverages the MTS/IEEE Oceans meetings, and the local MTS student chapter. The initial class will begin in the summer of 2018.**

Keywords—education, ocean observatories, marine technology.

I. Introduction – Growing Global Demand

Today's students will be challenged over their professional lifetimes with providing 60% more food, 55% more water and 80% more energy to a growing global population forecast to approach 10 billion by 2050. Our students will be required to meet this challenge while the climate is warming, sea level is rising, the ocean is acidifying, coastal waters are more often hypoxic, and extreme weather events are increasing. Sustainable solutions that provide for basic human needs, minimize climatic impacts, and build resilient societies will require increasingly efficient green and blue economies on land and at sea. A sustainable blue economy requires information to support decisions that enable maritime sector industries while maintaining safety, improving the environment, and supporting the ecosystem. This can only be realized through scientific understanding that applies emerging technologies to optimize sustained observations and forecasts.

An ocean that is physically complex, biologically diverse, and inadequately sampled challenges the lofty goal of a sustainable blue economy. New at-sea sampling and land-based cyber technologies are required to bridge this gap. Scientific advancement may be supported by a few select academic groups of early adopters, but the compact scales of the energetic mesoscale, and the diversity of coastal large marine ecosystems, demand that we enhance multi-disciplinary spatial observations at regional scales globally. These observing systems can be organized into global networks for efficiency, but ultimately, they must be locally implemented and sustained at the relevant regional scale, requiring significant capacity development across the globe.

II. Program Design – Requirements and Experience

A. New Workforce Requirements

The Global Ocean Observing System's (GOOS) uses the Framework for Ocean Observing (FOO) to provide a structure by which societal goals can be met through the integration of a

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE
978-0-692-94690-9/$31.00 ©2017 MTS

wide variety of ocean observing technologies. Key integrated ocean observing gaps identified by the FOO process include lack of a global High Frequency Radar network, lack of a global underwater glider network, and the need for numerous biological and chemical sensors that can be effectively deployed on autonomous platforms. Global implementation will requires a new workforce with a variety of skills capable of working together as a team to operate new observing technologies in frontier areas, curate the data flow, and produce forecasts with quantifiable uncertainties appropriate to inform decision makers. They will be faced with real data and imperfect models, and will be required to turn what they have into actionable information.

Guidance to educators interested in workforce development for the blue economy was gathered through a discussion panel at the 2017 Oceanology International North America conference. Specific guidance included that workers must understand both *why* they are collecting data (a collaborative skill) as well as *how* to accomplish the goal (a technical skill). That data is never perfect, and one must see the sensors and platforms, and understand how they work, to fully understand their limitations. It was noted in the discussion that many of today's oceanographers have not gone to sea, yet our need for oceanographers has grown beyond our ability to train everyone at sea. Students therefore must gain this experience through new approaches. Present training approaches need to be more experiential, where students are encouraged to ask questions, and to determine if a piece of critical data makes sense. Individuals should be trained to collect and review the data, understand it, and work collaboratively to understand what it really means as a launching point for where to go next. Ultimately, to be employable in the marine sector, the students need to have worked with real data and be ready for action. This is rarely the case in undergraduate education, but a full 5+ year Ph.D. experience is overkill. A shorter but intensive program that goes beyond the necessary general undergraduate education to focus on operational needs is what is missing. To be accepted in their future positions, the operational students will be drawn from and resemble a cross section of the communities they serve. This will move new frontier technologies beyond the scientific early adopters into widespread use.

B. *Proven Educational Expertise*

Rutgers developed and delivered since 2006 a new hands-on undergraduate research program in ocean observatories to compliment its existing Marine Science major [1]. The centerpiece of the program is a flexible research experience that can begin as early as freshman year and can continue over a student's full undergraduate career. The research follows the cognitive apprenticeship model, where more experienced students lead small teams of student researchers using real data collected in operational ocean observatories to investigate research questions they formulate [2][3]. The program enables students to gain experience working with real data, promotes teamwork, and provides near-peer mentorship opportunities in modern ocean and coastal observing networks (Fig.1). The program has grown to involve an average of 30-50 students in research projects each semester. Over the last decade, undergraduate Marine Science student involvement in research has increased by an order of magnitude and the percentage of minority students has doubled [4].

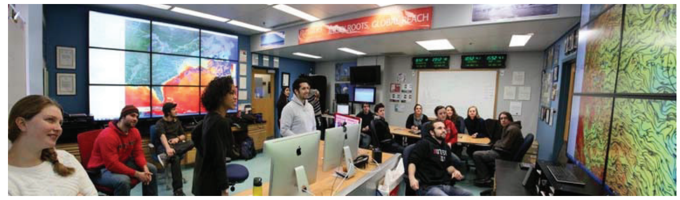

Fig. 1. The U.S. IOOS-certified ocean observing operations center at Rutgers University.

III. A GLOBALLY UNIQUE MASTERS PROGRAM

The Rutgers University Center for Ocean Observing Leadership (RU COOL), an international leader in the development and sustained operation of new observing system technologies as an integrated network, has designed a new Operational Masters in Integrated Ocean Observing to begin in the summer of 2018. The compact 15-month program, that includes 2 semesters of coursework sandwiched between two summers of research, can fulfill all the requirements for a Rutgers Masters degree if 6 credits of graduate work can be drawn from the student's undergraduate coursework (Table 1). The preferred 6 credits are the equivalents of Rutgers' Introduction to Physical Oceanography and Introduction to Biological Oceanography courses that are cross-listed as both undergraduate and graduate courses. This ensures that the students have at least a basic background level of experience and are familiar with the ontology of oceanography so that they can proceed quickly with the more technical aspects of the Masters. For Rutgers students, this is effectively a 4+1 Bachelors+Masters degree program.

TABLE I.

Masters in Integrated Ocean Observatories - Course Sequence		
Semester	**Course Title**	**Credits C=Course R=Research**
Equivalent Undergraduate Experience	Intro to Physical Oceanography	3 C
	Intro to Biological Oceanography	3 C
Summer 1	Software Bootcamp	3 R
Fall	Integrated Ocean Observatories I	3 C
	Ocean Observing Field Lab I	3 C
	Ocean Observing Cyber Lab I	3 C
Spring	Integrated Ocean Observatories II	3 C
	Ocean Observing Field Lab II	3 C
	Ocean Observing Cyber Lab II	3 C
Summer 2	Thesis Completion and Defense	3 R
Total		**24 C, 6 R**

Students in the Masters program will occupy year-round open-concept desk space in the operations center of a U.S. IOOS-certified ocean observatory (Fig. 1) so that they spend their entire day inculcated by operational activities on a college campus fueled by technology development and scientific discovery. The first summer includes a Software Bootcamp, where students are spun up on typical data analysis tools like R, Matlab and Python, the typical oceanographic data formats such as netCDF and ERDDAP, and available oceanographic processing toolkits for data and model analysis. A new coastal research vessel provides on-campus access to the Raritan Estuary and Bay so that at sea training can begin immediately (Fig. 2).

Fig. 2. The R/V Rutgers can dock at the on-campus Rutgers boathouse, providing students easy access to salt water conditions for instrument testing and deployments. Photo by Sean O'Grady.

The school year includes a series of three 6-credit courses encompassing both fall (part I) and spring (part II) semesters. The Integrated Ocean Observing I & II course sequence runs across both semesters and introduces students to the wide variety of Eulerian and Lagrangian platforms and sensors that comprise a modern observing network. Each type of platform or sensor has a series of at least 3 classes that first introduce the sensor itself and quality assurance protocols, a second class that accesses actual data for homework and the application of specific quality control measures, and a third class where students orally presents the results of their homework to the rest of the class for discussion in a supportive environment designed to enhance oral communications skills. The course is interspersed with coaching classes on best practices in data visualization techniques, and how to communicate with data. A second two-semester sequence is the Ocean Observing Field Lab. Here students have hands-on opportunities to prepare (Fig. 2), quality assure, deploy/recover (Figs. 2 & 4), operate, quality control and curate data they acquire within an operating ocean observatory. Some of this data may contribute directly to student theses. A third two-semester sequence is the Ocean Observing Cyber Lab, where data analysis techniques and forecast models for winds, waves and currents are introduced. Model validation with data and the impacts of data assimilation are included.

Fig. 3. The Glider Lab where the annual Rutgers Glider School is taught serves as a staging area for the Ocean Observatories Field Lab.

The capstone is an Operational Masters thesis conducted during the spring and final summer based on the MTS/IEEE Oceans conference. Students work with a faculty advisor to submit an abstract to the semi-annual Oceans conference as their thesis proposal. Their research is completed over the spring and summer, and culminates with the submission of an MTS/IEEE Oceans conference proceedings paper. During a student's second summer, they also serve as mentors to the students entering their first summer, transferring their knowledge of software and their analysis programs to the new students, building an operational software toolkit that is constantly being updated and will remain publicly accessible throughout their future career. In an end of summer research symposium, each student presents their 15-minute MTS/IEEE Oceans oral presentation they will eventually present at the conference if accepted.

Applications for the class of Masters students will be accepted in January of 2018, with the first summer semester beginning in June of 2018. As the courses are matured, international accreditation by the UK-based IMarEST will be sought to ensure that the courses meet the educational needs of the maritime sector.

ABSTRACT. Coastal river-dominated oceans are physically complex, biologically productive, and intimately connected to human socioeconomic activity. The Deepwater Horizon blowout and subsequent advection of oil into coastal waters of the northern Gulf of Mexico (nGOM) highlighted the complex linkages among oceanographic processes within this river-dominated system and knowledge gaps about it that resulted in imprecise information on both oil transport and ecosystem consequences. The interdisciplinary research program implemented through the CONsortium for oil exposure pathways in COastal River-Dominated Ecosystems (CONCORDE) is designed to identify and quantitatively assess key physical, biological, and geochemical processes acting in the nGOM, in order to provide the foundation for implementation of a synthesis model (coupled circulation and biogeochemistry) of the nGOM shelf system that can ultimately aid in prediction of oil spill transport and impacts. CONCORDE field and modeling efforts in 2015–2016 focused on defining the influence of freshwater input from river plumes in the nGOM. In situ observations, combined with field-deployed and simulated drifters, show considerable variability in the spatial extent of freshwater influence that is related to wind direction and strength. Increased primary production and particle abundance (a proxy for secondary production) was observed during the spring when nGOM shelf waters were becoming stratified. Zooplankton and marine snow displayed intense vertical and horizontal patchiness during all seasons, often aggregating near the halocline. Simulations of a neutrally buoyant tracer released offshore of the Mississippi Bight showed surface advection of low tracer concentrations onto the inner shelf under high river discharge, high stratification, and variable wind conditions compared to almost no advection onto the inner shelf under low discharge, negligible stratification, and generally northeasterly winds. The interconnectedness of environmental variables and biological activity indicate that multiple factors can affect the transport of oil and the resulting ecological impacts. The process-oriented understanding provided by CONCORDE is necessary to predict ecosystem-level impacts of oil spills, and these results are applicable to other river-dominated coastal systems worldwide that often support oil extraction activities.

BACKGROUND

The April 2010 explosion of the Deepwater Horizon (DWH) drilling rig resulted in the loss of 11 lives, as well as the release into the Gulf of Mexico of ~5 million barrels of oil, 1.7×10^{11} g of methane, and other gaseous hydrocarbons from the Macondo well located at ~1,500 m depth (Reddy et al., 2012). The unprecedented magnitude of this 87-day spill eventually led to oil washing up along the northern Gulf of Mexico (nGOM) coast from Louisiana to Florida, producing substantial environmental damage (Michel et al., 2013; Murawski et al., 2016). Wind-driven circulation interacting with complex freshwater flows derived from numerous river inputs influenced the trajectory of oil on the shelf (Kourafalou and Androulidakis, 2013; Özgökmen et al., 2016) and made predictions of oil transport and impacts difficult (Joye et al., 2016; Özgökmen et al., 2016). The ability to forecast the movement of the oil was further complicated by river diversions that augmented river discharge in an attempt to keep oil from coming ashore in certain areas (O'Connor et al., 2016).

The challenges of predicting DWH spill effects were exacerbated by the three-dimensional (3-D) movement of the oil from depth. Approximately half of the released oil reached the surface (Federal Interagency Solutions Group, 2010; Passow and Hetland, 2016) as a weathered, reddish-brown substance, less cohesive compared to crude oil (Peterson et al., 2012). The other half formed a deepwater plume that settled at approximately 1,100 m (Diercks et al., 2010), where it was advected by midwater and deep-sea currents (Camilli et al., 2010). Marine snow particles provided a mechanism to export some of this midwater oil to depth (Hazen et al., 2010; Valentine et al., 2014; Daly et al., 2016; Passow and Ziervogel, 2016), where it likely had an impact on sensitive and poorly studied deep-sea ecosystems (Schrope, 2011; Fisher et al., 2014). Surface oil was observed in the Mississippi Bight (MacDonald et al., 2015) and reached the nearby coastlines (Nixon et al., 2016), yet there are no reliable estimates of the exact percentage of spilled oil that was transported to the coast, which necessitates approximations in oil fate budgets accounting for oil recovery/burning, evaporation, microbial degradation, sedimentation, and advection (Passow and Hetland, 2016). Because biological production and fisheries activity is concentrated on the nGOM shelf and in coastal habitats (Grimes, 2001), oil in this region can have a disproportionately strong ecological impact that is directly connected to human social and economic well-being.

The Mississippi Bight region of the nGOM (Figure 1) represents a critical intermediary between the DWH oil spill site and coastal ecosystems. Flanked by the Mobile Bay outflow to the east and barrier islands to the north and west, this region is characterized by dynamic river- and wind-influenced flows. In addition to the substantial freshwater discharge from Mobile Bay (annual average of ~2,200 $m^3\ s^{-1}$; Gelfenbaum and Stumpf, 1993), numerous smaller rivers empty directly into Mississippi Sound (shallow waters north of the barrier islands) or enter indirectly through Lake Pontchartrain, totaling ~928 $m^3\ s^{-1}$ (Sikora and Kjerfve, 1985). While an estimated 47% of the Mississippi River discharge travels east and offshore (Dinnel and Wiseman, 1986), the amount that moves toward the inner shelf of the Mississippi

FACING PAGE. Surface convergence at a density front near Main Pass at the mouth of Mobile Bay. Bight has not been quantified. Under circumstances when the Mississippi River reaches flood stage near New Orleans, as it did in January 2016, the Bonnet Carré Spillway is used to divert river water into Lake Pontchartrain, which then flows into Mississippi Sound.

The wide and shallow nGOM shelf receives a seasonally variable supply of nutrients and particulates from the rivers that flow into Mississippi Sound and Mobile Bay, or directly onto the shelf. This riverine input is essential to maintaining the high primary production (Lohrenz et al., 1997) and fertile fishing grounds (Grimes, 2001) that characterize the nGOM. Circulation near the shelf edge and beyond is influenced by winds, river plumes, and mesoscale eddies spawned by and interacting with the Loop Current (Sturges and Leben, 2000; Ohlmann et al., 2001; Oey et al., 2005). The physical processes that affect nGOM shelf circulation act at a range of spatiotemporal scales, making accurate forecasting of oil transport patterns challenging. The biological and chemical processes that impact oil fate and toxicity contribute additional complexity to these challenges.

The clear need to understand transport and oil exposure pathways in the pulsed, river-dominated Mississippi Bight led to the implementation of the CONsortium for oil spill exposure pathways in COastal River-Dominated Ecosystems (CONCORDE). The CONCORDE research agenda centers on three scientific objectives: (1) to characterize the complex, 3-D physical oceanographic setting in order to understand potential oil pathways; (2) to describe spatiotemporal distributions of planktonic organisms, as well as geochemical and bio-optical parameters at scales relevant to processes transporting oil; and (3) to generate a synthesis model (Box 1) to predict oil transport on continental shelves and potential ecological impacts during future spill events for pulsed, river-dominated coastal ecosystems that incorporates new information on physical,

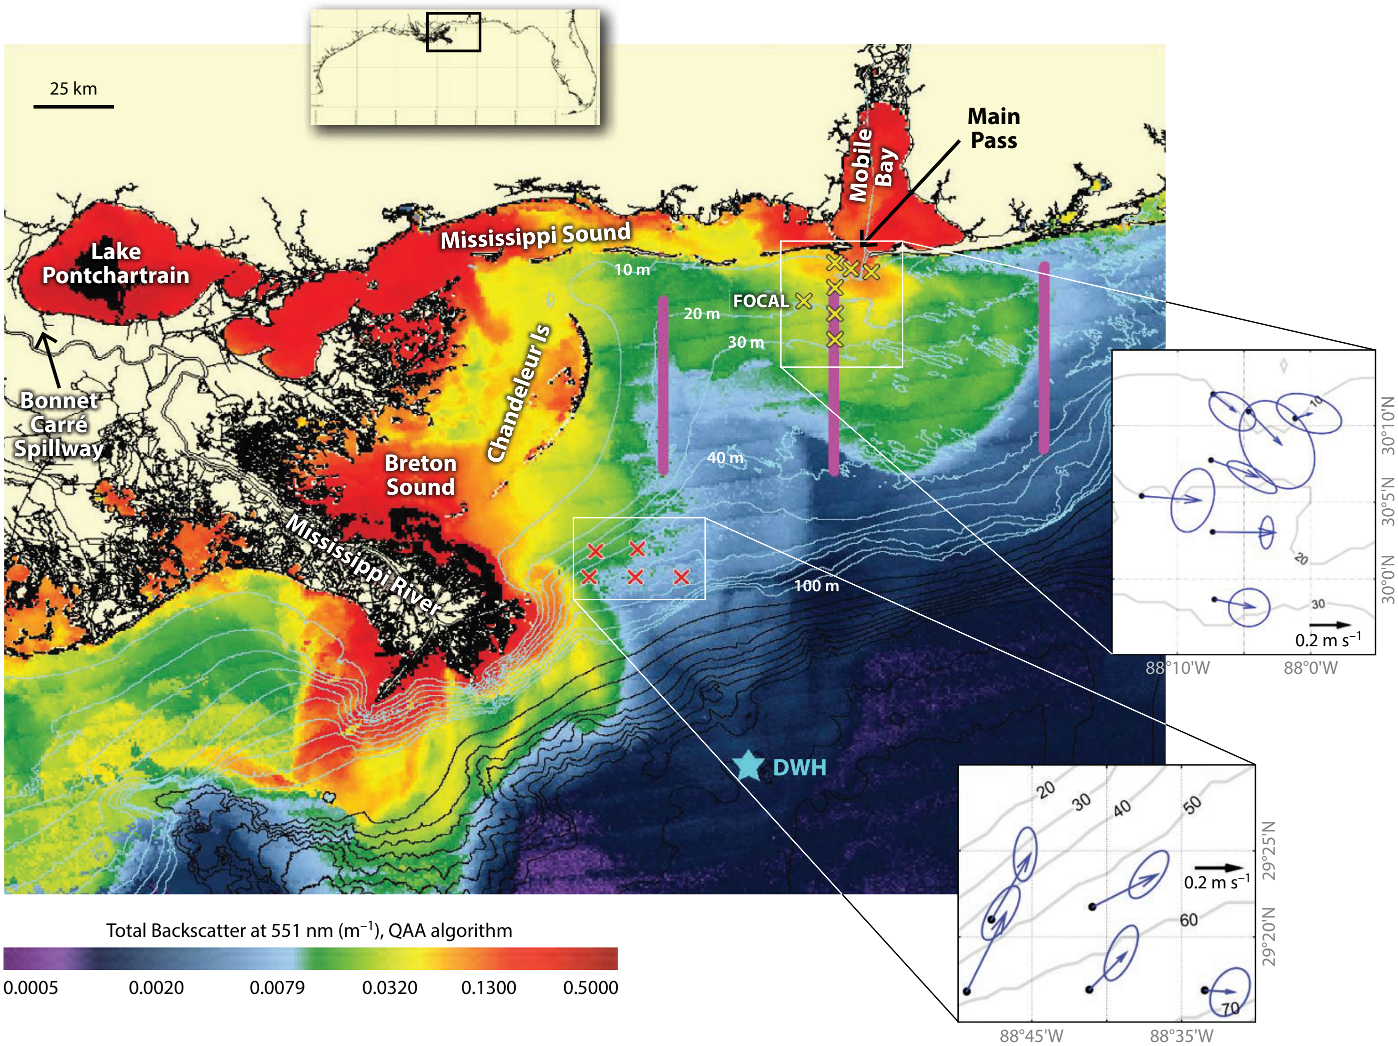

FIGURE 1. Map of the CONCORDE (CONsortium for oil exposure pathways in COastal River-Dominated Ecosystems) study region showing field sampling corridors within the Mississippi Bight (magenta lines, samples between corridors not shown) and the locations of moored instruments (red and yellow Xs). The color shading shows surface optical backscatter (a proxy for relative chlorophyll-*a* distribution obtained from the Visible Infrared Imaging Radiometer Suite, VIIRS) on April 5, 2016, corresponding to a high river discharge event. Inset maps for the mooring arrays show the depth-averaged current vectors with ellipses encompassing, on average, 93% of the current variability for April 5, 2016. The blue star marks the location of the Deepwater Horizon (DWH) drilling platform.

Box 1. Synthesis Model

The CONCORDE synthesis model, which simulates various oceanographic conditions by incorporating several data sources, can be used for assessment and prediction of the effects of future oil spills entering the Mississippi Bight. The circulation model is based on a 400 m resolution implementation of the Regional Ocean Modeling System (ROMS; Shchepetkin and McWilliams, 2005; Haidvogel et al., 2008) within the Coupled Ocean-Atmosphere-Wave-Sediment Transport (COAWST) modeling system (Warner et al., 2010). The model encompasses Mobile Bay and the Mississippi Sound and Bight, extending to 87.30°W and 29.25°N. Boundary conditions are from the 1 km resolution Navy Coastal Ocean Model (NCOM), with river discharge estimated from US Geological Survey data. The biogeochemical model is based on a nitrogen, phytoplankton, zooplankton, detritus model (Fennel et al., 2006; Hofmann et al., 2008; Druon et al., 2010) and simulates nitrogen in various states (dissolved organic nitrogen, nitrate, ammonium, inorganic suspended particulate matter) using two size classes of phytoplankton and detritus, three size classes of zooplankton, and larval fish, all of which can be used to estimate dissolved oxygen concentrations (following Wiggert et al., 2017). CONCORDE field measurements and routine in situ data sets provide calibrations and verification of the ecosystem parameter settings.

Atmospheric forcing is from an hourly 0.01° gridded meteorological reanalysis product composed of several parameters. The Real-Time Mesoscale Analysis (RTMA; De Pondeca et al., 2011) provides surface momentum and thermodynamic atmospheric data. Radiation parameters and total cloud cover percentage are from North American Mesoscale Forecast System (NAM) fields. Hourly precipitation is provided by the Next Generation Weather Radar Level-III (NEXRAD). Gridded sea surface temperature fields (SST) are computed daily using a 10-day running mean of the Advanced Very High-Resolution Radiometer (AVHRR) SST product. The Coupled Ocean-Atmosphere Response Experiment (COARE) flux algorithm calculates sensible heat flux and surface momentum stresses (Fairall et al., 2003).

The CONCORDE synthesis model examines responses to oceanographic conditions and river plume dynamics, providing insights into ecosystem impacts from oil reaching the shelf and nearshore waters. The simulations are designed to evaluate several processes, including (1) environmental controls (e.g., river discharge) on retention/flushing of plankton and dissolved constituents in the study region; (2) physical-biological controls on organism distributions; and (3) suspended particle dynamics and its role in particle aggregation and sinking, with emphasis on toxin transport, removal/retention, and resuspension. Additional simulations consider climate change or management responses (e.g., spillway openings, agricultural practices) that modify freshwater discharge, nutrient forms, and concentrations of terrigenous particulates into coastal waters of the nGOM.

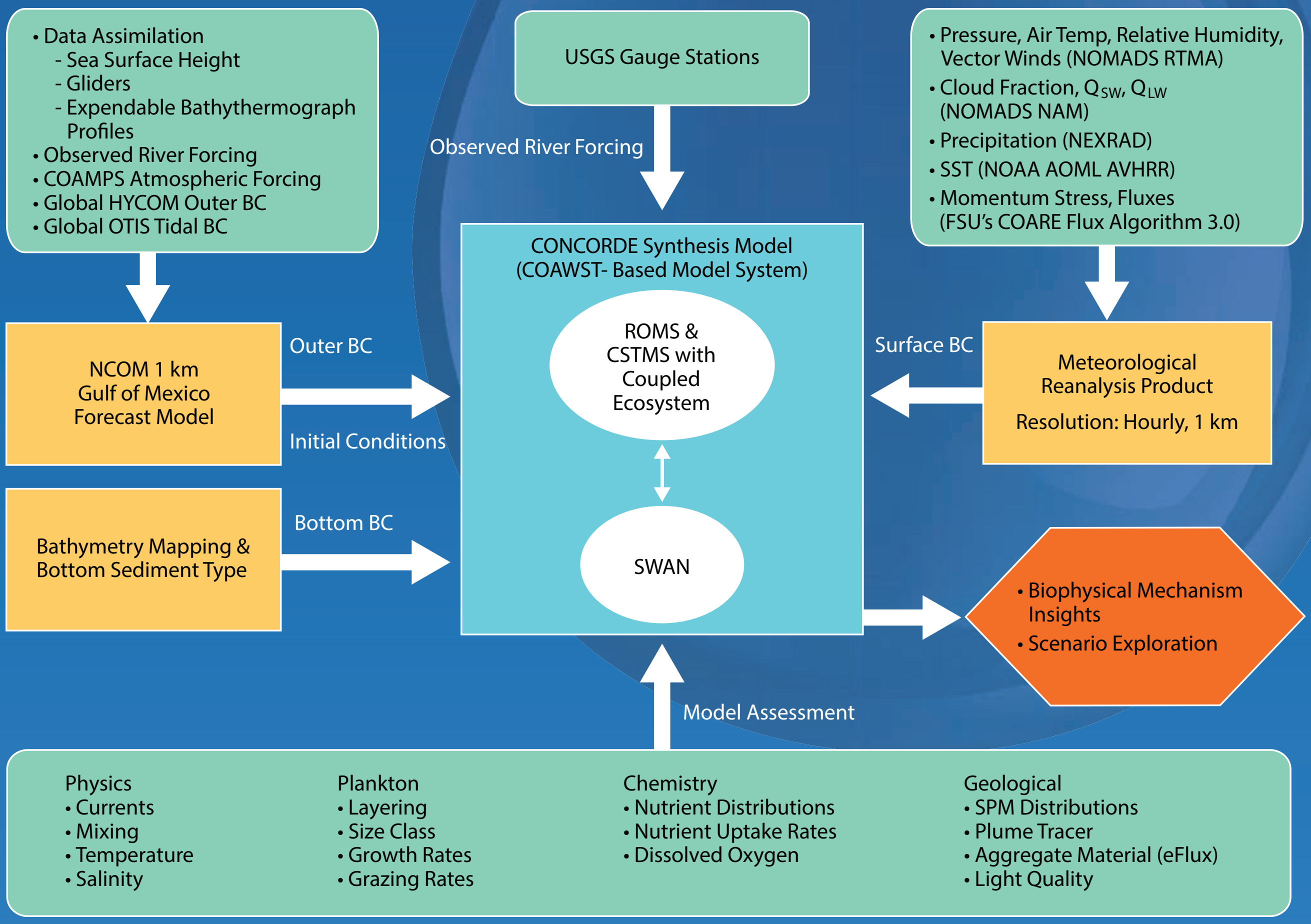

FIGURE B1-1. Conceptual diagram showing the data (green boxes) informing the initial and boundary conditions (BC; tan boxes) for the 4-D synthesis model. Field-collected data (green box at the bottom) are used for model assessment and validation. SWAN (Simulating WAves Nearshore) and the CSTMS (Community Sediment Transport Modeling System) simulate the impact of surface wave-current interactions and suspended sediment fields, respectively, within the coupled physical-biogeochemical model. The model runs under different oceanographic conditions to examine mechanisms of oil impact on the nGOM ecosystem (orange hexagon).

biological, and biogeochemical processes. This effort includes outreach activities designed to disseminate findings and build public trust in scientific information related to the DWH spill (see Box 2).

CONCORDE results are directly applicable to risk assessment, coastal system management, and examination of how ecosystem-level oil impacts may vary depending on the season when an oil spill occurs. Here, we highlight new information generated from sampling different zones of freshwater influence, and we explore how this information supports an emerging oil spill response paradigm (Graham et al., 2011; Peterson et al., 2012) that involves the use of four-dimensional (4-D) descriptions (3-D spatial plus temporal) to predict transport patterns and ecosystem impacts. The processes elucidated from this research are relevant to other ecologically and economically important river-dominated coastal ecosystems found throughout the world.

CONCORDE APPROACH

Research Cruises

The CONCORDE field research approach combined continuous observations from satellites, moored platforms, and autonomous gliders with seasonal ship-based field sampling campaigns in 2015 and 2016 under differing vertical stratification regimes and shifts in wind direction/intensity (Figure 2, Table 1). The ship-based sampling, which focused on zones in the Mississippi Bight with varying degrees of freshwater influence, consisted of fixed surveys and adaptive sampling to document fine-scale processes that influence oil transport and exposure of organisms (e.g., river plumes, fronts, layers with high plankton concentrations).

Physical Oceanography

Physical oceanographic measurements were obtained using a variety of instruments deployed from small boats, moorings, autonomous gliders, and research vessels, providing a 4-D description of the physical dynamics. The moored (fixed position) observations were supplemented by three deployments of autonomous underwater gliders prior to and during cruises. Small boat surveys were conducted to examine the freshwater pulses exiting Main Pass at the mouth of Mobile Bay, an example of a major tidal inlet associated with the barrier islands found in the nGOM. The near-field physical properties (e.g., plume depth, spreading rate, and frontal features) and their impact on the overall fate of freshwater discharge and particulate export along the coastal boundary of the CONCORDE sampling domain were determined from drifter releases and CTD and Laser In Situ Scattering and Transmissometer casts (for suspended particulates).

Moorings were deployed in two regions to capture the freshwater flows over different seasons (Figure 1). During the fall, a season typically characterized by low freshwater discharge, five line and bottom moorings were placed near the shelf break on the western side of the study area, where Mississippi River plumes were most likely to traverse (Figure 1, red Xs). Line moorings with sensors measuring temperature, salinity, and turbulence were deployed for the month of November 2015. Bottom moorings with upward-looking acoustic Doppler current profilers (ADCPs) and pressure sensors remained until mid-April 2016. In the spring, an array of six bottom moorings and three line moorings (Figure 1, yellow Xs) was placed just south of the Main Pass of Mobile Bay to observe plume dynamics and exchanges onto the shelf. This mooring array near the Mobile Bay outflow supplemented existing long-term observations by the Fisheries Oceanography in Coastal Alabama (FOCAL) mooring, allowing better resolution of the complex plume structure. Turbulence was estimated using bottom ADCPs and high-resolution thermistors and pitot-static tubes on χ-pods (Moum and Nash, 2009) tethered to line moorings.

Research vessels collected high-resolution measurements over broad

Box 2. Outreach Program

Because CONCORDE research is directly applicable to several environmental and economic issues affecting the nGOM coast (e.g., fisheries, hypoxia, tourism), outreach activities are organized to distill research findings in order to make them accessible to a broader audience. Outreach activities targeted to specific audiences include (1) a seminar series about scientific progress in the nGOM five years after the Deepwater Horizon spill, (2) teacher professional development, and (3) a citizen science initiative with multi-ethnic fishing community members from the nGOM coast.

Three teacher workshops coincided with the deployment of several autonomous underwater vehicles (known as the "AUV Jubilee") and aircraft in July 2015. In the first workshop, participating teachers worked with CONCORDE researchers and external scientists to conduct a synchronous data collection event in the nGOM to explore basic concepts in oceanography. At the end of this workshop, each teacher submitted a lesson plan based on concepts relating to the nGOM oil spill. Teachers in subsequent workshops offered input on the lessons, which are being distributed as a high school science curriculum.

Members of the fishing community are engaged with the CONCORDE project by learning to collect oceanographic data (e.g., YSI CastAway portable CTD) that can be used to validate model outputs. During training sessions, scientists and fishermen interact with the objective of improving trust in scientific findings within the fishing community, which is frequently at odds with regulatory agencies. Additionally, local knowledge provided by the fishing community may inspire new lines of scientific inquiry, and scientists provide advice on effective participation in local decision-making. These efforts are examples of fruitful collaboration among public, research, and regulatory groups.

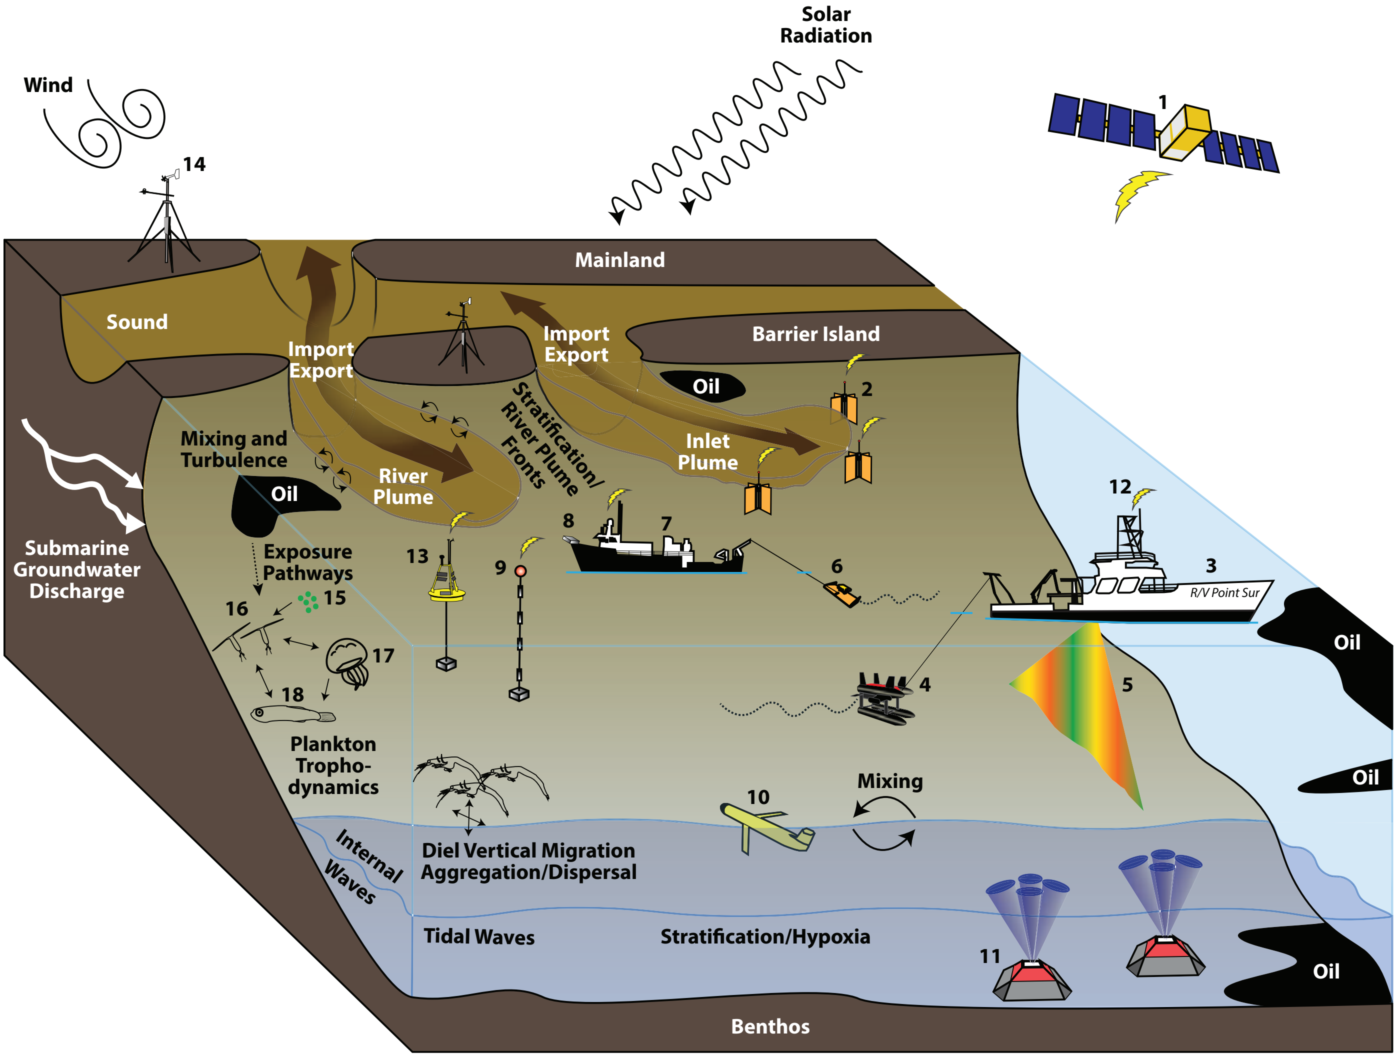

FIGURE 2. Schematic representation of the dynamic processes in the nGOM that influence the distribution, transport, and exposure pathways of oil in the planktonic community. Measurements related to these processes were collected with (1) the Suomi National Polar-Orbiting Partnership satellite equipped with a Visible Infrared Imaging Radiometer Suite; (2) surface drifters; (3) R/V *Point Sur* equipped with a CTD rosette, a sediment multicorer, a BIONESS multi-net system sampling at different depths, and an incubator as well as (4) an In Situ Ichthyoplankton Imaging System (ISIIS) and (5) Reson multibeam acoustics; (6) a Scanfish system shown being towed by (7) R/V *Pelican*, which is equipped with a CTD, a Chameleon microstructure profiler, and (8) ship-based Lidar; (9) a line mooring with sensors measuring current velocity, temperature, salinity, dissolved oxygen, turbulence, and optical properties; (10) an autonomous underwater glider; (11) bottom moorings with ADCPs and bottom pressure sensors; (12) satellite communication; (13) a Central Gulf of Mexico Ocean Observing System (CenGOOS) buoy and Fisheries Oceanography in Coastal Alabama (FOCAL) moorings; and (14) weather stations that include anemometers and various samplers for measuring biological properties of the plankton community, which includes (15) phytoplankton, (16) micro- and mesozooplankton, (17) gelatinous zooplankton, and (18) ichthyoplankton.

spatial and short temporal scales compared to moored and glider observations, which were limited in their spatial coverage. R/V *Point Sur* towed the undulating In Situ Ichthyoplankton Imaging System (ISIIS; Cowen and Guigand, 2008), which provided measurements of temperature, salinity, depth, dissolved oxygen, and downwelling irradiance while collecting in situ images of planktonic organisms. In conjunction with the ISIIS tows, a Reson SeaBat 7125 multibeam sonar was used to map the bathymetry of the study region and to collect water column backscatter data to detect physical and biological features. R/V *Pelican* towed a Scanfish to measure temperature, salinity, depth, and bio-optical properties in the water column. In the spring, R/V *Pelican* also deployed the Chameleon microstructure profiler (Moum et al., 1995), which measured microscale turbulence, temperature, conductivity, optical backscatter (800 nm), and fluorescence throughout

Summer Cruise	July 24–July 30, 2016	*Point Sur*

the water column from the surface to within 2 cm of the seafloor. The resultant 4,201 Chameleon profiles were combined with acoustic imaging, radar tracking of fronts, shipboard ADCP, and a near-surface towed temperature-conductivity chain to yield a detailed view of river plume dynamics and corresponding oceanographic changes.

Shelf Biological Productivity, Plankton Distributions, and Nutrients

The ISIIS acquired images with two cameras in ~0.06 second intervals, capturing planktonic organisms between ~400 µm and ~13 cm in size using a shadowgraph lighting technique, with no discernible bias in detectability among zooplankton groups (Cowen et al., 2013). The ISIIS images were processed following methods similar to those described in Greer et al. (2015). Images from the smaller camera (4.3 cm field of view, 8.9 cm depth of field, ~40 µm pixel resolution) were automatically segmented, a process that extracted particles greater than 500 pixels in cross-sectional area (~1.0 mm equivalent spherical diameter). These high-resolution images were supplemented with depth-discrete and surface plankton net tows, both of which provided biological samples needed for verification of the image classifications and further laboratory analyses.

Discrete water samples were used to characterize lower trophic level biological processes and nutrient concentrations. Rates of primary production, nitrate-based uptake, and biogenic silica production were measured from shipboard incubations. Chlorophyll (>0.6 µm and >5.0 µm size fractions) concentrations, bulk particulate organic carbon, and particulate organic nitrogen concentrations (among other parameters) were obtained from the water samples. Microplankton (20–200 µm) assemblage composition, size distribution, and abundances were described by imaging water samples with a FlowCAM® Benchtop B3 Series.

Chemical Tracers of Water Masses

Seawater samples for chemical tracer analysis were collected at the surface to characterize the freshwater river input, at midwater depth, and at the bottom to investigate the development of hypoxia based on evidence of previous hypoxic events that occurred in the Mississippi Bight (Brunner et al., 2006). The sampling and analysis strategies follow the methodology previously applied on the Louisiana Shelf (Joung and Shiller, 2014). Conservative parameters such as water isotopes (δ^{18}O and δD) and molybdenum (Mo) and cesium (Cs) concentrations were measured to identify the sources of freshwater to the Mississippi Bight. Barium (Ba) concentrations and radium isotopes (Ra) provided an estimate of the role submarine groundwater discharge plays in the development of bottom water hypoxia (Moore, 2010; Peterson et al., 2016).

Remote Sensing and Circulation Model

Satellite-derived products were combined with circulation model forecasts to characterize daily nGOM biophysical properties. The ocean circulation forecast fields, obtained from a 1 km horizontal resolution implementation of the Navy Coastal Ocean Model (NCOM), were used in planning portions of the CONCORDE field sampling campaigns. The three-hourly circulation fields were integrated with daily satellite-derived temperature and ocean color to provide visualization of environmental conditions that were used to optimize cruise and glider sampling in near-real time. This approach allowed for targeting features of interest, such as fronts and river plumes.

The effects of different environmental scenarios on transport pathways were evaluated with the CONCORDE synthesis model (Box 1) using simulations in which a neutral tracer (neutrally buoyant, passively following the current field) was released continuously throughout the water column along the southernmost boundary of the CONCORDE model domain. Simulations illustrated the fate of the tracer released over 21 days in the fall (October 1–October 21, 2015) and the spring (March 18–April 7, 2016). The integrated tracer concentration in the shallowest 1 m was used to determine surface transport patterns. This depth range was chosen because the mixed layer is shallow in the Mississippi Bight, and using a fixed depth allows for a comparison that is independent of seasonal and spatial changes in mixed layer depth. The tracer was designed to simulate surface water transport that could contain surface crude oil or droplets mixed just below the air-sea interface. Wind roses at 88.5°W, 29.4°N (near the southern boundary of the model domain) were calculated from the wind analysis field.

RESULTS AND DISCUSSION

River Plume Transport

Results from one survey day (April 10, 2016) illustrate some physical processes and transport mechanisms involving the Mobile Bay plume. River plumes flowing into the nGOM contribute to vertical stratification that varies in strength throughout the year. The highest freshwater input occurs in spring, resulting in a stratified system with high-salinity shelf water at depth, an intermediate layer of old plume water that has been mixed over time with deeper waters (Figure 3a), and the occasional presence of a thin surface plume from the Mobile Bay outflow (Dzwonkowski et al., 2015). The strong stratification between layers limits vertical exchange of passive constituents such as sediments (as observed in optical backscatter, Figure 3b) and chlorophyll-*a* (inferred from fluorescence, Figure 3c). To counteract the effects of stratification, opposing current velocities (surface vs. bottom, Figure 3e) create vertical shear, inducing turbulence via shear instability (Figure 3d; Smyth and Moum, 2012) that drives a Fickian-like diffusion of salt and other constituents between layers (Shroyer et al., 2016). The depth-integrated change in salinity over time (dS/dt) within the intermediate layer (thickness H) correlates with the turbulent salt flux across the pycnocline (depicted in Figure 3f as the product of turbulence diffusivity, K_ρ, and the vertical salinity gradient). This correlation suggests that turbulent mixing can account for the exchange of passive constituents between layers despite the stratification that opposes this exchange. Strong winds, which enhance mixing, would erode stratification and homogenize the water column in the absence of periodic injections of freshwater by river plumes.

Secondary lateral currents also impact the transport of these constituents (Figure 3e). Southeasterly winds can drive a current in the intermediate layer to the northeast, forcing the intermediate layer toward shore. Consequently, constituents near the surface are advected toward shore, while deeper waters are advected offshore due to the pressure head of the outflow and downwelling wind. Mixing between layers defines a more complex pathway in which initially deep constituents are mixed upward and then transported shoreward. Lateral transport is further complicated by the presence of tidally reversing currents and rotating inertial oscillations, the clockwise turning near the local inertial frequency (~24-hour period at nGOM latitudes) caused by Earth's rotation.

In mid-April, the river plume was advected along the coast, but its position varied in response to other environmental conditions. Under weaker wind conditions, plume-tracking drifters moved offshore and to the west, consistent with a buoyancy-driven plume (Figure 4a). However, the stronger upwelling conditions (westerly winds) forced the plume offshore where it continued to be pushed eastward by shelf currents (Figure 4b). The trajectories of simulated drifters are similar to those of observed drifters under different wind forcing conditions, indicating the model skill in resolving the Mobile Bay plume response to winds. The observed and simulated drifter pathways show that the eastern-most CONCORDE sampling transect (87.53°W, Figure 1) can receive freshwater input derived from Mobile Bay during periods of upwelling wind.

Additional drifter releases simulated by the circulation model (Box 1) show transport pathways for different prevailing wind, tidal, and freshwater discharge conditions. Transport depicted from drifter simulations for the winter cruise (during the period of the Bonnet Carré Spillway opening) agreed with water mass distributions determined from underway bio-optical measurements.

Oxygen isotope analysis showed that the Mississippi River plays a surprisingly small role in freshwater input to the Mississippi Bight (relative to freshwater from Mobile Bay and other sources). The Bonnet Carré Spillway opening was an exceptional freshwater discharge event where Mississippi River water entered through Lake Pontchartrain, north of the main Mississippi River Delta, with a seemingly more direct connection to the Bight. Even under these circumstances, only waters in the westernmost part of the Bight showed Mississippi River influence. Chemical tracers also indicated

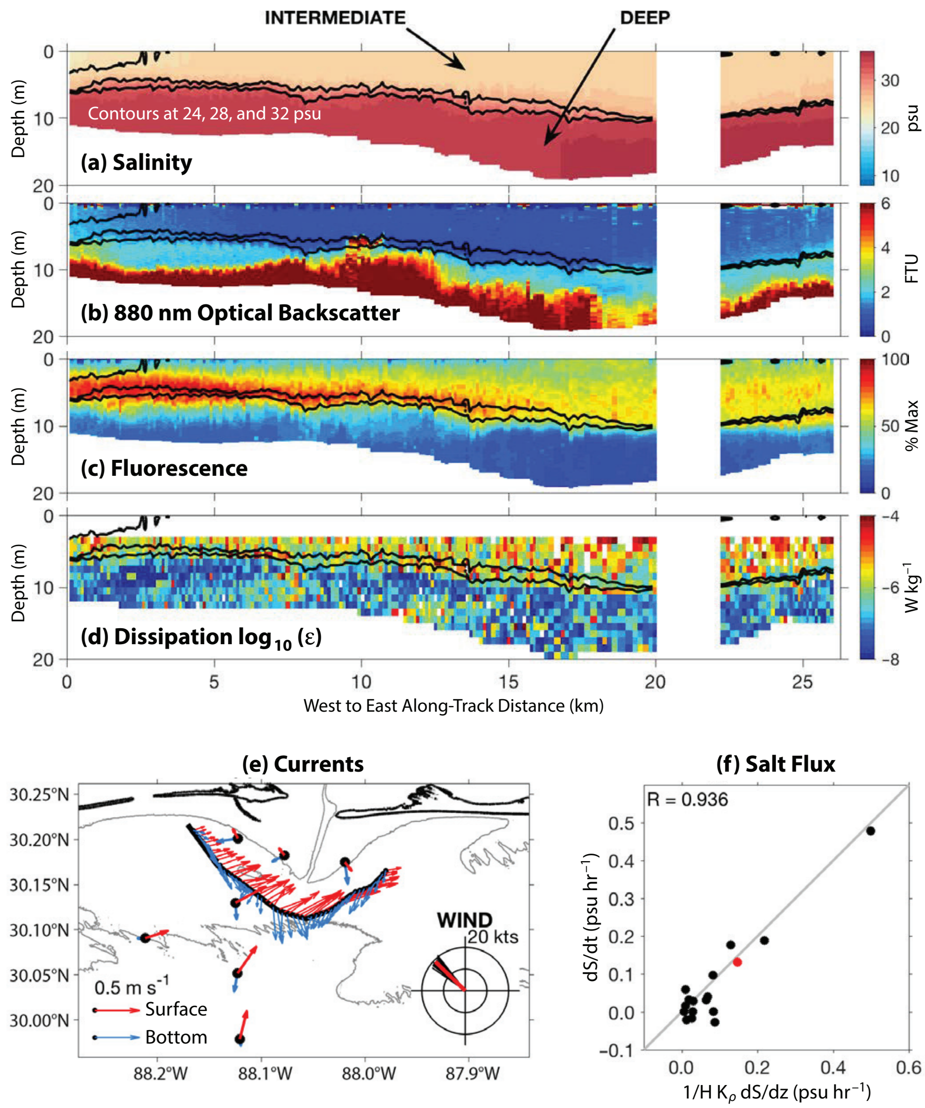

FIGURE 3. Observed distribution of (a) salinity, (b) 880 nm optical backscatter, (c) chlorophyll fluorescence, and (d) turbulent kinetic energy dissipation rate measured with the Chameleon microstructure profiler during the evening of April 10, 2016, along the semicircular transect shown in (e), located ~5 km south of Mobile Bay. (e) Near-surface (red) and near-bottom (blue) currents measured by a 1,200 kHz shipboard ADCP along the transect path, and current vectors at the mooring locations averaged over the 4.5 hours it took to complete the shipboard transect. Inset shows average wind direction (southeasterly) and speed (20 knots). (f) Turbulent salt flux divergence across the intermediate layer (x-axis) compared with the measured change in salt in the intermediate layer (y-axis). The transect shown in a–d is plotted in red.

transport of local river waters, including Mobile Bay outflow, to the western part of Mississippi Sound during this event. Most of the Mississippi River water (from both the Delta and the Bonnet Carré Spillway) appears to hug the Louisiana coast and move toward the south and west, leaving the Bight to be primarily influenced by Mobile Bay outflow and smaller rivers. This oxygen isotope data set, indicating strong south and eventually westward trajectory of the Mississippi River outflow, provides an approach for assessing the skill of the simulated circulation patterns.

Shelf Circulation and Transport Pathways

Throughout the sampling period between fall 2015 and spring 2016, mooring arrays (Xs in Figure 1) provided a broader context for the higher-resolution physical and biogeochemical measurements. Currents near the Mississippi River Delta were generally oriented along the isobaths, with typical variation ranging between 30 cm s^{-1} and 50 cm s^{-1} in both along-isobath directions (e.g., Figure 1, lower inset), while mean speeds were an order of magnitude smaller at 2–5 cm s^{-1}. The large difference between the variations and mean suggests that there is no dominant orientation for the currents east of the Mississippi River Delta from fall to spring. Currents often oscillated with a near-inertial frequency (clockwise rotation), primarily forced by the passage of cold fronts through this region that occur every 2–15 days. Despite its proximity, the Mississippi River outflow did not play a significant role in driving weekly variations of currents during the study period. Rather, local southeasterly winds drove southwestward currents with slight offshore fluxes, and northwesterly winds drove northeastward currents with slight onshore fluxes.

The potential pathways that result in oil exposure on the nGOM continental shelf and their variability were assessed with the circulation model using simulations that tracked the concentration of a continuously released neutral tracer throughout the model domain. Tracers were released during the fall and spring for a 21-day period. The fall tracer release (October 1–October 21, 2015) shows consistent surface transport from west to northeast, with little northward advection into the inner shelf region of the Mississippi Bight (Figure 5a). In contrast, the spring release (March 18–April 7, 2016) shows the tracer transported northward to the nGOM inner shelf region, as well as surface spreading of the tracer over most of the CONCORDE model domain (Figure 5b). Major differences between these two cases include the winds (Figure 5c,d—stronger speed peaks and greater directional variability in the spring period relative to the fall), the stratification (stronger in spring), and the river discharge (higher in spring). The fall and spring simulated tracer patterns indicate that the timing of an oil spill can greatly influence its distribution on the shallow nGOM shelf, and high river discharge does not necessarily obstruct the onshore transport of surface water constituents to the shelf and coastal habitats. These simulations provide a basis for further studies that address the effects of environmental complexity and uncertainty on oil transport in the nGOM and on ecosystem processes.

Biological Production and Aggregation on the Shelf

Biological constituents responded to variable salinities and nutrient inputs from nearby rivers. During the fall, minimal freshwater input led to a well-mixed

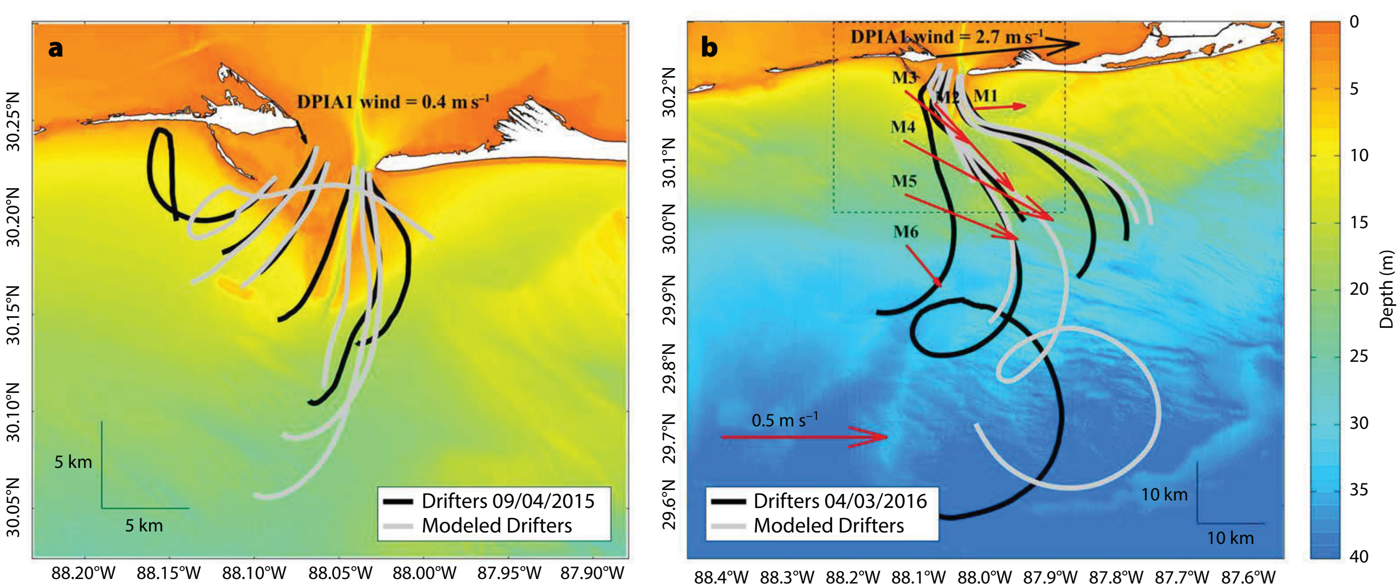

FIGURE 4. Example trajectories for observed (black) and simulated (gray) drifter releases on (a) September 4, 2015, during a weak sea breeze cycle, and (b) April 3, 2016, after a frontal passage. The drifters were released at Main Pass approximately a quarter of the way into the ebb tide; however, the drifter recovery varied from 5 hours to 60 hours, resulting in extended trajectories for some drifters. Wind vectors (black) at Main Pass show average wind speed and direction during drifter releases (NOAA/NDBC station DPIA1). Red vectors (panel b only) indicate the near-surface currents at the moorings averaged over the duration of the drifter release.

water column with relatively high salinity (Cambazoglu et al., 2017) and low biological productivity (Figure 6a,b), as measured by both primary production and zooplankton abundances (Dzwonkowski et al., 2017). The water column underwent a dramatic change as spring rains led to increased river discharge from Mobile Bay, directly affecting large portions of the shelf and producing a large vertical salinity range (salinity of ~24 at surface and ~36 at depth). These nutrient-rich river discharges produced higher biological productivity, with the zooplankton and marine snow particle distributions closely following the halocline (Figure 6c,d). The mooring near the northern end of the transect (southernmost yellow X in Figure 1) showed two-layer cross-shelf transport caused by an inertial oscillation likely created by a wind event. During the inertial cycle, currents were oriented offshore in the surface layer and onshore in the lower layer. They slowly turned clockwise in each layer to reverse course over the next 12 hours, reaching the opposite pattern of onshore flow in the surface layer and offshore flow at depth. These currents then slowly turned clockwise over the next 12 hours to return to the original flow pattern (the period of inertial oscillations is diurnal at these latitudes). This is an example of differential advection set up by stratified conditions, which has implications for understanding oil transport in this region.

During summer, the vertical salinity range was lower, but the halocline was strongest with apparent vertical oscillations (i.e., internal waves; Figure 6e,f). The zooplankton and marine snow distributions were confined to a narrow range of intermediate salinity levels, but the peak concentrations were not as high as those measured during spring. The spring to summer halocline strengthening appeared to correspond to vertically confined distributions of zooplankton, as well as to a reduced capacity for ventilation of the deeper shelf waters that generates favorable conditions for the development of hypoxia. In summer, bottom waters showed radium enrichment, a key indicator of submarine groundwater

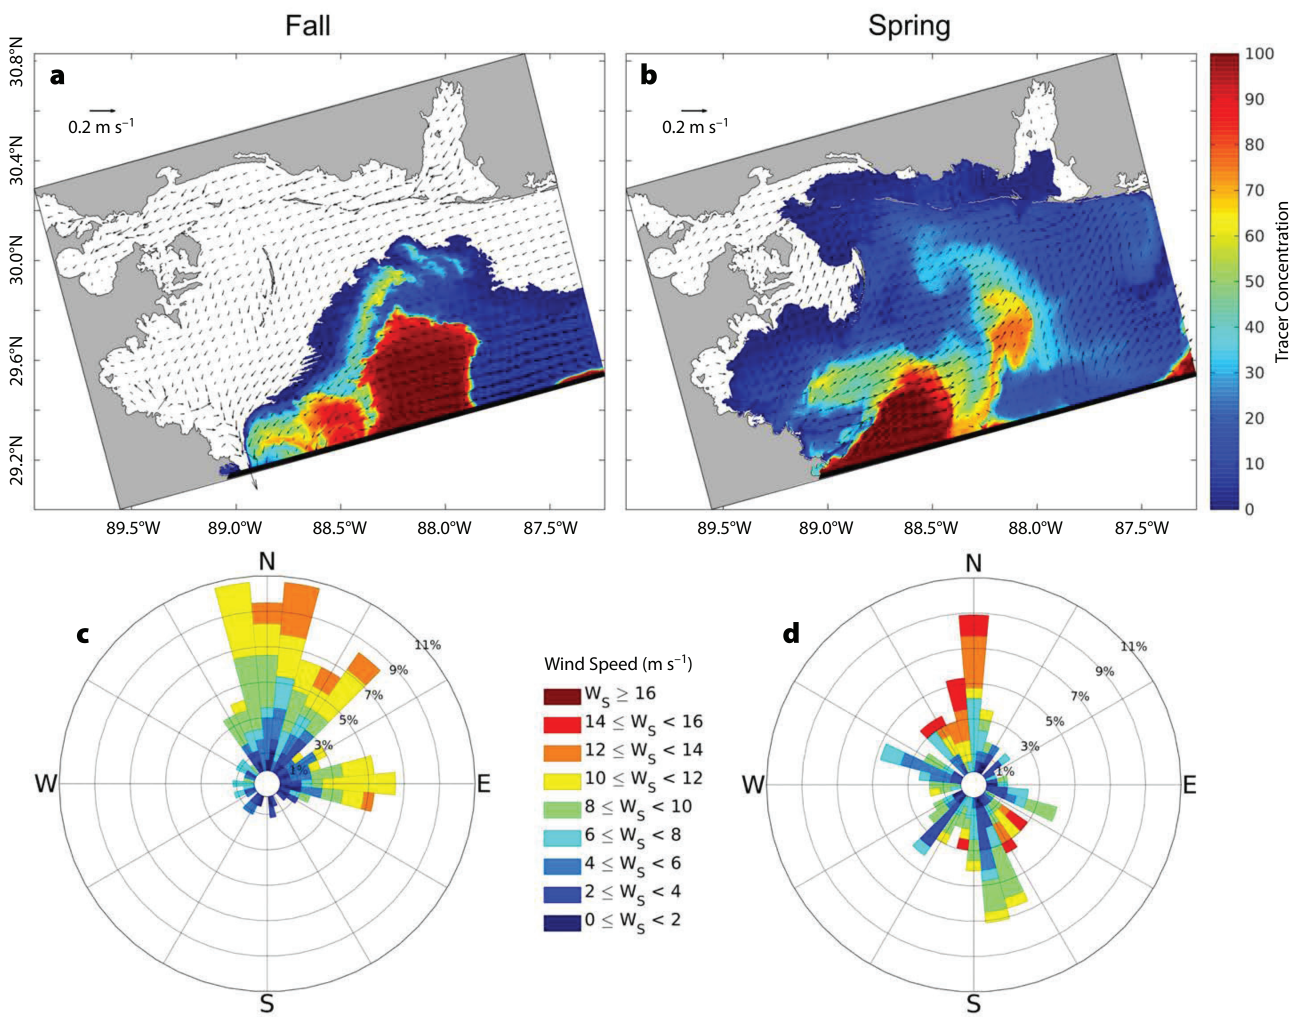

FIGURE 5. Simulated neutrally buoyant tracer release (color shading) at the southern edge of the CONCORDE model domain in the Mississippi Bight. Tracer distribution (integrated 1 m surface concentration in arbitrary units ranging from 0 to 100—concentration is 100 at the site of the release) is shown after 21 days of continuous release and passive advection during (a) fall (October 1–21) and (b) spring (March 18–April 7) seasons, respectively (see online supplemental material for tracer advection animation). Regions with tracer concentrations <0.1 (white areas) and current vectors (simulation day 21) are also shown. Wind roses (showing direction wind is coming from) were produced from the wind analysis field (meteorological reanalysis product – see Box 1) from the (c) fall and (d) spring during the same 21-day period near the southern boundary of the model domain (29.4°N, 88.5°W).

discharge, and this was correlated with high dissolved silica, inorganic nitrogen, and phosphate, and low dissolved oxygen. Thus, in addition to river discharge, submarine groundwater appears to play a role in nutrient delivery in the Mississippi Bight, with possible concomitant effects on productivity and bottom water hypoxia.

The intense aggregation of plankton and marine snow, particularly during spring and summer, has important implications for the propagation of oil and contaminants throughout the food web (Figure 6b,d,f). Sinking marine snow provides a mechanism for transport of oil to depth and potentially serves as a trophic exposure pathway for oil into the planktonic food web (reviewed by Daly et al., 2016). The association between seasonal changes in salinity structure and zooplankton/marine snow distributions provides requisite data for quantifying spatial overlap (e.g., Greer and Woodson, 2016) and contact rates between marine snow particles and various zooplankton groups, along with information about behavioral interactions (e.g., orientation and predation events; see Figure 6g–m for example images). These measurements can be used to generate taxon-specific understanding of vulnerability to oil exposure and of detailed trophic pathways for oil incorporation into the planktonic food web (Graham et al., 2010; Buskey et al., 2016).

SUMMARY AND FUTURE APPLICATIONS OF CONCORDE

Analysis of high-resolution, near-synoptic measurements that cross traditional oceanographic disciplines has improved

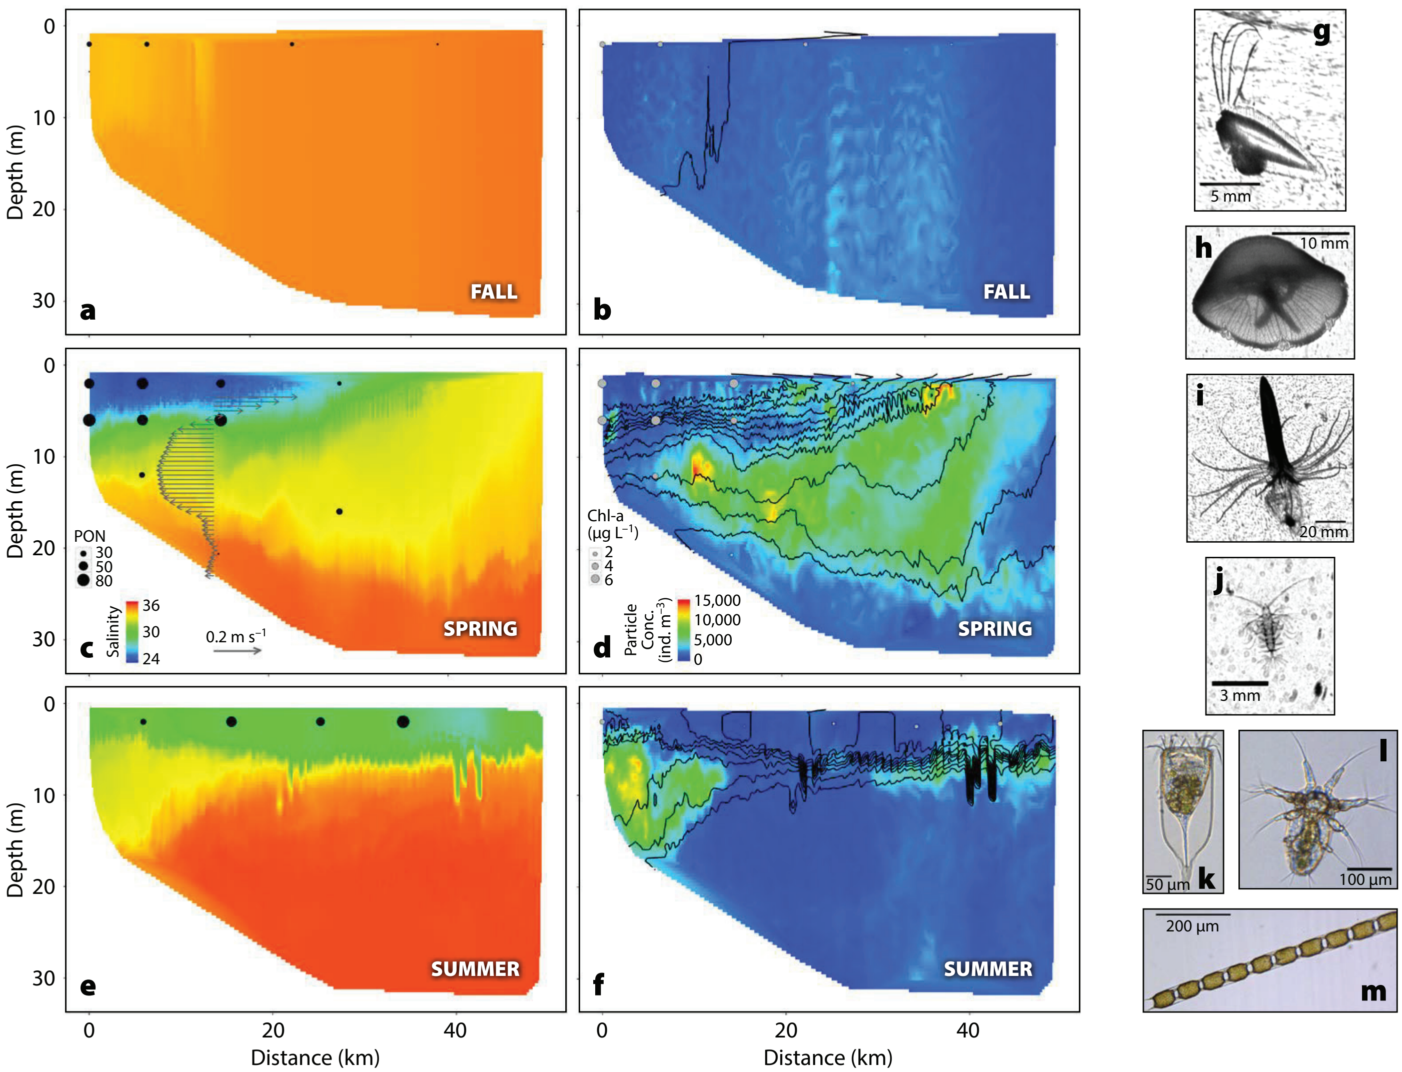

FIGURE 6. Measured salinity versus distance from start of the ISIIS transect (left is north) in (a) fall (October 30, 2015), (c) spring (April 4, 2016), and (e) summer (July 25, 2016) along the middle sampling corridor (Figure 1) and measured particulate organic nitrogen concentrations (black dots). Panel c shows the current vectors from a mooring averaged between 10:00 and 12:00 CDT on April 4, 2016 (southernmost yellow X in Figure 1). Particle concentrations (zooplankton and marine snow) during (b) fall, (d) spring, and (f) summer, with measured chlorophyll-*a* (Chl-a) concentrations (gray dots) along the same sampling corridors. Salinity between 25 and 35 is indicated by black lines in 1 unit increments. The legend for (c) also applies to (a) and (e), and (d) contains the legend for (b) and (f). Example images of fauna captured with the ISIIS and within the size range of particles show (g) a larval flatfish, (h) a juvenile moon jelly (*Aurelia* spp.), (i) a larval tube anemone consuming a salp, and (j) a eucalanoid copepod. Images k–m, captured with the FlowCAM®, show (k) a tintinnid ciliate, (l) a copepod nauplius, and (m) a diatom chain (*Odontella sinensis*) that were all below the ~1 mm size threshold of plankton plotted in (b), (d), and (f).

our understanding of the Mississippi Bight, a critical region separating offshore oil drilling sites and coastal habitats. Complex physical processes in this river-influenced region of the nGOM contribute to the structuring of ecological communities, but measurements on scales appropriate for resolving many processes relevant to oil transport (hourly temporal scales and centimeter to meter spatial scales), and the interactions of oil with biological and other chemical components, have been lacking. Several new findings have emerged from this research, including the discovery of both direct and indirect transport pathways driven by the wind and consistent plankton aggregations that track salinity variations.

Wind has a major influence on transport of river plume waters, which in turn impacts other ecosystem properties. Mooring observations suggest that wind is the dominant control on the currents to the east of the Mississippi Delta, and wind variations can move Mississippi River water along the shelf break and into or out of the Bight. However, chemical distributions indicate that Mississippi River water actually makes up a relatively small proportion of the freshwater entering the Bight, suggesting that much of the Mississippi River water that flows eastward is advected either along the shelf break or offshore. Wind can also drive the Mobile Bay plume westward or eastward and plays an indirect role in setting up the shear observed in the Mobile Bay plume, producing the observed mixed layer salinity changes and generating inertial oscillations that diurnally advect plumes after a wind event. Biological sampling demonstrates that strong salinity gradients influence the distributions of zooplankton, marine snow, and nutrients. The distributions of plankton and geochemical constituents are therefore connected to wind speed and direction, as the wind forcing modulates the halocline through mixing and impacts plume fronts through advection. These connections, which can only be revealed with an interdisciplinary approach, show that different, seasonally dependent environmental factors structure the distribution of constituents and can also influence oil advection and the magnitude of oil spill impacts on the ecosystem.

Improved forecasting of oil spill transport and impacts requires understanding oceanographic processes that change with depth. Although most oil spill transport research has focused on atmospheric forcing and circulation near the sea surface, the Deepwater Horizon blowout demonstrates that understanding oil transport and interactions should be considered a 4-D problem, with depth adding a complex new dimension that is difficult to observe (Peterson et al., 2012). This understanding is becoming critical given that oil extraction is taking place in deeper, offshore sites (Graham et al., 2011). Accurate prediction of ecosystem-level impacts from oil spills is the foundation for effective response planning, so observations and modeling must be extended to include interactions throughout the water column between oil (and dispersants) and the biological and geochemical constituents that serve as a mechanistic link to bulk ecological and economic impacts. The dynamics of pulsed river plumes adds an additional degree of complexity for predicting physical advection and chemical-biological interactions. Even though river-dominated shelf ecosystems are relatively shallow, their physical, chemical, and biological properties can change dramatically with depth. CONCORDE provides detailed new information on river-dominated systems, as spilled oil traversing these regions directly threatens coastal habitats and human populations.

River-influenced coastal systems found throughout the world are productive habitats for a variety of culturally and economically important marine species. Oil drilling has resulted in repeated spills and significant environmental damage in areas such as the Niger River Delta (Ite et al., 2013) and will continue to threaten similar habitats globally (Figure 7). Principles derived, and patterns described, from CONCORDE's interdisciplinary approach to identifying and quantitatively assessing key physical, biological, and geochemical processes acting in the nGOM are applicable to other pulsed, river-dominated systems, even though there may be differing ecological communities, volumes of river discharge, and degrees of oil extraction activities relative to the nGOM. Moreover, many of these oil reserves near river mouths are currently relatively unexploited, such as those on the Alaskan shelf.

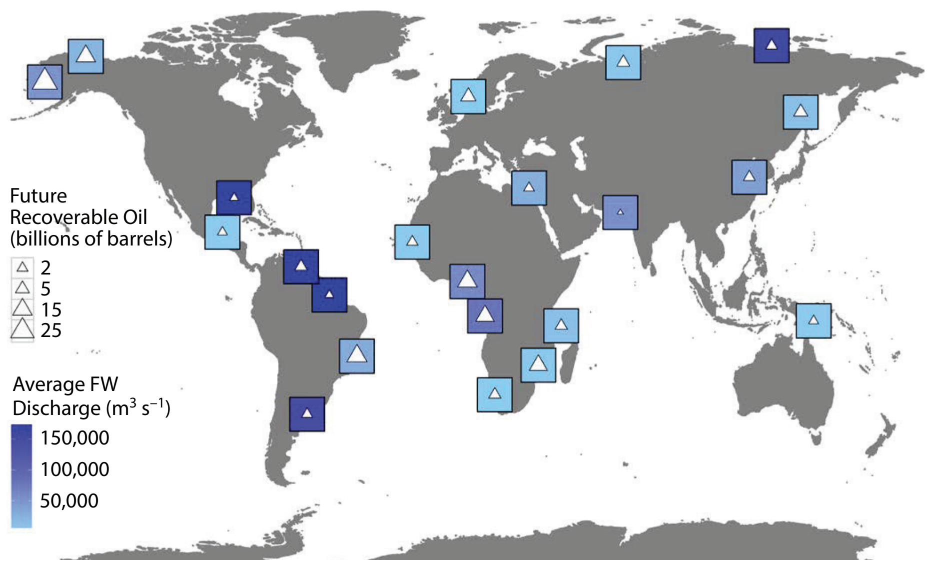

FIGURE 7. Locations of coastal river-dominated ecosystems around the world with nearby oil extraction activities that are similar to the CONCORDE domain. Color corresponds to the average freshwater (FW) river discharge, and the size of the triangle represents the current extent of oil reserves (see supplementary material data sets and references used to generate the figure).

Because accidents can have such dire consequences, as demonstrated during the Deepwater Horizon spill, understanding the physical pathways for oil and distributions of biological and chemical constituents under different oceanographic conditions must be a priority *before* extraction begins. This information provides the basis for oil spill transport modeling and estimation of exposure rates for planktonic organisms that can then be utilized in formulating response plans aimed at preserving the vital ecological functioning of the system.

SUPPLEMENTARY MATERIALS

An animation of simulated neutrally buoyant tracer release at the southern edge of the CONCORDE model domain, Gulf of Mexico is available at https://youtu.be/9FjC1bBnMSA. More information on global oil production in river-dominated ecosystems and the reference data sets used to generate Figure 7 and are available at https://doi.org/10.5670/oceanog.2018.302.

Lagrangian coherent structure assisted path planning for transoceanic autonomous underwater vehicle missions

Transoceanic Gliders are Autonomous Underwater Vehicles (AUVs) for which there is a developing and expanding range of applications in open-seas research, technology and underwater clean transport. Mature glider autonomy, operating depth (0–1000 meters) and low energy consumption without a CO_2 footprint enable evolutionary access across ocean basins. Pursuant to the first successful transatlantic glider crossing in December 2009, the Challenger Mission has opened the door to long-term, long-distance routine transoceanic AUV missions. These vehicles, which glide through the water column between 0 and 1000 meters depth, are highly sensitive to the ocean current field. Consequently, it is essential to exploit the complex space-time structure of the ocean current field in order to plan a path that optimizes scientific payoff and navigation efficiency. This letter demonstrates the capability of dynamical system theory for achieving this goal by realizing the real-time navigation strategy for the transoceanic AUV named Silbo, which is a Slocum deep-glider (0–1000 m), that crossed the North Atlantic from April 2016 to March 2017. Path planning in real time based on this approach has facilitated an impressive speed up of the AUV to unprecedented velocities resulting in major battery savings on the mission, offering the potential for routine transoceanic long duration missions.

Silbo, a deep Slocum glider in the Challenger mission was deployed in Massachusetts on the 13th April 2016 and was recovered at the South of Ireland on March 9th 2017. He completed 6506.8 km, gliding across the North Atlantic by following a saw tooth trajectory (see Fig. 1) through the top 1000 meters of the water column in 330 days by consuming 1.5 A · h/*day* (or 22.5 W · h/*day* at 15 V) from its lithium batteries (see https://marine.rutgers.edu/cool/auvs/index.php?gid=46).

Silbo's flight demonstrated that autonomous underwater deep gliders will play a preeminent role in transoceanic ocean observation in coming years[1–3]. Expectations for transoceanic gliders are high due to their ability to map and monitor the marine environment without requiring direct human control. For this reason, they provide opportunities for data acquisition in areas of the ocean otherwise difficult, dangerous or impossible to access, including areas beneath tropical cyclones or ice sheets in polar regions[3,4]. Glider's generate propulsion by modulating their buoyancy at specified depths (shallow or deep glider) and transferring a component of the induced vertical acceleration forward by means of a lifting body and swept wings. They are designed to have long endurance (months, years) and to navigate autonomously, being controlled by periodically surfacing for GPS fixes, data telemetry and opportunity for shore side operators to update the vehicle's mission. One operational consequence of designing for endurance is that the effective but low horizontal speed (0.2–0.4 m/s) makes them extremely sensitive to the current fields that they experience. As underactuated vehicles, gliders are not necessarily capable

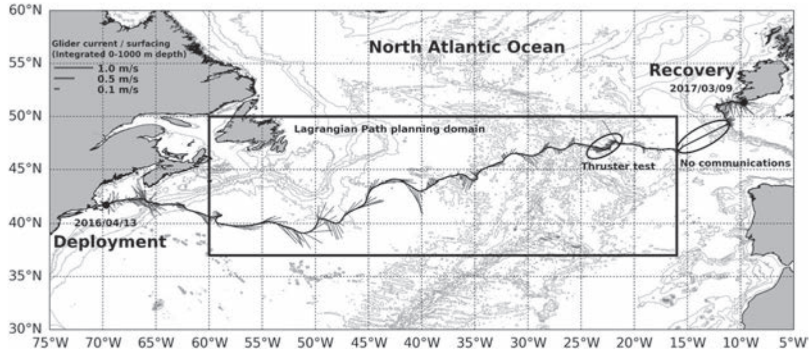

Figure 1. Silbo NE Atlantic crossing path. Silbo was deployed in Massachusetts on the 13th April 2016 and was recovered at the South of Ireland on the 9th March 2017 after completing a transect between 0–1000 meters depth of 6506.8 km in 330 days. The figure was created using python 3.5.2, matplotlib[36] module 1.5.1 (https://www.python.org/downloads/release/python-352/). Bathymetry data was obtained from Gebco[37] 2014 30 arc-second grid (http://www.gebco.net). Glider track and currents were derived from glider log navigation files. Coastlines were obtained from GSHHG - A Global Self-consistent, Hierarchical, High-resolution Geography Database (https://www.ngdc.noaa.gov/mgg/shorelines/gshhs.html).

of following an arbitrary trajectory to reach a required location. In this context, it would be a significant advantage to utilize the ocean current field in a way that could optimize the mission of the glider.

Typical conventional glider path planning methodologies for determining optimal paths have demonstrated their effectiveness in regional environments. Among these methodologies are linear programming, probabilistic sampling, potential fields or genetic algorithms and artificial intelligence methods such as A^* (see[5–11]). Some of these methods require the use of Regional Ocean Models (ROMs) forecast datasets with high space-time resolution (1/32^o, hourly). Nowadays in the open ocean only low space-time resolution models are available (1/12^o, daily) and therefore these techniques are not implementable in transoceanic glider crossing missions. In this regard if global models in the future would increase their resolution and accuracy it could be that regional methods provide efficient solutions also in these missions, but this is not the case for the current state of the art. Some attempts in this direction are references[12,13] that describe the path planning A* technique used at the end of the first Atlantic glider crossing, once it approached the Iberian coast. In particular the method was implemented with the ROM ESEOO Iberian domain data (1/32°, hourly, +72 h). Additional regional path planning requirements, as for instance the demand of environmental obstacles by the Theta algorithm, are not available at global scale, or the need of a rather stable environment just subjected to small perturbations, a must for incremental methods such as D* and Phi*, does not work in a highly dynamic and changing environment like that found in the open ocean. Long-term long-distance path planning missions require guiding techniques that are useful for highly dynamic open-sea areas, and thus they must be based on robust and fundamental ocean features.

Transoceanic Slocum glider missions are relatively recent and until now there has been only a few of them. The first successful North East transatlantic mission was achieved by the Scarlet Knight RU27 glider in 2009[1]. This mission was preceded in 2008 by the RU17 glider attempt, which was unfortunately lost just off the coast of the Azores. Other subsequent missions have been performed by Cook, Drake, Silbo and RU29 gliders[2]. Missions have been an adventurous path to learning about a completely unexplored terrain and to gain information about many different aspects of the missions, ranging from glider flight dynamics, battery consumption, resets, bathymetry risks, aborts, piloting error, physical and biological impediments (such as barnacles adhesion and fouling) and their effects on long term navigation, etc. In the Silbo mission described in this article, navigation has been in the 0–1000 m depth range, however the 2009 Scarlet Knight RU 27 flew between 0–200 meters depth range and this allowed taking a maximum advantage of the Gulf stream speed, aligned with the direction of the voyage. In other missions, with gliders Drake and Cook, deep flying has been shown to be an effective way to fight unfavorable currents since at large depths currents are weaker. Since the first missions, in order to gain insights into the ocean landscape, different approaches have been considered. The first missions were flown using Sea Surface Temperature (SST) fields as a primary reference for mesoscale flow features, and waypoints were programmed according to the displayed structures. SST was chosen for its global availability, its relatively fast update cycle from AVHRR satellite data, and its ability to resolve many surface flow features. Alternatives to this product have been currents derived from the Sea Level Anomaly, 3D current fields from models, etc. In this letter, we demonstrate the success and promise of a new approach to path planning for future AUV crossing missions that was implemented for Silbo. This is the dynamical systems approach to transport that involves using the space-time structure of the ocean current field in a way that optimizes the propulsion of the glider in a manner that promotes sustainable missions. More specifically, the methodology proposed in this mission for supporting the waypoint selection uses Lagrangian Coherent Structures (LCS). This is not disconnected from velocity fields, but based on them since LCS provide a time dependent Lagrangian pattern (i.e. based on fluid particle trajectories) which at each day encompasses information from the velocity field in past and future days, and therefore is suitable for advising about Lagrangian paths, such as those followed by gliders. Eulerian velocity fields or instantaneous temperature fields used in previous missions are more rudimentary in this regard.

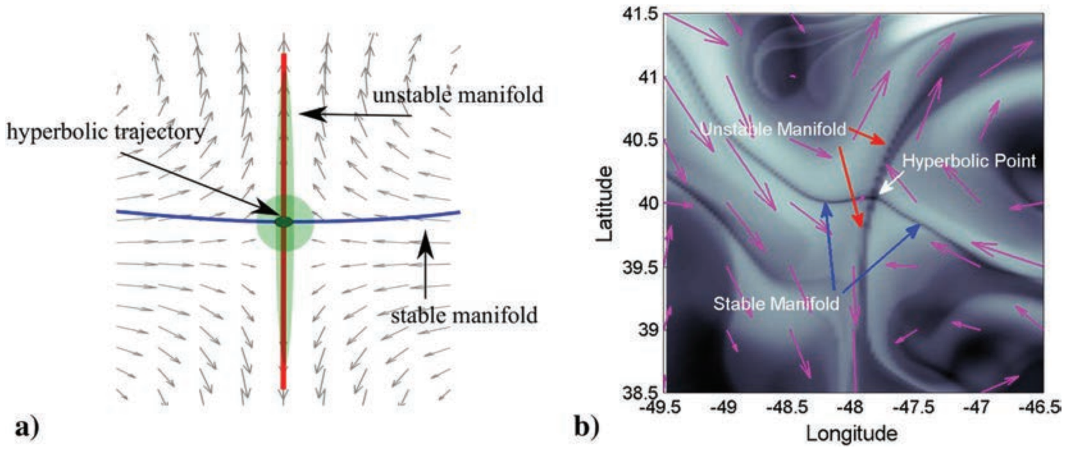

Figure 2. (**a**) A hyperbolic trajectory in a vector field. Particles at successive times evolve by approaching the hyperbolic point along the stable direction (blue) and getting away from it along the unstable direction (red). Green blobs illustrate this behavior. (**b**) Visualization of a hyperbolic point by means of the function M evaluated on Copernicus data on the 17th June 2016. The current field is drawn with magenta arrows.

The idea of exploiting natural dynamics for vehicle transport has been previously used in space mission design. The work is similar in spirit to our work in the ocean in the sense that the gravitational field of the planetary system is used to determine a desired mission trajectory for a spacecraft with low thrust capabilities[14,15]. These ideas have also been previously proposed in oceanic setting, for planning glider routes through ocean currents[16], but they have not been applied to transoceanic missions in the way that we have done for the Silbo mission.

Results

Silbo's control mechanisms allow the glider to control its heading so as to pass through manually defined waypoints (WPs) with or without compensating for local depth average current. Our goal is to extract information from the oceanic currents, in particular, about the natural dynamics of particle trajectories advected by ocean currents, since we expect that this knowledge will inform the choice of WPs. In the ocean, particles follow trajectories $\mathbf{x}(t)$ that evolve according to the dynamical system:

$$\frac{d\mathbf{x}}{dt} = \mathbf{v}(\mathbf{x}(t),\, t), \tag{1}$$

where $\mathbf{v}(\mathbf{x}, t)$ is the velocity field of the ocean in the region of interest. In our analysis we will assume that the motion of particles is mainly horizontal. Many LCS studies have been performed in a two-dimensiolnal scenario in which is assumed that fluid parcels remain on surfaces of constant density (isopycnals), which are quasi-horizontal[17–22]. We will discuss deviations from horizontal motion afterwards.

A challenge here is that even flows with smooth velocity fields may exhibit complex particle trajectories. An approach for exploiting this complexity derives from the methodology of nonlinear dynamical systems theory. Rather than seeking to understand the behavior of large ensembles of particle trajectories, this approach is based on finding geometrical structures, known as Lagrangian Coherent Structures (LCSs) that divide the ocean into regions corresponding to qualitatively distinct particle motions[23–25]. The boundaries or barriers between these regions are time dependent material surfaces (which, mathematically, are invariant manifolds). This spatio-temporal template can be constructed with a recent technique referred to as Lagrangian Descriptors (LDs). The particular LD that we use is a function referred to as M[26–28] which is defined as follows:

$$M(\mathbf{x}_0,\, t_0,\, \tau) = \int_{t_0-\tau}^{t_0+\tau} \|\mathrm{v}(\mathbf{x}(t;\, \mathbf{x}_0),\, t)\|\, dt, \tag{2}$$

where $\|\cdot\|$ stands for the modulus of the velocity vector. At a given time t_0, function $M(\mathbf{x}_0, t_0, \tau)$ measures the arclength of trajectories starting at $\mathbf{x}(t_0) = \mathbf{x}_0$ as they evolve forwards and backwards in time for a time interval τ. Large M values, represented in white color (see Fig. 2), are related to regions of high speed fluid (such as straight or circular jets), while dark colors denote calm regions. One expects that large M values will favor glider propulsion, as far as the commanded-glider trajectory is aligned with the current, and that calm ocean regions will be related to slower glider motions.

The pattern displayed by the function M depends on τ. For small τ, the function M has a smooth output, while as the parameter τ is increased, sharp features and structures emerge highlighting LCS. Typically patterns provided by very large τ values reveal a more detailed description of the dynamical history of the system. In our setting we use data from the Global Ocean Model provided by Copernicus that has forecasts for 10 days, and thus this value fixes the operational upper threshold for the forward time integration period. In practice the integration period necessary to display the required LCS depends on the characteristics of each velocity field. We have verified that $\tau = 8$ days is a sufficient choice for our data, and from the physical point of view this is consistent

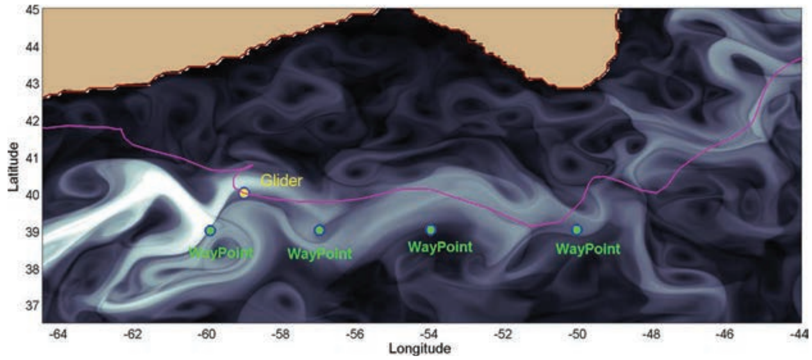

Figure 3. Lagrangian structures on the 30th May 2016 at 12:00 UTC in the NW Atlantic highlighted by the M function for $\tau = 8$ days from CMEMS velocities averaged across depths 0–902 m. The glider Lagrangian path planning panel shows WPs used to cross the Gulf Stream (27th May–27th July 2016) (see video S1). This figure was created with MATLAB version R2010b (https://es.mathworks.com). The map shown is generated with a mask of values included in the CMEMS velocity field dataset. This mask indicates regions which correspond to continental shelf and sea.

with the time required by the glider to navigate distances equivalent to the size of mesoscale ocean structures. In this way when the function M is computed for this sufficiently large τ it provides a detailed landscape from which it is possible to relate glider accelerations directly to the topography of this landscape. Of particular interest are features highlighting hyperbolic trajectories that are responsible for deflecting the grider's trajectory. Regions in the fluid characterized by high expansion and contraction rates generate the stable and unstable structures in the flow field that characterize hyperbolic trajectories. Figure 2a illustrates how blobs in the neighborhood of these trajectories evolve, contracting along the stable direction and expanding along the unstable direction. Curves associated with the stable and unstable directions of these hyperbolic trajectories are referred to as stable and unstable manifolds and they indicate optimal paths for approaching and leaving the vicinity of these trajectories. Hyperbolic trajectories are recognizable in the pattern of M as the crossing points of singular features that highlight stable and unstable manifolds. For instance, an evaluation of M on a typical data set used in this study for $\tau = 8$ days on the 17 June 2016 is displayed in Fig. 2b. Blue arrows mark the position of a stable manifold along which particles approach the hyperbolic trajectory at high speed and red arrows mark the position of an unstable manifold along which particles move away from the hyperbolic trajectory at high speed. Fluid particles slow their motion in the neighborhood of the hyperbolic trajectory. Magenta arrows representing the velocity field overlapped with the M pattern supports this interpretation of the stable and unstable directions. Next we describe how these effects, which are observed in the natural dynamics of particle trajectories advected by ocean currents, are also observed along the glider path. Given that hyperbolic points are objects for which there exist optimal pathways, they are a natural choice to be used as WPs for glider guidance. We describe next how this choice has proven to be effective.

The success of the described approach depends on how well the available velocity data represents the ocean state in the area in the domain of operation. The assessment of the ocean data with Lagrangian tools has been addressed in recent studies[20–22]. In particular[22], shows the success of the Copernicus Marine Environment Monitoring Service (CMEMS) data (available at http://marine.copernicus.eu/) for monitoring oil spill events in real time, thus supporting this product as reliably representing ocean transport and confirming its high quality. Our study supports those findings, since the Copernicus Global Ocean and Iberia-Biscay-Ireland sea models have provided data which successfully supported the guidance of Silbo.

During the Trans-Atlantic mission, Silbo navigated at depths ranging from the surface to 900 meters following a saw tooth trajectory. This means that during navigation Silbo experienced currents at different depths from the upper Atlantic layers. Fully 3D studies performed in quasi 2D flows such as the ocean or the stratosphere have shown that 3D Lagrangian structures are close to those obtained by a'vertical extension' of the evolving structures calculated in the 2D plane approximation[19,29,30]. Across most of this water column, Lagrangian patterns have a vertical curtain-like structure with only slight differences in each horizontal plane. Our approach to this problem then has been to study the 2D problem in Equation (1), by means of a representative 2D velocity field of the upper layers. To this end we have considered vertical averages of the instantaneous horizontal velocities components supplied by the model in the range 0–902 meters. We have compared these results with those obtained just by considering velocities at the 453 meters sigma layer, which is the mid layer of the total vertical range swept by the glider, and also averaged velocities over the water column 0–453 meters. We have found that Lagrangian structures are very similar in all cases, and we proceed to report results mainly with the first choice, i.e. averages across the range 0–902 meters. This choice is also supported by our observational experience as agrees well with the glider derived current field. Additional results with the other choices are also reported for comparative purposes.

Figure 3 shows the operational panel used for glider path planning. The integration period for these patterns is $\tau = 8$ days. Waypoints are introduced according to the hyperbolic trajectories observed in Lagrangian patterns highlighted in the background, by looking for favorable navigation routes between hyperbolic trajectories towards the final destination of the glider. Stable and unstable manifolds associated to the hyperbolic trajectories

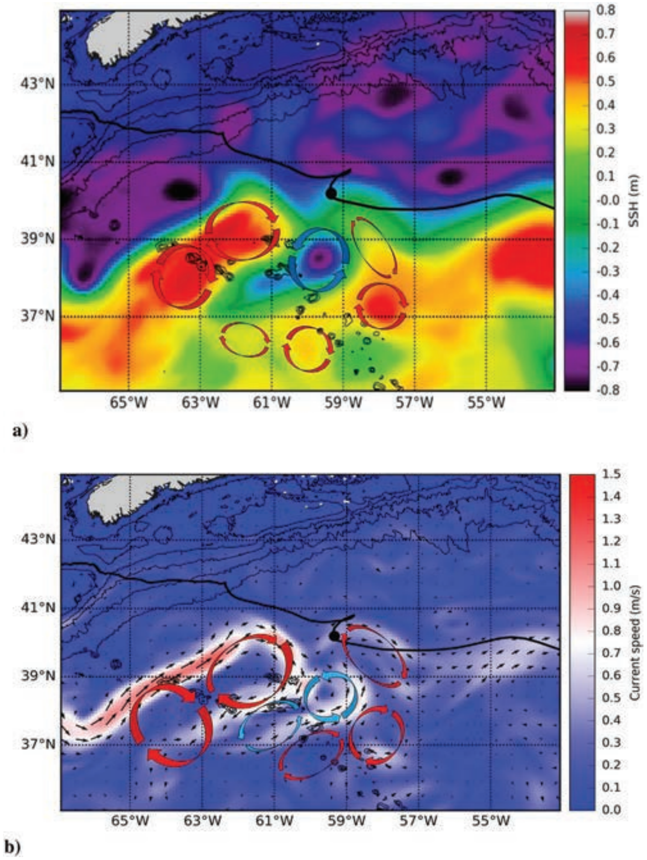

Figure 4. Glider path and Eulerian Gulf Stream description with the CMEMS dataset illustrating warm and cold vortex cores on the 30th May 2016. (**a**) Sea surface height (SSH) above geoid. (**b**) Velocity fields and averaged current speed (0–902 m). The figure was created using python 3.5.2, matplotlib[36] module 1.5.1 (https://www.python.org/downloads/release/python-352/). Bathymetry data was obtained from Gebco[37] 2014 30 arc-second grid (http://www.gebco.net). Glider track was extracted from glider log navigation files. Coastlines were obtained from GSHHG - A Global Self-consistent, Hierarchical, High-resolution Geography Database (https://www.ngdc.noaa.gov/mgg/shorelines/gshhs.html). SSH and current fields were obtained from Operational Mercator global ocean analysis and forecast (GLOBAL_ANALYSIS_FORECAST_PHY_001_024 product in Copernicus marine segment, http://marine.copernicus.eu).

are recognised as singular lines in the background. Hyperbolic trajectories are suitable to select as waypoints supporting glider bearing since these objects have invariant manifolds which provide an optimal path for reaching the WPs. Eulerian fields shown in Fig. 4 do not display such objects and therefore it is more difficult to find a criterion for fixing waypoints using solely Eulerian information.

The major findings of this work are summarized in the movie S1, which runs from the 15th April 2016 until the 1st November 2016. This animation overlaps the Lagrangian pattern provided by function *M* (obtained from velocities averaged in the 0–902 m range), with Silbo's speed at different points along the glider path. Additionally, the movie displays instantaneous averaged velocity fields and the waypoint positions at different times.

The analysis of the movie S1 confirms that the exploitation of natural dynamics efficiently optimizes glider transport. Alternatively, if the glider is forced to fly against this natural dynamic, speeds of the glider are notoriously small. We describe two events in the movie supporting the first assertion, and two events supporting the second one. Table 1 summarizes these findings. Between the 14th-17th of June and the 18th-23rd June 2016 two successive events (Events 1 and 2 in Table 1) take place which demonstrate the enhancement of glider speed due to the presence, in an appropriate configuration, of geometrical dynamical objects described as hyperbolic trajectories and their stable and unstable invariant manifolds. In these two events the glider shows high performance (high velocities) while it approaches to a hyperbolic trajectory (HT) through its stable manifold (SM) and when it leaves its neighborhood through the unstable direction (UM). In the vicinity of the HT the glider reduces its speed. Figure 5 supports this description by specifically selecting areas of the movie S1 at days 19th, 20th and 23rd June 2016 which encompass the glider and the hyperbolic point. In particular, Fig. 5a shows the glider position and its speed while approaching a hyperbolic point along its stable manifold on the 19th June 2016. Figure 5b confirms the speed reduction at the closest position to the hyperbolic point on the 20th June 2016. Figure 5c shows the glider moving away from the hyperbolic point through the unstable manifold on the 23rd June 2016. Remarkably, this day the glider speed achieves a record velocity (1.04 m/s), which is unprecedented for this type of missions, since typical operational velocities for this type of gliders are below 0.5 m/s. These findings confirm

Event	Time interva	Day/Glider speed (m/s)/Configuration	Day/Glider speed (m/s)/ Configuration	Day/Glider speed (m/s)/Configuration	Day/Glider speed (m/s)/Configuration
1	14–17 June 2016	14 June/0.95/(SM)	15 June/0.48/(SM)	16 June/0.23/(HT)	17 June/0.34/(UM)
2	19–23 June 2016	19 June/0.56/(SM)	20 June/0.41/(HT)	22 June/0.70/(UM)	23 June/1.04/(UM)
3	7–16 Sept 2016	7 Sept/0.16/(HT)	10 Sept/0.08/(SM)	11 Sept/0.06/(SM)	16 Sept/0.06/(SM)
4	17–29 Sept 2016	18 Sept/0.05/(UM)	22 Sept/0.03/(UM)	26 Sept/0.06/(UM)	29 Sept/0.11/(HT)

Table 1. Detailed description of five events with special configurations that propel or slow down glider motion. Each event is described by the day, the glider speed and its position with respect to the dynamical objects: hyperbolic trajectories (HT) and their stable (SM) and unstable (UM) manifolds. Sequences SM-HT-UM provide high speed along manifolds and reductions in the vicinity of HT. Configurations such as HT-SM or UM-HT force the glider to move against the natural dynamics resulting in a slowing down of the motion along manifolds.

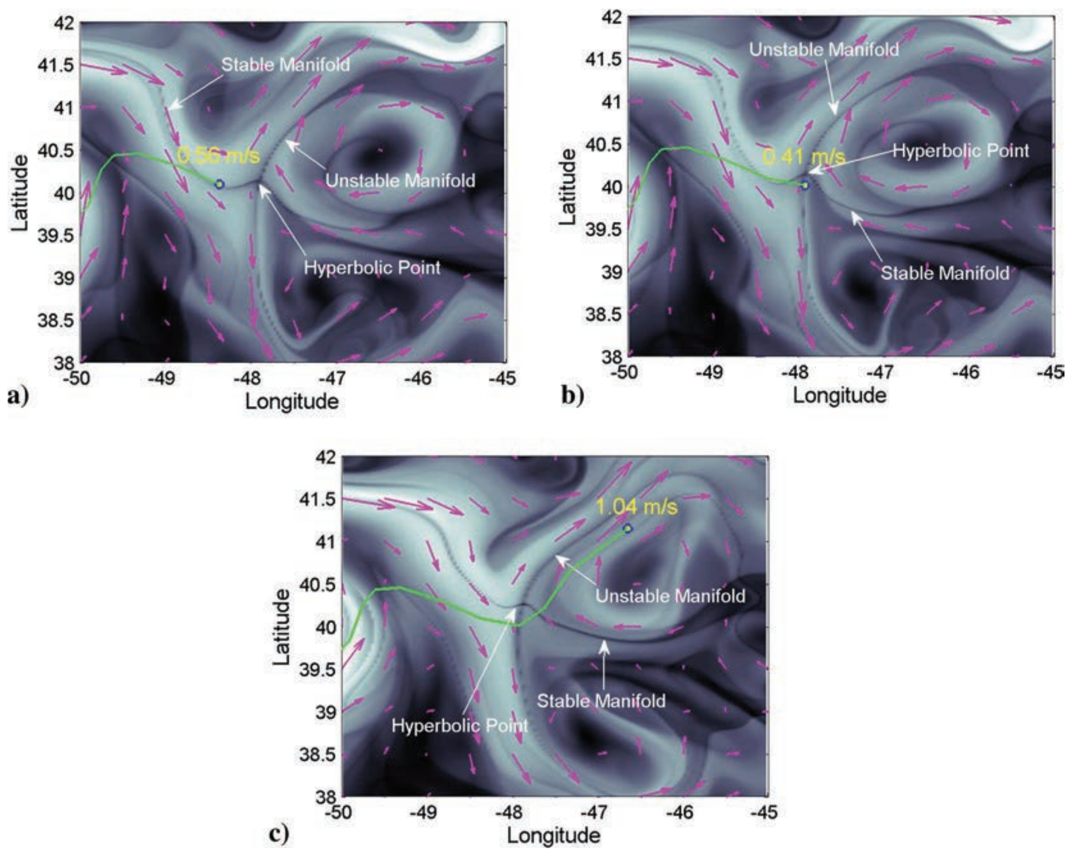

Figure 5. Glider path and Eulerian velocity fields in the neighborhood of a hyperbolic trajectory highlighted by the function M. (**a**) 19th June 2016. (**b**) 20th June 2016. (**c**) 23rd June 2016.

that stable manifolds (SM) are optimal paths towards the HT, i.e. the glider approaches to the HT very efficiently along this direction. On the other hand, unstable manifolds (UM) are the optimal path for moving away from the HT. In the neighborhood of the HT the glider slows down. Consequently, an optimal path to navigate is to follow the dynamical sequence SM-HT-UM. To avoid excessive slow down near the HT, it is appropriate that before approaching it to closely, the WP placed there is moved to a new HT. This HT must be selected in such as a way that its SM is aligned with the UM of the previous HT, so that the new WPs force the glider to leave the neighborhood of the previous HT along the direction of the UM. An appropriate navigation sequence thus would concatenate: SM-HT-UM/SM-HT-UM. This results in a wave-shape path with the glider moving alternatively from stable to unstable manifolds, as visible from Fig. 3. The video also shows that Silbo described this waving-path when it speeded up to 1 m/s and flied out the NE American waters heading to the open North Atlantic waters.

In order to make a correct interpretation of the stable and unstable directions of an HT the instantaneous depth-averaged current field must be superimposed onto the M field so that the direction of the manifolds is revealed. It is not possible to distinguish these directions just from the function M template. If a glider were to approach a HT along an unstable manifold, it would slow down since it would be navigating in a counter-current flow. Two events of this kind are described next.

Events 3 and 4 in Table 1 correspond to a period in which the glider was flown against the current to test its propulsion mechanism. In these events the glider navigates towards the HT along its unstable manifold or leaves the HT along its stable manifold. Therefore the glider follows inverse paths to those described above as it moves along manifolds that do not support its displacement. In this case the glider shows extremely low speeds when it is at positions along the manifolds, and speeds slightly increases in the neighborhood of the HT.

We also remark that during the mission, typically, Silbo navigated with the current correction mode off. Thus it was sensitive to strong currents as it was not forced to approach the WPs following a straight line. There exist days, visible from the movie, in which currents deviate the glider from a rectilinear path, at stages in which the glider is still far from the WP, however these deviations are not an obstacle to approaching the WPs.

Movie S2 and S3 represent, respectively, Lagrangian structures for velocities averaged in the range 0–453 m and at the 453 m depth layer. These movies support similar conclusions to the ones obtained from S1, thus confirming assumptions about the robustness of the Lagrangian structures and their ability to provide a fundamental ocean landscape for navigation in spite of uncertainties.

Conclusions

Long-time, long-distance transoceanic glider path planning is now possible using dynamical systems methodologies and techniques that have been used before in astronautics (e.g. the Mariner 10, Voyager 1, and Rosetta missions[31–33]) to support the flight of low cost space missions based on gravity assisted trajectories. However, the implementation of path planning based on dynamical systems ideas in the oceanic context, presents new challenges. The described dynamical analysis relies on the quality of the velocity fields (geometrical objects such as hyperbolic trajectories and their invariant manifolds depend upon knowledge of the flow field). Ocean motions are turbulent in nature, thus obtaining trusted ocean current forecast and analysis remains a challenge. The success of the application of the dynamical systems methodology to the Silbo transoceanic mission confirms the high reliability of Copernicus Global Data to accurately represent the ocean state across the North Atlantic, since the identified hyperbolic trajectories and their stable and unstable manifolds are indeed present in the ocean and visible to the glider, providing effective navigation routes on which the glider has reached exceptionally high speeds which have no precedent in this context. We expect that the described methodology and tools will contribute to the discovery of new underwater clean-transport pathways for crossing oceans. Effective path planning in transoceanic glider missions will open new possibilities for improving the quality and increasing the density of measurements in under-sampled open-ocean deep regions (0–1 km depth), which could be assimilated and incorporated into global operational marine forecasting systems. This, in turn, will positively impact the diagnostic of deep sea observed changes due to global climate change.

Methods

Glider Data. Silbo. North Atlantic crossing 2016–17. Challenger Glider Mission.

Ocean Data. The ocean velocity fields used in this work were obtained from the Copernicus Marine Environment Monitoring Service (CMEMS) available at http://marine.copernicus.eu/. In particular, we have used the datasets provided by the high resolution Global Ocean Model[34] for most of the mission (the global analysis and forecast product GLOBAL_ANALYSIS_FORECAST_PHY_001_024). The system contains daily 3D global ocean current field data. The horizontal resolution of the model is 1/12° (approximately 8 km) with regular longitude/latitude equirrectangular projection and 50 vertical geopotential levels ranging from 0 to 5500 meters. In particular, to perform the Lagrangian path planning simulations, the daily operational velocity fields have been derived from the dataset by averaging the currents over the water column that extends from 0 to 902 meters depth (glider diving depth).

Mathematical Model. We consider the trajectories of passive fluid particles in a two-dimensional surface (quasi-horizontal approximation) described by Equation (1). In particular, we consider the equations of motion written in spherical coordinates on a sphere of radius $R = 6371\, km$, which are given by:

$$\frac{d\lambda}{dt} = \frac{u(\lambda, \phi, t)}{R \cos\phi}, \quad \frac{d\phi}{dt} = \frac{v(\lambda, \phi, t)}{R}, \tag{3}$$

where λ is longitude and ϕ latitude, u and v represent respectively the eastward and northward components of the velocity field provided by the dataset. The computation of fluid particle trajectories is necessary in order to evaluate the function M in Equation (2). Trajectories are calculated by integrating Equation (3), and since ocean currents are provided on a discrete space-time grid, we need to deal with the issue of interpolation. We have used for that purpose bicubic interpolation in space and third order Lagrange polynomials in time according to the details given in[20,35].

ABSTRACT

Cross-isobath transport of Upper Circumpolar Deep Water (UCDW) provides a major source of heat to the Antarctic continental shelves. Adaptive sampling with a Slocum glider revealed that the UCDW regularly intrudes onto the western Antarctic Peninsula shelf within mesoscale eddies, and a linear stability analysis of the shelf-break current upstream confirmed eddy length scales and vertical structure are consistent with the baroclinic instability of the current. The properties of the most unstable mode are insensitive to current orientation but sensitive to bottom slope in accordance with modified Eady theory. Once on the shelf, the eddies' core properties mix with ambient shelf water to form modified CDW (mCDW). Concurrent shipboard CTD and ADCP data are used to diagnose the responsible mixing processes and highlight the importance of thermohaline intrusions. The genesis mechanism of the interleaving layers cannot be confirmed, however a simple analytic model suggests the upper limit contribution of advection by internal waves cannot account for the observed temperature variance unless the cross-eddy temperature gradient is large. Data-adaptive sampling of an eddy with the glider revealed it lost heat across two isopycnals and a fixed radius at a rate of 7×10^9 J s^{-1} over 3.9 days. This rate is corroborated by a diffusion model initialized with the eddy's initial hydrographic properties and informed by the heat fluxes parameterized from the shipboard data. The results suggest eddies predominately lose heat laterally and downward, which preserves subsurface heat for melting of marine-terminating glaciers.

1. Introduction

The West Antarctic Peninsula (WAP) is bordered by the Antarctic Circumpolar Current (ACC), which flows along the continental slope. Below the surface layer, the ACC advects a warm mass of Circumpolar Deep Water (CDW) with significant heat content relative to the in situ freezing point. The CDW spans a range of properties, though Gordon (1971) distinguishes between an upper (UCDW) and lower (LCDW) variety defined by temperature and salinity maxima, respectively. The southern boundary of the ACC is defined as the southernmost presence of UCDW (Orsi et al. 1995) and, unique compared to the rest of Antarctica, near the WAP the ACC flows immediately adjacent to the shelf break, making UCDW readily available to the shelf (Fig. 1).

The WAP is undergoing rapid climate change and the ocean is a primary heat source, particularly in winter when there is no direct radiative forcing. The marginal seas of West Antarctica are warming (Schmidtko et al. 2014) and the increase in heat content along the WAP margin has been attributed to a warming of the UCDW T_{max} (Martinson et al. 2008). Cook et al. (2016) confirm an oceanic role in glacier retreat along the WAP by demonstrating an asymmetry in glacial advance/retreat: southern marine-terminating glaciers that have access to warm subpycnocline waters are retreating whereas northern glaciers under the influence of much colder Bransfield Strait waters are not. More and/or warmer CDW has also left its imprint on the atmosphere. The northern portion of the WAP is undergoing rapid winter warming (Turner et al. 2013), presumably related to

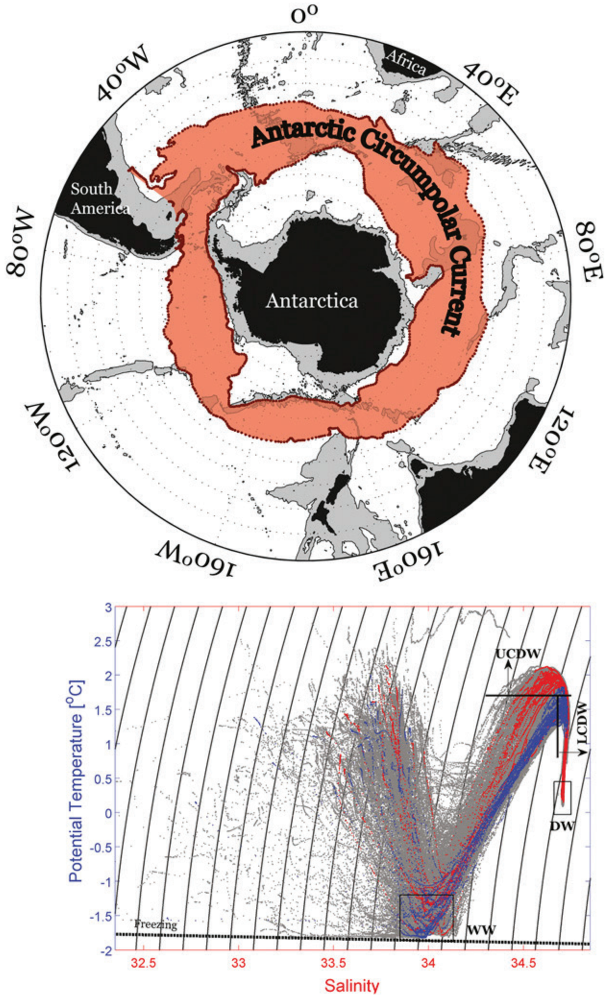

FIG. 1. (top) Location of climatological ACC (Orsi et al. 1995), transporting warm UCDW. Bathymetry shallower than 3 km is shaded. (bottom) Potential temperature–salinity properties within the LTER sampling grid (gray) highlighting those from a shelf station (300.100, blue) and a slope station (200.160, red) to emphasize the difference in UCDW properties. UCDW is identified as a potential temperature greater than 1.7°C, LCDW is identified as a salinity greater than 34.68 (with potential temperature less than 1.7°C), and WW and Deep Water (DW) are defined as in Martinson et al. (2008). The DW is a definition used by Martinson et al. (2008) in order to define a local end member for a water mass mixing analysis and is not an actual water mass of the Southern Ocean (and is not discussed here).

lighter sea ice cover venting ocean heat to the atmosphere. The reduced sea ice cover, in turn, may be related to changes in the winds and their effect on UCDW delivery and mixing across the pycnocline (Dinniman et al. 2012).

The myriad consequences of UCDW heat have made the exchange of CDW with the WAP shelf an active area of research (Klinck 1998; Smith et al. 1999; Klinck et al. 2004; Dinniman and Klinck 2004; Moffat et al. 2009; Dinniman et al. 2011, 2012; Martinson and McKee 2012; Spence et al. 2014, 2017; Graham et al. 2016; Couto et al. 2017), which is summarized in a recent review by Moffat and Meredith (2018). Various processes have been implicated in driving the cross-isobath transport of CDW onto the WAP shelf, each of which may dominate on different time and/or space scales. The importance of the mesoscale has been argued for by theoretical means (Stewart and Thompson 2015), demonstrated in high-resolution numerical models (St-Laurent et al. 2013; Graham et al. 2016; Stewart et al. 2018), and observed (Moffat et al. 2009; Martinson and McKee 2012; Couto et al. 2017). Warm-core, subpycnocline, primarily anticyclonic eddy-like features have been found within several tens of kilometers from the shelf break, particularly in the vicinity of Marguerite Trough, and are steered along isobaths. The hydrographic properties of the eddies indicate an injection of UCDW as it is found on the continental slope and their length scale is as large as or slightly larger than the first baroclinic Rossby radius, which near the shelf break is about 5 km. Decorrelation lengths of physical and geochemical scalars on the WAP shelf are also about 5 km (Eveleth et al. 2017), suggesting mesoscale eddies may dominate tracer stirring. The eddies' large heat content relative to surrounding waters indicates a potentially large onshore heat flux. For example, in numerical models, cumulative onshore heat transport is reduced by as much as 50% when model grid spacing is increased from 1 to 2 km (St-Laurent et al. 2013).

Still, very little is known about the origin of the eddies. Their core hydrographic properties and stratification suggest an origin along the continental slope and their observation along isobaths suggests they are, at least in part, advected within the mean flow. Consistent with the former, an idealized numerical model with a continental slope straddled by a jet similar to that observed along the WAP suggests that the jet soon becomes unstable and a Rossby wave containing alternating warm anticyclones and cold cyclones emerges (St-Laurent et al. 2013). Additionally, it is important to understand the processes that attenuate the mesoscale variability and work toward setting the larger-scale shelf stratification. Once UCDW intrudes onto the shelf it mixes to become modified CDW (mCDW), but attempts to understand UCDW transformation have been based on shelf-integrated budgets and have been process independent (Klinck 1998; Smith et al. 1999; Klinck et al. 2004).

In this study we seek to both understand the origin of mesoscale eddies observed on the WAP shelf and then identify and quantify the major processes responsible for their heat loss. Our focus is on the southern grid region of the Palmer Long Term Ecological Research project (Pal LTER; Smith et al. 1995) and in particular the vicinity of Marguerite Trough as this is a region of frequent eddy activity, is close in proximity to the shelf-break jet that we hypothesize generates the eddies, and contains well-defined bathymetric pathways by which to steer the eddies. We primarily use data from a novel Slocum glider survey designed to sample a known pathway for CDW exchange, documenting gradients along the axis of advection for any eddies encountered along the way, and then identify and track an eddy in real time through data-adaptive sampling. This allows, for the first time, high-spatial and temporal resolution transects directly through some of these eddies and a real-time quantification of the attenuation of their core properties. We supplement this with shipboard CTD and ADCP data used to quantify the mixing processes in the WAP environment around and within the eddies and to diagnose the instability that generates the eddies. Ultimately, we simulate the evolution of the eddy as documented by the glider with a simple diffusion model informed by our parameterized mixing processes.

2. Data and observations

The principal dataset used in this study is a set of temperature and salinity profiles collected by a Teledyne–Webb Slocum glider (Schofield et al. 2007) equipped with an unpumped Sea-Bird CTD. Slocum gliders traverse the water column (to 1000 m) in a sawtooth pattern by changing their buoyancy, traveling with average horizontal speed of $0.35\,\mathrm{m\,s^{-1}}$. There is a hysteresis effect apparent in the up versus down traces that we correct by applying the thermal lag correction of Garau et al. (2011). We also empirically correct for a salinity bias by regressing glider-recorded salinity against ship-recorded salinity, each averaged in subpycnocline temperature bins, for five stations that were occupied by both platforms (maximum temporal separation of 12 days). To facilitate analysis, all corrected up and down traces are binned into 1-m profiles whose latitude, longitude, and time coordinates are taken as the average of all intraprofile samples.

The glider was deployed at Palmer Station at the head of Palmer Deep Canyon (PD) and traveled downgrid before reaching grid station 400.100 (see Fig. 2 for grid convention and physical setting), at which point it began the first of two phases of sampling. In the first phase, the glider flew against the mean current within the anticyclonic cell extending out of Marguerite Trough in order to sample any eddies being advected across the shelf and to identify lateral gradients in their properties. In the second phase, after reaching station 290.115 within Marguerite Trough, it waited to come across an eddy in order to track it in real time. The sampling strategy and basic observations of each of these stages are described below.

a. *Glider survey: Advective Path*

1) SAMPLING STRATEGY

The Advective Path (highlighted in Fig. 2) refers to the anticyclonic cell extending out of Marguerite Trough that carries upwelled UCDW to the northern portion of the grid. This path was confirmed to carry UCDW by Martinson and McKee (2012), and its width and central location were inferred from the depth-averaged currents and CDW dye transport in Dinniman et al. 2011 (their currents superimposed on our Fig. 2). Because the width of the current is about the same as the expected diameter of the eddies we were confident that by flying straight through it we would be able to cross any existing eddies traversing the shelf. Nominal glider profile spacing is 1 km, which should afford several profiles through each eddy.

2) EDDY CHARACTERISTICS

As the glider flew upstream (downgrid), it encountered five eddies imbedded within the subpycnocline $T_{\max}$ layer. We define a mCDW temperature profile as the along-isopycnal average of all profiles whose $T_{\max}$ is <1.55°C and then compute heat content per unit area Q of the eddy profiles relative to this mCDW profile by differencing the two and integrating between $\sigma_{\mathrm{shal}} = 1027.64\,\mathrm{kg\,m^{-3}}$ and $\sigma_{\mathrm{deep}} = 1027.76\,\mathrm{kg\,m^{-3}}$. We use neighboring mCDW as our reference profile because we are interested in how the eddies mix with their surroundings. We choose these isopycnals since 1) they encompass a positive temperature anomaly within eddies, 2) σ_{shal} is relatively stable within the permanent pycnocline, and 3) σ_{deep} is near, but does not intersect, the bottom. Series of temperature, salinity, heat content per unit area, and geostrophic current at 280 dbar relative to the bottom are shown in Fig. 3, with the eddies labeled A–E (geographic locations of eddies A–E shown in Fig. 2). Fundamental statistics for each eddy developed and discussed below are given in Table 1.

To quantify the dimensions, gradients, and heat content of these eddies, we obtain an analytical representation for the eddy in terms of a Gaussian function that is fit to the data via nonlinear regression. Specifically, we

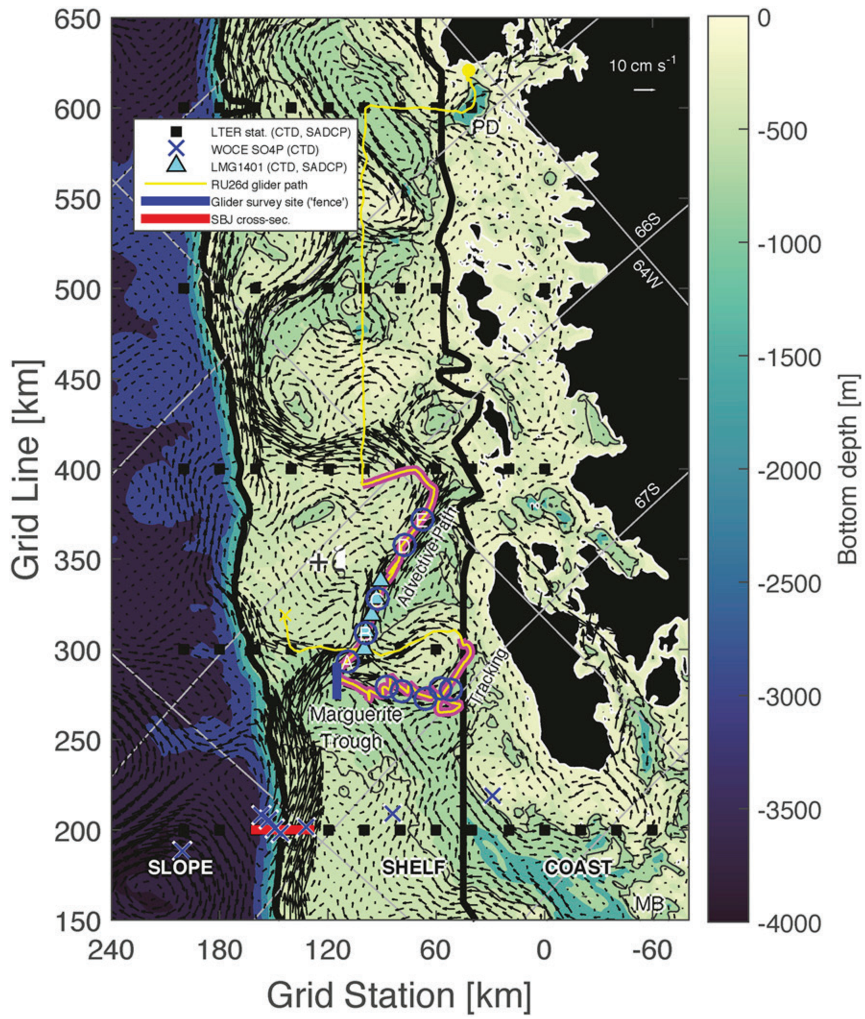

FIG. 2. Map of study region and all data used. LTER sampling grid (shipboard CTD, ADCP) shown as black squares (100 grid line is not shown but is used). All locations in the paper use the LTER coordinate system and are given as GGG.SSS where GGG is the grid line (km) and SSS the grid station (km). Origin 000.000 is at ~69.0°S, ~73.6°W, near Alexander Island. WOCE S04P CTD locations are shown as "x" symbols, and they are gridded onto the 200 line (red line, see text). Additional CTD casts taken in January 2014 are shown as triangles. The flight of glider RU26d is indicated by the yellow line (beginning at circle), and the survey fence is denoted by the blue line perpendicular to the eastern wall of Marguerite Trough. The two stages of the glider mission are described in section 2, are emphasized with a magenta outline, and are labeled; the eddies encountered are indicated by blue circles. Finally, for reference we present a snapshot of the depth-averaged currents during a CDW upwelling event from the model run of Dinniman et al. (2011) with reference vector in upper right corner. Marguerite Trough, which cuts across the center of the shelf into Marguerite Bay, is labeled along with Marguerite Bay (MB) and Palmer Deep (PD). The center of the anticyclonic cell extending out of Marguerite Trough is labeled $+\zeta$. Grid bathymetry is shaded between contours at 0, 200, 350, 500, and 750 m and then at 750-m intervals until 3750 m. The 480-m isobath, which is continuous between Marguerite Trough and the Advective Path, is indicated in black. The bold black lines separate the Slope, Shelf, and Coast regimes.

identify intraeddy profiles via positive heat content and assign them an along-eddy coordinate χ along an axis determined via orthogonal regression of profile grid line against grid station. This allows inversion of the following model

$$Q(\chi) = Q_{\max} \exp\left[-\left(\frac{\chi - \chi_0}{R}\right)^2\right], \qquad (2.1)$$

for core heat content per unit area $Q_{\max}$, center χ_0, and radius R. Implicit in this model is the assumption of

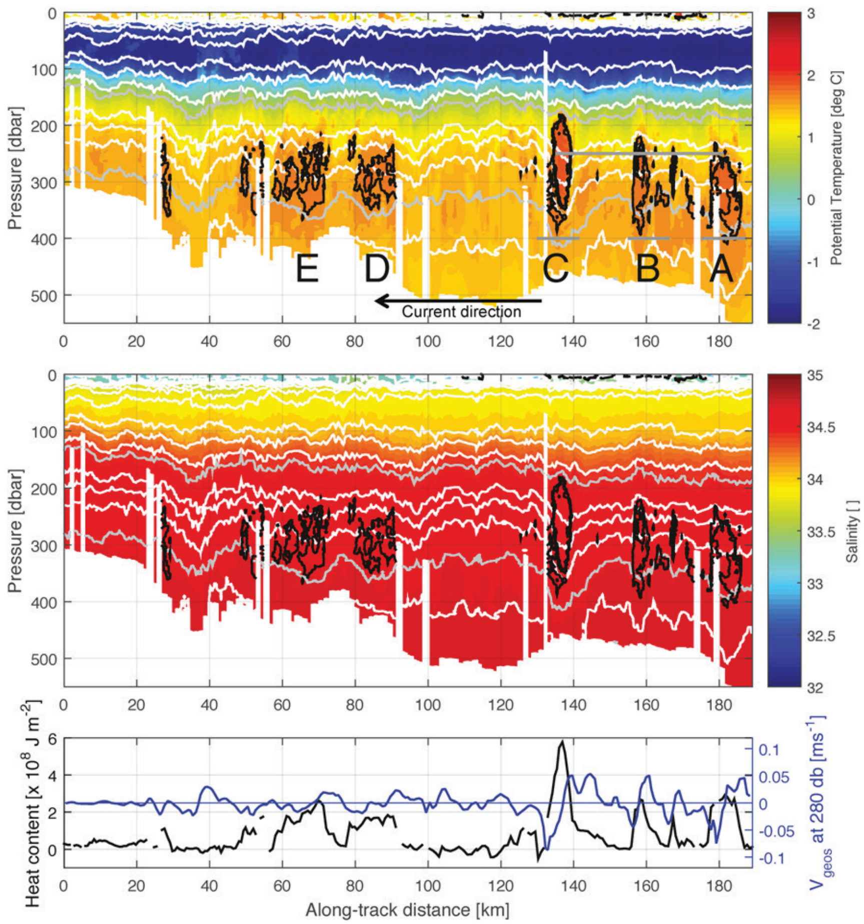

FIG. 3. Summary of glider observations over the Advective Path. (top) Potential temperature (colors) with the 1.7° and 1.8°C isotherms (black) and isopycnals (white; σ_{shal} and σ_{deep} in gray) indicated. Eddies are labeled A–E, alphabetically increasing with distance from shelf break. Scales and separation distance of the upstream (at right) eddies are indicated with thick gray lines. (middle) As in the top panel, but for salinity. (bottom) Heat content relative to mCDW integrated between σ_{shal} and σ_{deep} (black) and geostrophic current at 280 dbar relative to seafloor (blue).

axisymmetry, which we maintain throughout the paper. Our model is similar to those used by other authors (Couto et al. 2017), however we fit the function to integrated heat content as opposed to along-isopycnal temperature anomalies since integration smooths over some of the locally high temperature variance that can reduce the quality of fit. The total eddy heat content is given by the radial and azimuthal integrals of Q:

$$Q_{\mathrm{tot}} = 2\pi \int_{\chi_0}^{\chi_0+R} (\chi - \chi_0) Q(\chi)\, d\chi. \tag{2.2}$$

TABLE 1. Fundamental statistics for eddies sampled by glider along Advective Path, where gl_0 and gs_0 are the grid line and grid station coordinates, respectively, at χ_0.

	R (km)	R_{TD} (km)	H (m)	$Q_{\max}$ (10^8 J m^{-2})	Q_{tot} (10^{16} J)	gl_0 (km)	gs_0 (km)	V_{g} (m s^{-1})	$\partial T/\partial z\vert_{\mathrm{top}}$ (10^{-2} °C m^{-1})	$\partial T/\partial z\vert_{\mathrm{bot}}$ (10^{-3} °C m^{-1})	$\partial T/\partial r\vert_R$ (10^{-4} °C m^{-1})

It is important to note that radii (and heat content) determined from this method are underestimates because the glider may not be going straight through the eddy (they are half chord lengths) but also because the glider is deliberately flying against the mean flow which is advecting the eddy through the glider during sampling. Therefore, we provide an additional measure of eddy size as half the along-track distance spanned by intraeddy profiles (R_{TD}), which tends to be slightly larger.

The cores of the eddies contain as much as $5.5 \times 10^8\,\mathrm{J\,m^{-2}}$ relative to the reference profile. In T–S space, the properties of these eddies are consistent with UCDW. Particularly so, eddy C contains water disjoint from neighboring water, consistent with UCDW as found upstream on the continental slope and indicating warm-core isolation. The upstream eddies A–C are narrower than their downstream counterparts D–E, having radii R ~3 km (R_{TD} ~5 km) compared to R ~7 km (R_{TD} ~9 km). Eddies D–E are broader than the upstream eddies but do not have a substantially smaller heat content per unit area and in fact tend to have more total heat. The large discrepancy in upstream versus downstream total heat content might be more reflective of a sampling bias (offset trajectory through eddy center and stronger head current encountered through eddies A–C) as opposed to an actual difference in heat content. The injection of UCDW into the shelf water column means that the eddies are associated with a downward deflection of isopycnals and anticyclonic shear (Fig. 3). The deflection of isopycnals is largest in the weakly stratified portion of the water column at and below the T_{max}, which leads to a cross-track geostrophic velocity signal. To quantify this, we evaluate the geostrophic current at 280 dbar relative to the bottom. We choose this depth as it is the approximate depth of the moored current meters used by Martinson and McKee (2012) upstream where they found the largest eddy signal. A composite over all of the eddies (Fig. 4) reveals a well-defined signature of anticyclonic rotation centered about a warm core, similar to the composites of Moffat et al. (2009).

We measure temperature gradients at the eddy boundaries via a least squares approach. We define $\partial T/\partial z|_{top}$ by regressing a straight line to the portion of the temperature profile spanning 10 m above and below the depth of σ_{shal} and then averaging the slopes laterally across all profiles within $\chi_0 \pm R$. We define $\partial T/\partial z|_{bot}$ similarly, considering the region 40 m above and below the depth of σ_{deep}. To estimate $\partial T/\partial r|_R$, we fit a straight line on each isopycnal to the

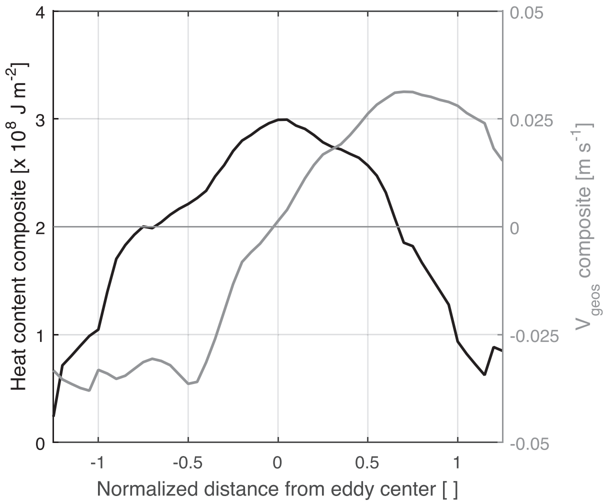

FIG. 4. Composite heat content per unit area (black) and geostrophic current at 280 dbar relative to bottom (gray) for eddies A–E. To account for different eddy sizes, each is first stretched or squeezed by interpolating onto a dimensionless grid with values −1 and +1 at the downstream and upstream edges $\chi_0 - R$ and $\chi_0 + R$, respectively.

temperature value at the profile nearest to $\chi_0 \pm R$ and up to two values on either side of that profile and then average the slopes between σ_{shal} and σ_{deep} and across both hemispheres. Owing to the nature of glider sampling, for the same reasons radius estimates are underestimates, lateral gradient estimates are overestimates. Vertical gradients are similar for all eddies while lateral gradients are larger for the three upstream eddies.

b. Glider survey: Tracking Stage

1) SAMPLING STRATEGY

We conducted transects along a ''fence'' perpendicular to the eastern wall of Marguerite Trough (Fig. 2, blue line) to find an eddy and then track it via real-time adaptive sampling. Given the local Rossby radius (~5 km), the mean flow speed, an assumption that eddies are advected within the mean flow, and the lateral deviation of the mean flow, we determined that the fence should be 15 km wide and that it should be surveyed back to back in a 24 h period, which is within the operational constraints of the glider. During sampling, profiles were inspected for a $T_{max} \geq 1.8°C$ as evidence of a UCDW-core eddy and, if found, trajectories were forecast by integrating along both the vector of 24-h mean glider depth-averaged currents and along a streamline fit to the Dinniman et al. (2011) model time–depth-averaged currents, both of which generally agreed within one Rossby radius. We encountered an eddy shortly after initiating sampling and crossed it five

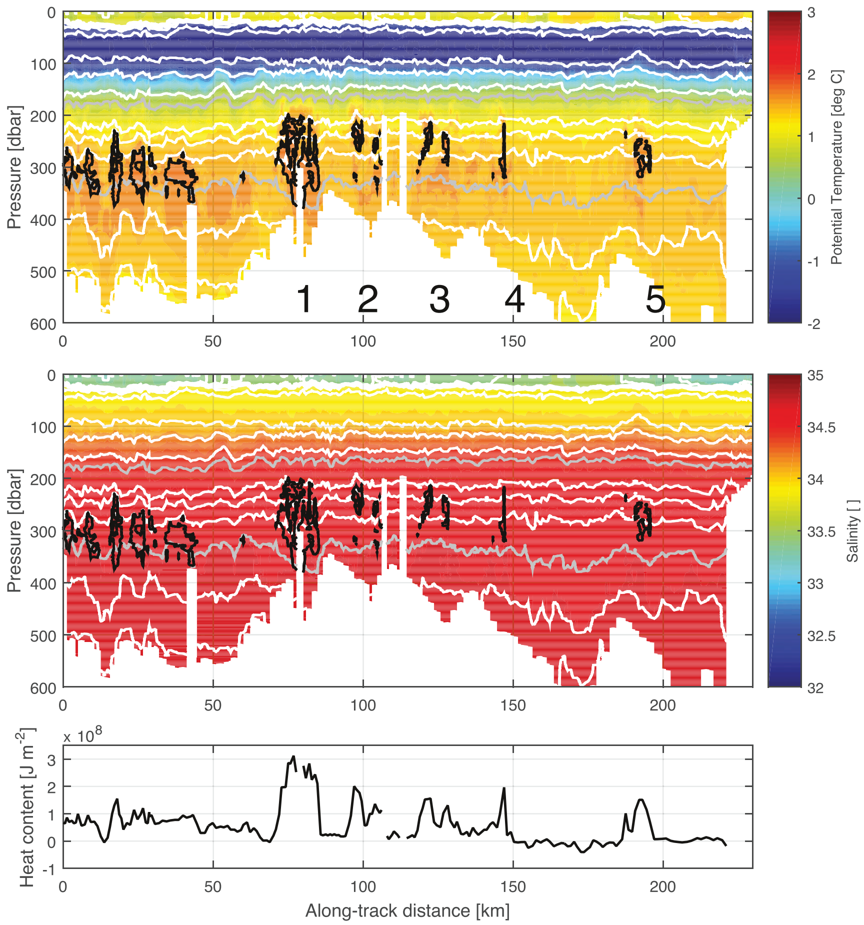

FIG. 5. As in Fig. 3, but showing data for the Tracking Stage. The repeat glider crossings of the single tracked eddy are numbered 1–5. Since the glider path did not always cleanly intersect the eddy, geostrophic currents do not provide a meaningful measure of azimuthal velocity and they are not shown.

times over 4 days. The trajectory followed the eastern wall of Marguerite Trough, consistent with the eddy-like features observed by Moffat et al. (2009).

2) EDDY CHARACTERISTICS

We define a local reference profile in the same manner as before and subtract it in order to obtain Q. Analogous to the Advective Path, sections of data are shown in Fig. 5. However, unlike in that stage, we are not confident that we consistently crossed the eddy via a chord length. Connecting spatial end-members of threshold $T_{\max}$ along a line perpendicular to isobaths leads to an estimated mean diameter of 8.5 km, similar to the eddies observed on the Advective Path. There is, in general, a decrease in heat content per unit area over time. Anticyclonic shear is less apparent beyond the first few crossings, and the vertical structure of temperature and salt anomalies is much more complicated. We will quantify the heat loss of this eddy in section 5.

c. *Shipboard data*

1) PAL LTER CTD AND SADCP

Shipboard data are used to supplement the glider data and to apply mixing parameterizations. CTD profiles are collected as part of the standard sampling on the annual cruises to the WAP each austral Summer since 1993 and are currently (since 1999) collected with a dual-pumped Sea-Bird 911+ CTD system (see Martinson et al. 2008 for details). The standard grid locations are indicated as black squares in Fig. 2. The entire grid was occupied until 2008 whereas now only a subset of stations is occupied (nominally one coastal, shelf, and slope station per grid line), though this is generally complemented by various process-study

CTD casts at nongrid locations that are not plotted but are utilized here.

Processed, high-resolution (5 min in time, 8 m in vertical) velocity profiles from the ARSV *L. M. Gould*'s hull-mounted RDI 150 kHz narrowband instrument were obtained from the Joint Archive for Shipboard ADCP (SADCP). The 150 kHz instrument provides velocity profiles good to about 300 m (depending on weather and sea state) when the vessel is on station. For mixing parameterizations we need concurrent shear and stratification profiles, so only the overlapping portion of the database is used (Januaries 2000–15; SADCP installed in mid-1999). For those applications, the hydrographic data are bin-averaged onto the same 8-m grid of the velocity data. Stratification and shear are computed as first differences on the 8-m grid as $N^2 = -(g/\rho)(\Delta\rho/\Delta z)$ and $S^2 = (\Delta U/\Delta z)^2 + (\Delta V/\Delta z)^2$. For bins with very weak stratification ($N^2 < 1 \times 10^{-6}\,\mathrm{s}^{-2}$), N^2 is set to a constant value ($1 \times 10^{-6}\,\mathrm{s}^{-2}$).

2) Casts on Advective Path

We draw special attention to 5 CTD casts collected in January 2014 along the Advective Path that was sampled by the glider the year prior (triangles in Fig. 2). These casts fortuitously sampled one or more eddies and indicate substantial interleaving structure, particularly in the pycnocline (Fig. 6). The layering connects cores of injected slope-type UCDW to the surrounding cooler pycnocline. These data are used to assess the importance and origin of thermohaline intrusions into the eddies.

3) S04P casts across continental slope

We suspect the eddies are generated along the continental slope. To diagnose the structure and stability of the shelf-break current upstream of Marguerite Trough we use CTD data from the WOCE S04P cruise in February 1992 (''x'' symbols in Fig. 2). Though it is possible that the hydrographic structure over the continental slope has changed in the long interim period, we use these data as they provide a high spatial resolution transect across the slope, slightly finer than the 2011 reoccupation of the line. The stations are ''moved'' from their original location to the 200 line by tracing the isobath at the actual station location to the 200 line, a small correction (a few kilometers). Neutral density is computed using the Jackett and McDougall (1997) software and profiles of neutral density, temperature, and salinity are filtered with a third-order Butterworth filter with width 100 dbar to remove noise and filter out Charney-type instabilities. We choose to do this because surface-trapped Charney-type instabilities do not convert significant available potential energy (APE) to eddy kinetic energy (EKE) compared to the pycnocline-level instabilities we are seeking (Smith 2007). Geopotential anomaly is calculated from the smoothed temperature and salinity profiles and is linearly extrapolated to handle bottom triangles. Both neutral density and geopotential anomaly are mapped with a Gaussian weighting function to a two-dimensional grid across the slope using the WOCE global climatology vertical grid (Gouretski and Koltermann 2004) and uniform 5-km horizontal spacing.

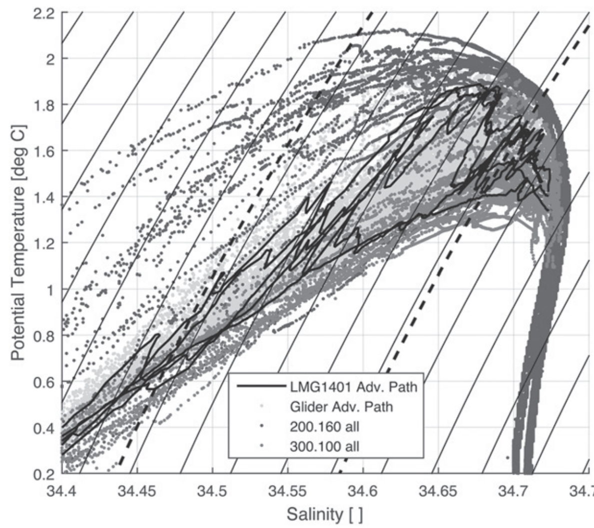

FIG. 6. Potential temperature–salinity diagram zoomed in to the UCDW region showing the five CTD casts along the Advective Path (black lines) along with all historic casts from a slope station (200.160; dark gray) and a shelf station (300.100; medium gray). The interleaving layers join slope-type UCDW with cooler, shelf-type pycnocline waters. Isopycnals σ_{shal} and σ_{deep} used for integrations are indicated as black dashed lines, and the glider profiles in the same region are shown as light gray dots.

3. Origin of mesoscale structure

a. QG model and background state

To understand the theoretical characteristics of eddies on the WAP, we begin by diagnosing the stability of the shelf-break current upstream of where UCDW intrudes onto the shelf. We follow the inviscid quasigeostrophic model of Smith (2007), assuming a local, slowly varying mean stratification N and horizontal flow $\mathbf{U}$ depending only on z. Assuming plane-wave solutions $\Re\{\hat{\psi}(z)\exp[i(kx + ly - \omega t)]\}$ where $\hat{\psi}$ is the complex amplitude of the perturbation streamfunction,

ω the complex perturbation frequency, and $\mathbf{k} = (k, l)$ the wavevector, the linearized quasigeostrophic equations in geographic coordinates lead to the eigenvalue problem

$$\left.\begin{aligned}
&(\mathbf{k}\cdot\mathbf{U}-\omega)(\Gamma-\mathbf{k}\cdot\mathbf{k})\hat{\psi} = -\left(k\frac{\partial Q}{\partial y} - l\frac{\partial Q}{\partial x}\right)\hat{\psi}, && -H < z < 0\\
&(\mathbf{k}\cdot\mathbf{U}-\omega)\frac{\partial\hat{\psi}}{\partial z} = \left[k\left(\frac{\partial U}{\partial z} - \frac{N^2\alpha^y}{f}\right) + l\left(\frac{\partial V}{\partial z} + \frac{N^2\alpha^x}{f}\right)\right]\hat{\psi}, && z = -H\\
&(\mathbf{k}\cdot\mathbf{U}-\omega)\frac{\partial\hat{\psi}}{\partial z} = \left(k\frac{\partial U}{\partial z} + l\frac{\partial V}{\partial z}\right)\hat{\psi}, && z = 0
\end{aligned}\right\}. \tag{3.1}$$

Here, $\Gamma = (\partial/\partial z)[(f^2/N^2)(\partial/\partial z)]$ is the potential vorticity stretching operator and $\alpha^{x,y}$ are the bottom slopes. We caution that the assumption of a linearly growing wave in a stable background state that is steady in time is highly idealized. Surely interactions with the evolving turbulence field of the ACC are relevant for the dynamics of the shelf-break flow. Nevertheless, we suspect that the regularity of the eddies and their common statistical metrics (Figs. 3, 4; Moffat et al. 2009; Couto et al. 2017) demonstrate that there is a preferential length scale and vertical structure for instabilities in this environment.

The background state is defined by the gridded stratification and geostrophic velocity profiles at grid location 200.150. This site is chosen as it is located midway across the slope and the geostrophic shear there agrees well with climatological SADCP shear. The current is assumed to flow parallel to isobaths, specifically at an angle of 40° north of east. The local bottom slope is calculated by fitting a 2D plane to all ETOPO1 bathymetry data (Amante and Eakins 2009) within a radius of 0.25° about the grid location.

One assumption of this model is that the background state varies slowly in the horizontal. Since there is clearly lateral shear in the shelf-break current, we need to justify excluding the potential of barotropic instability. For a generic, mixed baroclinic–barotropic instability, the contribution to the growth rate from baroclinic instability scales as $\sigma_{\mathrm{BC}} \sim (fL/ND)|\partial U/\partial z|$ and the contribution from barotropic instability scales as $\sigma_{\mathrm{BT}} \sim |\partial U/\partial y|$ (Pedlosky 1987). For these data, the latter is one order of magnitude smaller than the former ($\sigma_{\mathrm{BC}} \sim 13\,\mathrm{day}^{-1}$, $\sigma_{\mathrm{BT}} \sim 2\,\mathrm{day}^{-1}$). This is corroborated by Stern et al. (2015) who found baroclinic instability to grow much faster than barotropic instability in their QG model of a similar shelf-slope configuration, though their model was fully turbulent and not limited to the linear growth stage.

b. Most unstable mode

The equation is discretized as in Smith (2007) and solved for a range of wavenumbers. For each wavenumber, the most unstable mode is that with the largest imaginary part of ω. We find the overall most unstable mode to have an inverse wavenumber $|\mathbf{k}_{\max}|^{-1} = 4.4\,\mathrm{km}$ and growth rate $0.4\,\mathrm{day}^{-1}$ (Fig. 7). Over the wavenumber space evaluated, this is both the global and only local maximum. The mode's vertical structure is characterized by nonzero amplitude below the permanent pycnocline in the CDW depth range with a maximum at about 600 m and a secondary maximum at about 350 m. Specifically, this depth range spans the water column presence of UCDW ($T \geq 1.7°\mathrm{C}$) and LCDW ($S = S_{\max}$) within the four profiles across the slope. The instability appears to be qualitatively similar to a Phillips type instability (Phillips 1954) for the following reasons: 1) vertical structure seems to be dictated by interior sign changes in the potential vorticity gradient, 2) ~33° phase shift within the amplitude maximum indicates APE release there, and 3) horizontal scale obeys $L \approx (N/f)h_{\mathrm{pycnocline}} \approx 5\,\mathrm{km}$.

Overall these findings are in very good agreement with the glider observations over the Advective Path (Fig. 3). First, the vertical structure of the mode is concentrated within and below the permanent pycnocline, which is where the eddies exist. Second, the observed diameters of eddies A–C upstream and average crest-to-crest separation are ~8.3 km (averages of $2R$ and $2R_{\mathrm{TD}}$) and 22.3 km, respectively, which are comparable to the theoretical diameters $2|\mathbf{k}_{\max}|^{-1} = 8.8\,\mathrm{km}$ and crest-to-crest separation $2\pi|\mathbf{k}_{\max}|^{-1} = 27.8\,\mathrm{km}$ for eddies spun off of an unstable Rossby wave. Temperature anomalies relative to mCDW and geostrophic currents provide some evidence for a cold cyclone between eddies B–C, though in general, only warm anticyclones tend to be found on the shelf. The eddies D–E downstream on the path are broader than A–C but have a similar separation. With the caveat that this is a linear model, note that the wavelength implies delivery of (365 days) × $u|\mathbf{k}_{\max}|/2\pi$ = 57–114 eddies per year (for typical shelf

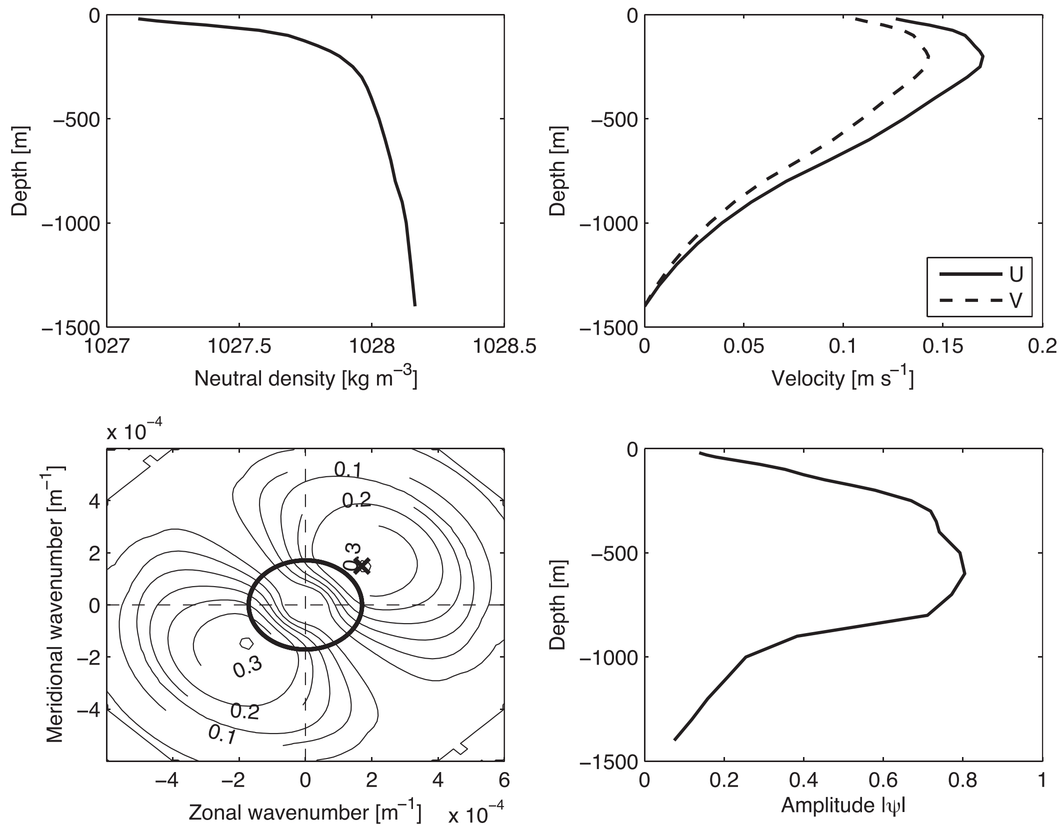

FIG. 7. Profiles used for linear stability analysis and results. (top) Profiles of (left) neutral density and (right) geostrophic velocities used. (bottom left) Perturbation growth rates as a function of wavenumber. The overall most unstable mode is indicated with black x. Locus of points $|k| = L_R^{-1}$ is given by solid black circle. (bottom right) Amplitude structure of the most unstable mode.

currents of 0.05 or 0.10 m s^{-1}), which could account for the totals observed by Moffat et al. (2009) and Martinson and McKee (2012).

c. Roles of bottom slope and current orientation

Exploring the parameter space of bottom slopes and current orientations allows us to simultaneously understand the sensitivity of the most unstable mode's structure and growth rate to these parameters and to understand how generalizable these results are to other regions around Antarctica. Using the same geostrophic shear and stratification profiles, we repeat the above analysis for all bottom slopes between −0.15 and +0.15 at increments of 0.01 and for all current orientations between 0° (zonal) and 90° (meridional) counterclockwise from east at 10° increments and examine changes in the growth rate, wave vector, and structure of the most unstable modes. Evaluating positive and negative bottom slopes effectively allows consideration of both prograde (isopycnals slope in same sense as bathymetry; e.g., WAP) and retrograde (isopycnals slope in opposite sense as bathymetry; e.g., Ross Sea) jets.

Figure 8 shows the growth rate and inverse wavenumber of the most unstable mode over the entire parameter space. The orientation of the current has essentially no effect on the instability. This is likely because the planetary beta effect is so small at this latitude that potential vorticity gradients are dominated by the stretching term and bottom slope. Indeed the topography plays a large role in determining the strength and properties of the most unstable mode. It is found that negative bottom slopes are stabilizing while increasing positive bottom slopes are destabilizing to a point and then stabilizing. Blumsack and Gierasch (1972) demonstrate that the relevant parameter for the stability problem under QG scaling is not the bottom slope itself but rather the ratio of the bottom slope to the isopycnal slope, $\delta \equiv \alpha/s$ (Blumsack and Gierasch 1972; Poulin et al. 2014). In the QG model of Smith (2007) that we use, the bottom slope only enters the problem as a boundary condition in the bottom layer's potential

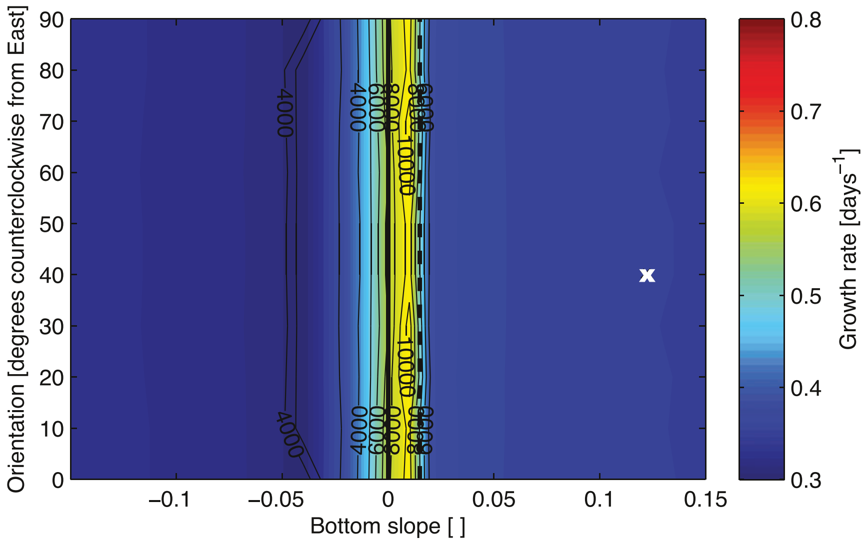

FIG. 8. Growth rate (color) and inverse wavenumber (contours) of most unstable mode for various bottom slopes and current orientations. All cases use the same shear and stratification from Fig. 7 and assume that the current flows exactly parallel to the shelf break. Slope of the 1028.0 kg m^{-3} neutral surface is indicated by a black dashed line. Actual bottom slope and current orientation indicated as white "x."

vorticity gradient. When the bottom slope exceeds the slope of the 1028.0 kg m^{-3} neutral surface, the potential vorticity gradient vanishes in the lower layer which has the effect of suppressing the growth rate in accordance to the Charney–Stern criteria (Pedlosky 1987). Nevertheless, this does not change the fact that there are still sign changes in the interior potential vorticity gradient and therefore instability persists where $\delta > 1$ or $\delta < 0$ (Isachsen 2011). These regions of weaker instability with inverse wavenumbers of 4–5 km all have similar vertical structure as the most unstable mode obtained in the realistic scenario analyzed earlier.

The fastest growing modes for prograde currents with relatively flat bottoms ($0 \leq \delta \leq 1$) are qualitatively consistent with Eady modes for the following reasons: 1) they have amplitude maxima at both ~350 m and near the bottom; 2) they have an inverse wavenumber $L \approx NH/(1.6f) \approx 9.4$ km, probably since the weakly varying N is dynamically similar enough to the uniform N of Eady's model. These modes have a pronounced spike at ~350 m near the UCDW temperature maximum and, in regions with a flatter bottom slope than the WAP, could also be expected to contribute to exchange of CDW. The region between $-2 \leq \delta < 0$ represents a sort of transition between the Eady-type modes and the Phillips-type modes. They have smaller length scales (~2 km) and are bottom-boundary trapped. This trend fits the qualities described by Blumsack and Gierasch (1972) for increasingly negative slope parameter, namely decreasing length scale and boundary trapping.

4. Attenuation of mesoscale structure

Having identified a plausible origin for the UCDW eddies, we here consider the processes responsible for their decay. Box inversions of steady heat budgets on the WAP point to diapycnal mixing between overlying remnant winter mixed layer Winter Water (WW) and a constantly replenished CDW layer as the maintenance of the permanent pycnocline. For some context, using a steady advective–diffusive balance, Klinck et al. (2004) place an upper bound on the vertical (lateral) diffusivity of heat at 7.7×10^{-4} m^2 s^{-1} (1600 m^2 s^{-1}) in the limit of no lateral (vertical) mixing. In an earlier study, Klinck (1998) used seasonal changes in water properties and a similar integrated budget to find a vertical (lateral) diffusivity of heat as 1×10^{-4} m^2 s^{-1} (37 m^2 s^{-1}). Martinson et al. (2008) used interannual variability of WW heat content and assumed a UCDW replenishing time to suggest a vertical diffusivity of 8.5×10^{-5} m^2 s^{-1}. Our study, however, focuses on how the properties of the subpycnocline "box" are set by the mixing of advected parcels of UCDW, within which the vertical and lateral gradients are quite different from those used in mean-shelf balances.

a. Shear-driven instability

Shear-driven instability is thought to be important in maintaining the permanent pycnocline and is thought to yield larger heat fluxes on the WAP than double-diffusive instabilities (Howard et al. 2004). Regarding sources of shear, internal tides are likely not important but near-inertial waves may be. Howard et al. (2004) suggest the semidiurnal tide is weak, as is the stratification, making baroclinic conversion unlikely. Further, Beardsley et al. (2004) use rotary spectral analysis of drifter velocity to show power in the semidiurnal band is two orders of magnitude less than that in the near-inertial. In general, we might expect that vertical mixing should be elevated over seamounts or within cross-cutting canyons. At seamounts, internal waves with frequency at the critical slope may be generated whereas in canyons internal waves may become trapped and focused toward the canyon head (Gordon and Marshall 1976).

Because we do not have microstructure measurements within eddies or on the surrounding midshelf, our approach is to use SADCP and CTD data to estimate diffusivities, temperature gradients, and heat fluxes across the permanent pycnocline, which we define globally to be between 98 and 250 m. We exclude grid stations below the 000 grid line as the hydrography there is very different (very deep and cold remnant winter mixed layers). Note that winter mixing by entrainment of the thermocline during brine rejection is not considered here, but is important in the annual heat budget (Martinson and Iannuzzi 1998).

1) General shear-driven instability

The method of Pacanowski and Philander (1981, hereafter PP81) computes a diffusivity $K_z(z)$ as a function of the Richardson number, with the idea being that when shear overcomes stratification, instability and mixing result. This method was developed for steady currents in equatorial ocean models and assumes nothing about the underlying sources of shear. Nevertheless, it has been applied to the WAP (Howard et al. 2004) and other high latitude environments (Dewey et al. 1999). For every 8-m binned CTD cast we have we pair it with all concurrent on-station SADCP profiles and compute a time-averaged Richardson number $\overline{\mathrm{Ri}} = \langle N^2/S^2 \rangle$. Because this is essentially a space–time-averaged Ri based on finite-differenced data, it is best interpreted as a probabilistic measure of potential instability at space (and time) scales lower than the differencing (and averaging) scales. The PP81 parameterization is

$$K_z = 10^{-5} + \frac{5\times 10^{-3} + 10^{-4}(1+5\overline{\mathrm{Ri}})^2}{(1+5\overline{\mathrm{Ri}})^3}\,\mathrm{m^2\,s^{-1}}, \tag{4.1}$$

and a vertical heat flux can then be calculated at each depth as

$$Q_f = \rho_0 c_p K_z \partial T/\partial z. \tag{4.2}$$

2) Internal wave parameterizations

Various authors have modeled the energy transfer through the steady Garrett–Munk (GM; Garrett and Munk 1975) internal wave vertical wavenumber spectrum via nonlinear interactions down to dissipation scales and turbulence production by scaling the GM shear spectrum by observed shear variance (e.g., Gregg 1989, hereafter G89). By assuming a steady turbulent kinetic energy balance and assuming a constant mixing efficiency ($\Gamma = 0.2$), one can then estimate a diffusivity coefficient from parameterized dissipation via the relation $K_z = \Gamma\varepsilon/N^2$. We use a modified version of the G89 parameterization, which is

$$K_z(z) = K_0 \frac{\langle S^4 \rangle}{\langle S^4_{\mathrm{GM}} \rangle} h(R_\omega) j(f, N). \tag{4.3}$$

In this expression, $\langle S^4 \rangle$ is the 8-m SADCP shear squared, multiplied by 2 (correcting for the finite-difference filter; Gregg and Sanford 1988), and then squared again and averaged in time; $\langle S^4_{\mathrm{GM}} \rangle$ is the GM shear spectrum (with local scaling parameters for the WAP shelf; see appendix) integrated up to a cutoff wavenumber $\beta = 0.2\pi$ rad m^{-1}, squared, and then multiplied by 2 (assuming Gaussian statistics); and $K_0 = 5.6 \times 10^{-6}\,\mathrm{m^2\,s^{-1}}$ is a nominal diffusivity for the underlying internal wave spectrum (see appendix). The functions h and j are corrections added later and are not part of the original G89 model.

First, $h(R_\omega)$ is a polynomial function of R_ω, the N^2-normalized-shear–strain variance ratio, which is designed to adapt the model to non-GM wave fields with different aspect ratios and frequency content:

$$h(R_\omega) = \frac{3(R_\omega + 1)}{2\sqrt{2}R_\omega\sqrt{R_\omega - 1}}. \tag{4.4}$$

The GM spectrum has $R_\omega = 3$ ($h = 1$), and larger values of R_ω indicate elevated importance of near-inertial waves. Most of the open ocean has $R_\omega \sim 7$ (Kunze et al. 2006), and values in the Southern Ocean are generally between 8 and 12 (Thompson et al. 2007; Naveira Garabato et al. 2004). Calculating shear and strain spectra for each cast as in Kunze et al. (2006), we find $R_\omega = 9$ ($h = 0.42$) averaged over the LTER grid, and, owing to the difficulty involved in estimating strain, we use that constant value for all casts.

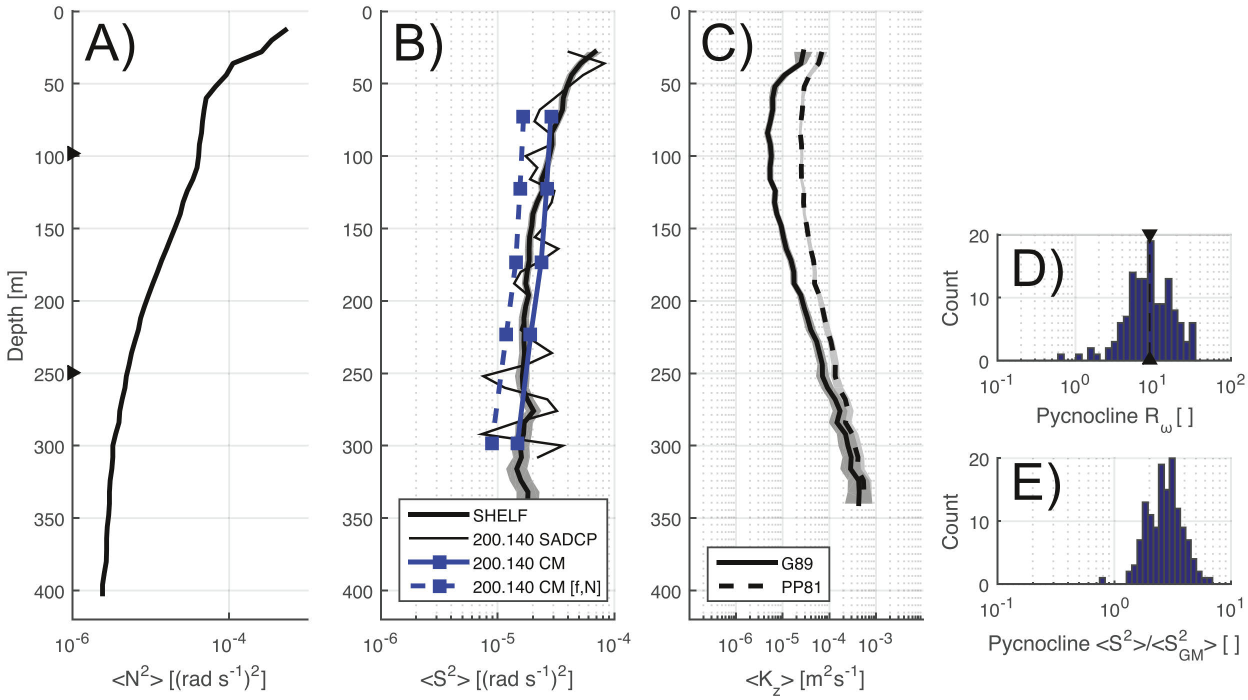

FIG. 9. Summary of vertical mixing parameterizations for Shelf region. (a) The N^2 calculated on shelf-averaged density profile (see appendix). Range of the permanent pycnocline as defined in the text indicated with black wedges. (b) Composite S^2 profile from all SADCP profiles log-averaged on depth coordinates (bold black) with $\pm$ 2 log standard errors (gray shading); composite S^2 profile from all SADCP profiles at station 200.140 log-averaged on depth coordinates (thin black); log-averaged total (solid blue) and internal wave band (dashed blue) S^2 from moored current meters at station 200.140. (c) Composite K_z profiles log-averaged on depth coordinates (G89 solid; PP81 dashed) along with $\pm$2 log standard errors (gray shading). (d) Histogram of shear-to-strain variance ratios for all Shelf profiles with complete pycnocline coverage; $R_\omega = 9$ indicated with black dashed line. (e) Histogram of observed-to-GM pycnocline shear variance ratios for all Shelf profiles with complete pycnocline coverage.

The second term $j(f, N)$ is a correction for latitude arising because the rate at which waves are Doppler shifted depends on the ratio of their horizontal and vertical wavenumbers, which depends on Coriolis frequency f (Gregg et al. 2003):

$$j(f, N) = \frac{f\,\text{acosh}(N/f)}{f_{30}\,\text{acosh}(N_0/f_{30})}. \tag{4.5}$$

This dependence was in the scaling used by G89, but he held $f\,\text{acosh}(N/f)$ to be constant. We use a typical latitude for the WAP (66.5°S) for all casts. After developing a diffusivity profile, a heat flux profile is calculated from Eq. (4.2).

3) RESULTS AND INTERPRETATION

Fundamental results are presented in the form of profiles of N^2, S^2, and K_z averaged over the Shelf region (see Fig. 2 for regional boundaries) in Fig. 9. In general, S^2 decreases more slowly with depth than does N^2, becoming nearly white below the pycnocline and yielding diffusivities that increase with depth. To confirm that the apparently unusual behavior of S^2 with depth is real, we compare the SADCP shear at station 200.140 to the shear calculated from a set of six moored current meter records at that site [corrected for finite differencing following Gregg and Sanford (1988) using local GM scaling]. The current meter shear (bold blue line) and SADCP shear (thin black line) at site 200.140 agree remarkably well, suggesting that, at least at this site, the large shear variance (and hence the large diffusivities) at depth is real (Fig. 9b).

While the SADCP shear variance represents an integral across all frequencies, we can bandpass filter the current meter observations between $[f, N_0]$ to retain only shear in the internal wave band. Doing so (dashed blue line in Fig. 9b) suggests that the internal wave band shear profile has the same shape as the total shear profile but that SADCP shear might be overestimating internal wave shear by a factor of ~1.6. Because we cannot evaluate this relation at other sites, we do not attempt to make any correction for non-internal wave shear. The histogram of $\langle S^2\rangle/\langle S^2_{GM}\rangle$ in the pycnocline depth range (Fig. 9e) suggests observed shear variances are generally a factor of 2–3 greater than GM. Spectra of shear and strain in the pycnocline confirm that

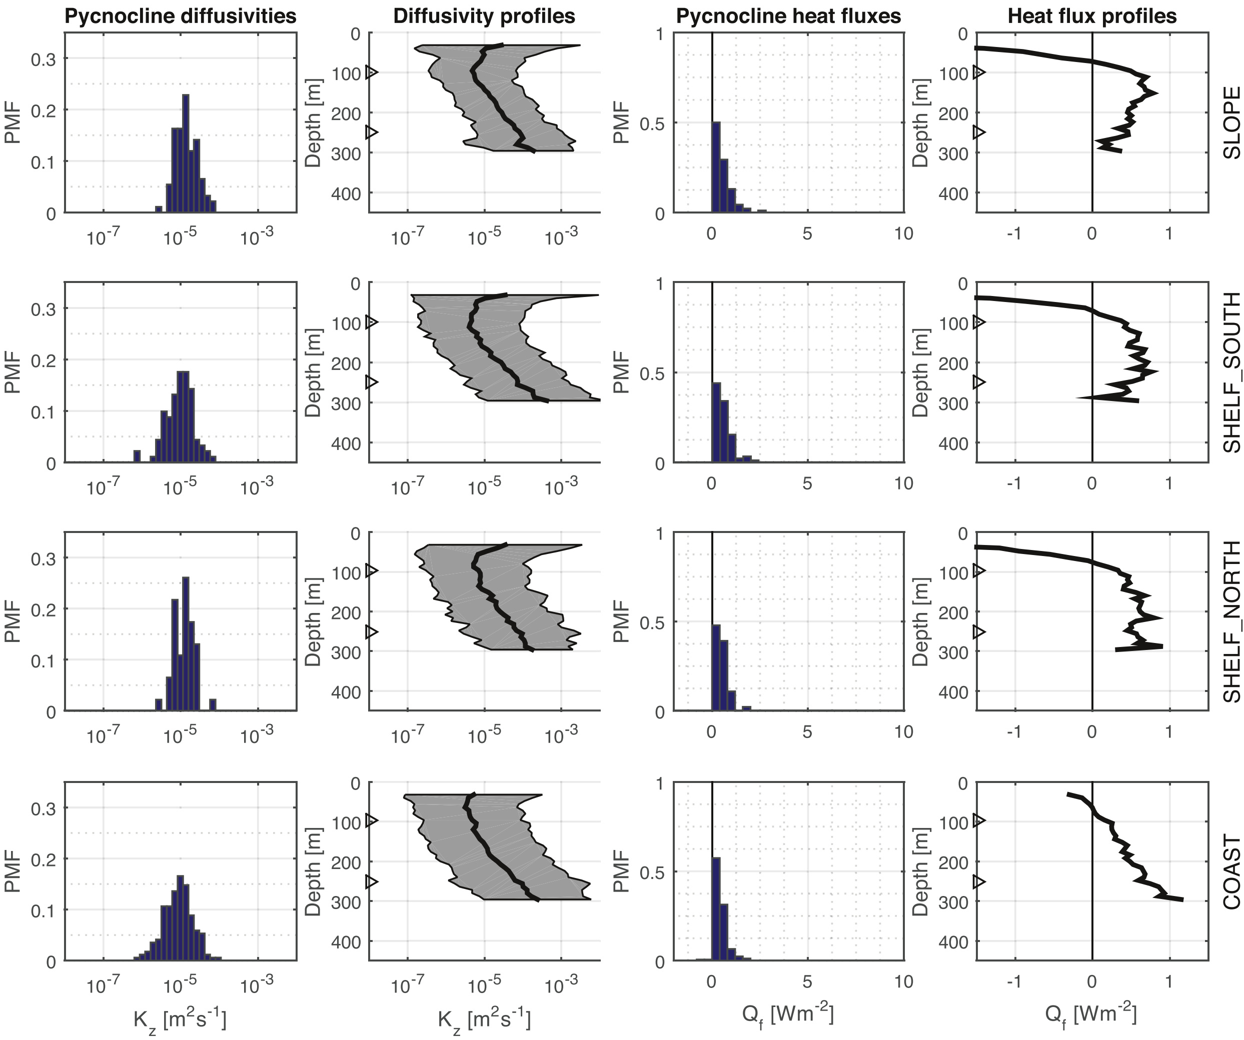

FIG. 10. Summary of regional variability of vertical diffusivities and heat fluxes. Rows indicate different regions (Shelf, Slope, and Coast indicated in Fig. 2; North Shelf and South Shelf are separated by 450 grid line). (first column) Histograms of G89 K_z, log-averaged over depth of pycnocline (blue bars). (second column) Profile of G89 K_z, log-averaged across all profiles at each depth. Gray shading indicates two log standard deviations. (third column) As in the first column, but for vertical heat fluxes, where depth-reduction is accomplished by using the median. (fourth column) As in the second column, but for vertical heat fluxes, where space reduction is accomplished by using the median. Because the heat fluxes do not follow a simple distribution, error bars are not shown. In total there are 1073 CTD casts north of the 000 grid line matched to an SADCP profile. Of those, 963 contain at least one good N^2 and S^2 value (used for composite profiles), 859 contain at least one good value within the pycnocline, and 398 contain good values throughout the pycnocline (used for depth-reduced histograms).

$R_\omega = 9$ is a good fit on the WAP shelf (Fig. 9d) and reveal an elevated importance of near-inertial waves in comparison to a standard GM spectrum.

Both the G89 and PP81 diffusivities increase with depth for reasons discussed above. Diffusivity values in the permanent pycnocline are small ($<10^{-5}$ m^2 s^{-1}), so much so that the asymptotic lower limit of the PP81 method renders it inapplicable there (Fig. 9c). Although the two methods agree better deeper in the water column, all further analyses will exclusively consider the G89 parameterization. The shear (Fig. 9b) and diffusivity (Fig. 9c) profiles are presented as means with the shaded region enclosing two standard errors, where both the means and standard errors are computed on log-transformed data. Owing to the large number of stations sampled, uncertainty in the mean is small.

To get a sense of how diffusivity and vertical heat fluxes vary regionally, Fig. 10 shows composite profiles of diffusivity and heat flux for data partitioned by region alongside histograms of the pycnocline-averaged quantities. The small diffusivities that characterize the permanent pycnocline operating on the background T profile yield vertical heat fluxes across the permanent pycnocline of $<1\,\mathrm{W\,m^{-2}}$ which is smaller than values reported by Howard et al. (2004), who used PP81. Diffusivities increase approximately log-linearly with depth to about $10^{-4}\,\mathrm{m^2\,s^{-1}}$ at 300 m (Fig. 10), which is as deep as the SADCP yields useable data.

As in Fig. 9, the central values are computed on log-transformed data, however now the spread is indicated by two standard deviations in order to indicate potential values instead of uncertainty in the mean. While the central values are small, the spread at any given depth is large and spans about two orders of magnitude, suggesting that the potential for strong mixing at any depth is high and that mixing is intermittent. Pycnocline diffusivities are significantly different between the Shelf and Slope, the Shelf and Coast, and between the Northern Shelf and Southern Shelf at an $\alpha = 10\%$ level. The variance seems to be larger in the Coast. The larger variance there is driven by larger variance in the shear. We also constructed two composites that should be more representative of the environment that most of the eddies are in. The first averages all profiles in the subregion of the Southern Shelf that is bounded by the 250 and 450 lines between stations 030 and 130 (the vicinity of Marguerite Trough) and the second averages only those profiles in that domain with a $T_{\max} \geq 1.55°\mathrm{C}$. The heat fluxes in those regions are qualitatively different with a much greater heat flux divergence centered about the $T_{\max}$ but are statistically indistinguishable from the more comprehensive Southern Shelf in terms of cross-pycnocline metrics. However, compared to the Northern Shelf, the Southern Shelf and both Marguerite Trough composites have significantly lower pycnocline diffusivities, significantly lower shear variance ratios, and insignificantly larger pycnocline heat fluxes. The results suggest that any enhanced vertical heat flux within an eddy compared to its surroundings is due to the altered gradients of the temperature profiles and not the shear.

While the SADCP does not allow for estimates of diffusivity or heat flux below about 300 m, extrapolating the log-linear trend in K_z with depth and using observed temperature gradients suggests that below the $T_{\max}$, the vertical temperature gradient is about one order of magnitude smaller than that in the permanent pycnocline, however the diffusivity should be about two orders of magnitude larger. This combines for a heat flux about 10 times greater below the eddy, and the spatial variability in the heat flux profiles is consistent with this scaling. The stratification on the Slope and Southern Shelf is dominated by pure UCDW and a middepth temperature maximum as in the eddies. The middepth maximum in temperature results in an upward heat flux above the $T_{\max}$ and a downward heat flux below, the former of which is apparent in the observed profiles and the latter of which is implied by the trend toward a $\sim 0\,\mathrm{W\,m^{-2}}$ heat flux at 300 m (Fig. 10). Because the downward heat flux is about 10 times greater than the upward heat flux, the temperature maximum is mixed downward in the water column as the UCDW is advected northward and shoreward. This is consistent with the positive vertical heat flux increasing with depth on the Northern Shelf and Coast stations (Fig. 10).

b. Thermohaline intrusions

Four of the five CTD casts taken along the Advective Path reveal that within and surrounding the eddies there is substantial along-isopycnal temperature and salinity variance associated with thermohaline intrusions (Fig. 6). Those data are plotted as profiles of temperature in Fig. 11 along with a background profile, which is constructed as a running median in density space with a window size of $0.015\,\mathrm{kg\,m^{-3}}$. The UCDW eddies are essentially moving fronts. Joyce (1977) derived a model in which medium-scale advection of heat and salt across a density-compensated large-scale front is balanced by small-scale diffusion across thermohaline intrusions, attenuating their T–S characteristics. The medium-scale advection is taken to be in the form of alternating interleaving structures, initiated by velocity perturbations with the energy source coming from thermoclinic energy of the cross-frontal property contrasts. His model makes no distinction as to what small-scale processes conduct the mixing.

The model balance leads to an effective cross-frontal diffusivity for T of

$$K_h = \overline{K_z^T\left(\frac{\partial T'}{\partial z}\right)^2} \Bigg/ \left(\frac{\partial \overline{T}}{\partial r}\right)^2, \qquad (4.6)$$

where primes indicate small-scale variance, overbars indicate large-scale averages (scales larger than intrusions), and the vertical eddy diffusivity is taken to encompass all mixing processes. To apply Eq. (4.6) we estimate the cross-frontal temperature gradient from the glider data along the Advective Path by averaging the lateral gradients of the 5 eddies encountered (A–E; $8.5 \times 10^{-5}\,°\mathrm{C\,m^{-1}}$). The small-scale intrusion variance in the vertical is derived from the CTD profiles at approximately the same location: the background profile is subtracted and the variance of the derivative of the residual is calculated. We calculate K_h in two ways: once using a constant K_z typical of the midwater column ($10^{-4}\,\mathrm{m^2\,s^{-1}}$; Hebert et al. 1990, Pelland et al. 2013) and once using the diffusivities as parameterized from the modified G89 method. The results are 3.2 ± 1.4 and $7.9 \pm 4.2\,\mathrm{m^2\,s^{-1}}$, respectively (two standard errors indicated).

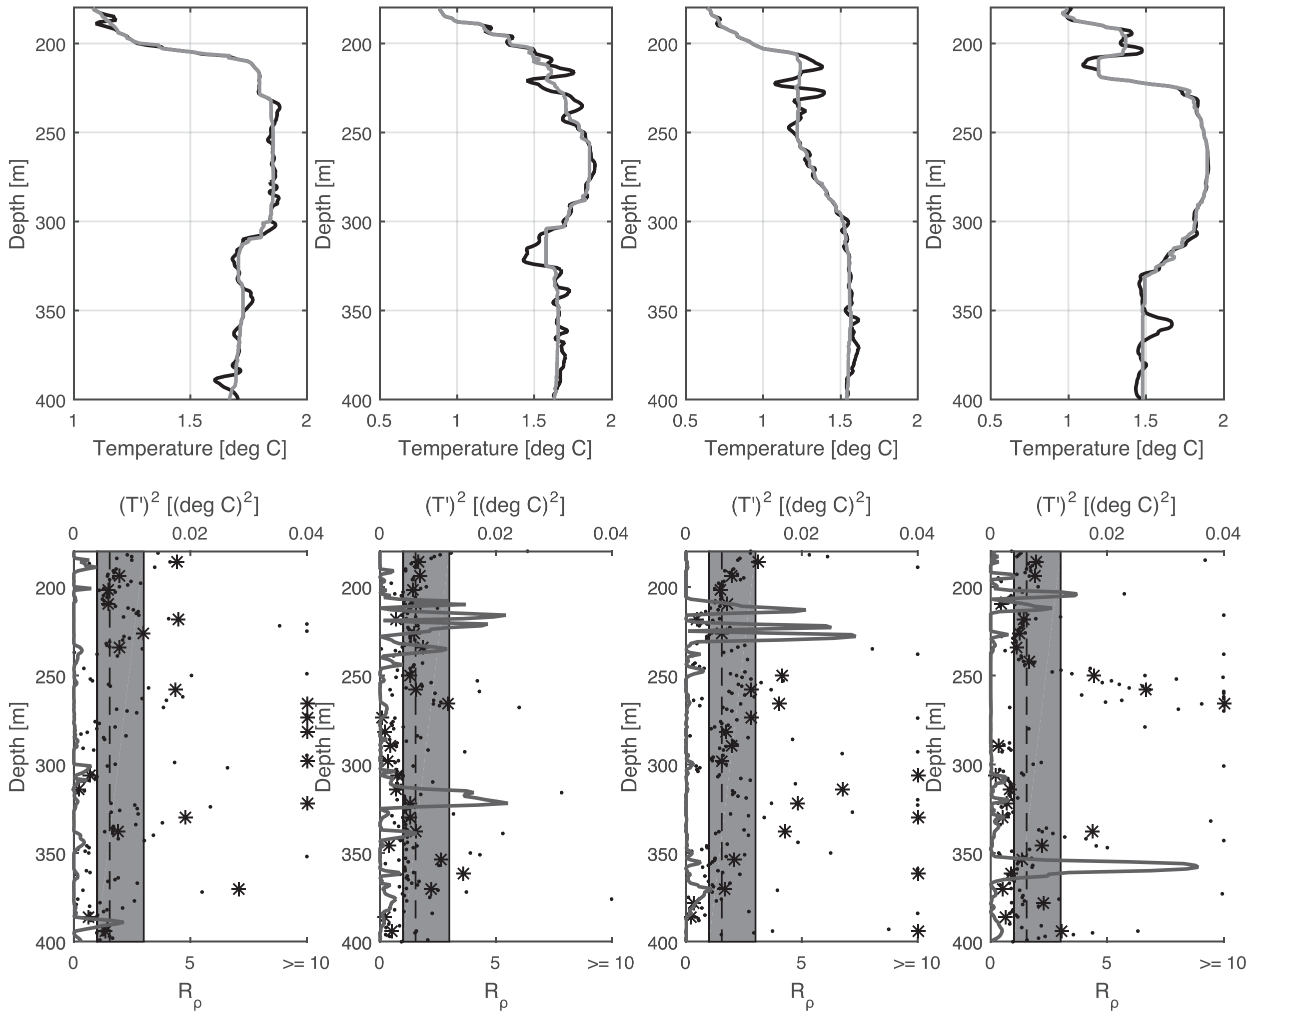

FIG. 11. Summary of temperature variance in the four out of five Advective Path CTD casts that indicate substantial thermohaline intrusions (time and downstream-distance increase from left to right). (top) Full temperature profile (black) along with background temperature profile (gray; see text for definition). (bottom) Temperature anomaly squared (gray line) along with density ratio computed on 8-m profiles (stars) and on 1-m profiles (dots). Axes are saturated so that depths with $R_\rho > 10$ are shown at 10 and doubly stable and statically unstable values are not shown. The shaded region indicates highly diffusively unstable region [1, 3], and the dashed line indicates the critical threshold of Bormans (1992a) below which diffusive stratification contributes significantly to cross-frontal heat fluxes.

We now consider processes that may be responsible for generating the thermohaline intrusions.

1) Double-diffusive growth

Theories for the growth of thermohaline intrusions (e.g., McDougall 1985a,b) in a region of density-compensated thermohaline gradients depend on one of the components of density being unstably stratified in order for an infinitesimal disturbance to grow to finite length. Figure 11 shows that the WAP water column between the WW $T_{\min}$ and the UCDW $T_{\max}$ is diffusively unstable and that the layer immediately below the UCDW core can be salt finger unstable. One way to quantify how much the unstably stratified component contributes to the stability of the water column is via the density ratio $R_\rho = (\beta\partial S/\partial z)(\alpha\partial T/\partial z)^{-1}$. A statically stable column is diffusively unstable if $1 < R_\rho < \infty$, salt finger unstable if $0 < R_\rho < 1$, and doubly stable if $R_\rho < 0$. As the ratio approaches 1, double-diffusive fluxes increase because the effect of the gravitationally unstable gradient is increasingly canceled by that of the stably stratified component's gradient. Bormans (1992a) found that diffusively unstable fronts had lateral intrusion heat fluxes significantly exceeding those of doubly-stable fronts only when R_ρ went below 1.54. Values in the lower pycnocline/eddy upper hemisphere occasionally breach that threshold, and there is a correspondence between the locations of largest temperature variance and the locations of density ratio nearest to 1 (Fig. 11, lower panels).

2) Internal wave advection

Another possibility is that the intrusion-scale temperature variance is caused by advection due to internal waves. If we consider the simplest advection equation and the square of its Fourier transform,

$$\frac{\partial \tilde{T}}{\partial t}(z) = u_r(z)\frac{\partial \overline{T}}{\partial r} \Leftrightarrow \omega^2 \Phi_{\tilde{T}} = \Phi_{u_r}\left(\frac{\partial \overline{T}}{\partial r}\right)^2, \quad (4.7)$$

we can rearrange it to construct an inequality for the maximum contribution by internal waves to the intrusion-scale (tilde) temperature variance:

$$\Phi_{\tilde{T}_z} \le \frac{1}{f^2}\left(\frac{\partial \overline{T}}{\partial r}\right)^2 \Phi_{u_z}. \quad (4.8)$$

Here we have assumed that all waves are purely horizontal (inertial waves) and we have differentiated in depth by multiplying each side by β^2, the vertical wavenumber squared. Shear spectra are calculated over our defined pycnocline range and temperature spectra are calculated over [180, 400] m, encompassing the eddy itself, the range of intrusions, and avoiding remnant diffusive staircases. The large-scale (overbar) temperature gradient is again the average across eddies A–E (Table 1). Figure 12 shows the two sides of Eq. (4.8) and it implies that observed temperature variance is greater than the maximum contribution of internal waves acting on the cross-eddy temperature gradient. It is worth noting, however, that if we instead use the lateral temperature gradient of only the three upstream eddies (A–C; 1.2×10^{-4}°C m^{-1}) then the 90% error bars in Fig. 12 begin to overlap in the range of intrusion thicknesses.

3) Geostrophic turbulence

Under geostrophic turbulence, the steep roll-off of energy spectra in comparison to the more gradual roll-off of potential enstrophy and tracer variance spectra means that the density field is dominated by the large, low-mode energy containing eddies that stir along isopycnals (such as the first-mode baroclinic instability; section 3) whereas the T–S variance is dominated by small-scale filamentary features that must be density compensated (Smith and Ferrari 2009). The cascade of tracer variance is halted at high vertical wavenumbers by vertical mixing, which counters the variance production by mesoscale stirring. If the along-isopycnal passive tracer variance surrounding the eddies was generated by their own stirring, we would expect their sizes to match the eddy length scale associated with

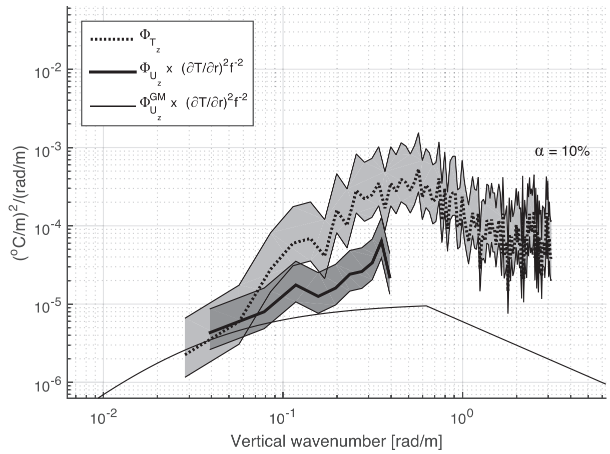

FIG. 12. Spectra of vertical derivatives of medium-scale temperature anomalies (dashed) and shear times $(\partial\overline{T}/\partial r)^2 f^{-2}$ for observations (bold black) and local GM (thin black). Error bars at the $\alpha = 10\%$ level are indicated by the shaded regions. If internal waves could account for all medium-scale temperature variance then the solid spectrum would exceed the dashed.

tracer variance generated by stirring across a mean gradient in accordance with mixing length theory (Tennekes and Lumley 1972):

$$L_{\mathrm{mix}} = \frac{(\overline{C'C'})^{1/2}}{\partial\overline{C}/\partial x}, \quad (4.9)$$

where C is some passive tracer, x is the cross-slope coordinate, and overlines indicate an average in time or space.

To unite density-compensated variations into a single variable we consider spice (Flament 2002) which effectively serves as a quantification of distance in T–S space orthogonal to isopycnals. We compute spice profiles $C(z)$ from the glider data along the Advective Path in addition to high-passed spice profiles $C_{\mathrm{HP}} = C - C_{\mathrm{LP}}$, which are the total profiles minus a filtered profile (triangular filter with width 25 m), thus retaining only the interleaving layers. Inspection of composites of $\overline{C'_{\mathrm{HP}}C'_{\mathrm{HP}}}$ across eddies A–E, where the over line indicates averaging in the vertical between [σ_{shal}, σ_{deep}], reveals that thermohaline variance is indeed largest at the eddy edges (Fig. 13). To visualize how spice variance is distributed more generally along the Advective Path, Fig. 14a shows a section of C on isopycnals and Fig. 14b collapses along-isopycnal variations into profiles of $\overline{C'C'}$ and $\overline{C'_{\mathrm{HP}}C'_{\mathrm{HP}}}$, where now primes are relative to the along-isopycnal mean and the products of anomalies are averaged on each isopycnal. Unsurprisingly, $\overline{C'C'}$ exhibits largest values in between [σ_{shal}, σ_{deep}], being overwhelmed by the presence or absence of warm core eddies. On the other hand, $\overline{C'_{\mathrm{HP}}C'_{\mathrm{HP}}}$ is less affected by the

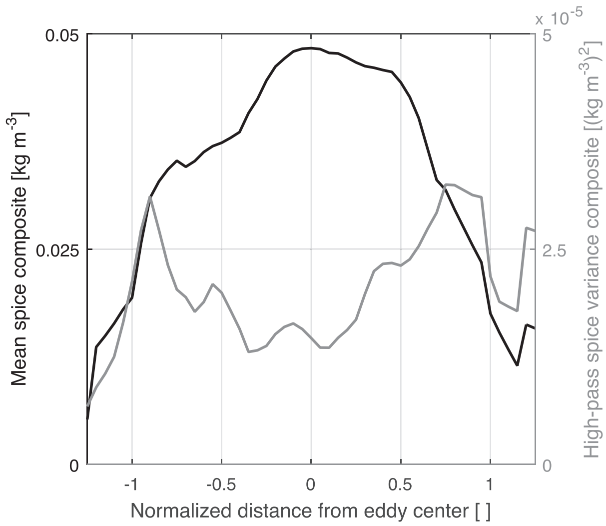

FIG. 13. Composite depth-mean spice anomaly (black) and high-pass-filtered spice variance (gray) between σ_{shal} and σ_{deep} for eddies A–E. Horizontal coordinate is stretched as in Fig. 4.

presence of eddies, making it much smaller within [σ_{shal}, σ_{deep}] but of comparable magnitude above.

Estimation of the mixing length requires knowledge of the mean spice gradient that is presumably stirred. Figure 14c shows time-averaged spice $\overline{C}$ along the 300 line (location of Marguerite Trough) as computed from the historic Pal LTER CTD data. There is a very strong gradient at the continental slope (180 station; gray line in Fig. 14d), however, unlike other grid lines, on the 300 line there is also a secondary region of large cross-slope spice gradient within [σ_{shal}, σ_{deep}] near the shoreward 130 station (blue line in Fig. 14d). We suspect that the gradient there is associated with the quasi-permanent diversion of the shelf-break current onto the shelf upon interacting with Marguerite Trough (Fig. 2).

Importantly, it is not known whether the interleaving layers are generated locally or remotely, so it is not obvious which is the relevant gradient to be stirred. Likewise, it is not immediately clear whether the relevant variance is $\overline{C'C'}$ or $\overline{C'_{HP}C'_{HP}}$ (i.e., should the high spice cores of the eddies be removed?). A conservative estimate is to assume that the variance is strictly that of the interleaving layers and that the gradient that is stirred is the local gradient within Marguerite Trough. That would suggest $L_{mix} = (\overline{C'_{HP}C'_{HP}})^{1/2}(\partial\overline{C}/\partial x\,|_{x=130})^{-1} = 5.6\,\mathrm{km}$ averaged between [σ_{shal}, σ_{deep}] (with range 3.4–7.5 km). An alternate perspective is to treat the warm eddy cores themselves as filamentary structures associated with stirring of the larger cross-slope gradient. In that case, $L_{mix} = (\overline{C'C'})^{1/2}(\partial\overline{C}/\partial x\,|_{x=180})^{-1} = 11.1\,\mathrm{km}$ (with range 3.4–17.2 km). Either way, the estimates are of the same order of magnitude as R and $|\mathbf{k}_{max}|^{-1}$. This suggests that the observed eddies are of sufficient size to generate the observed spice variance by stirring the mean spice gradient.

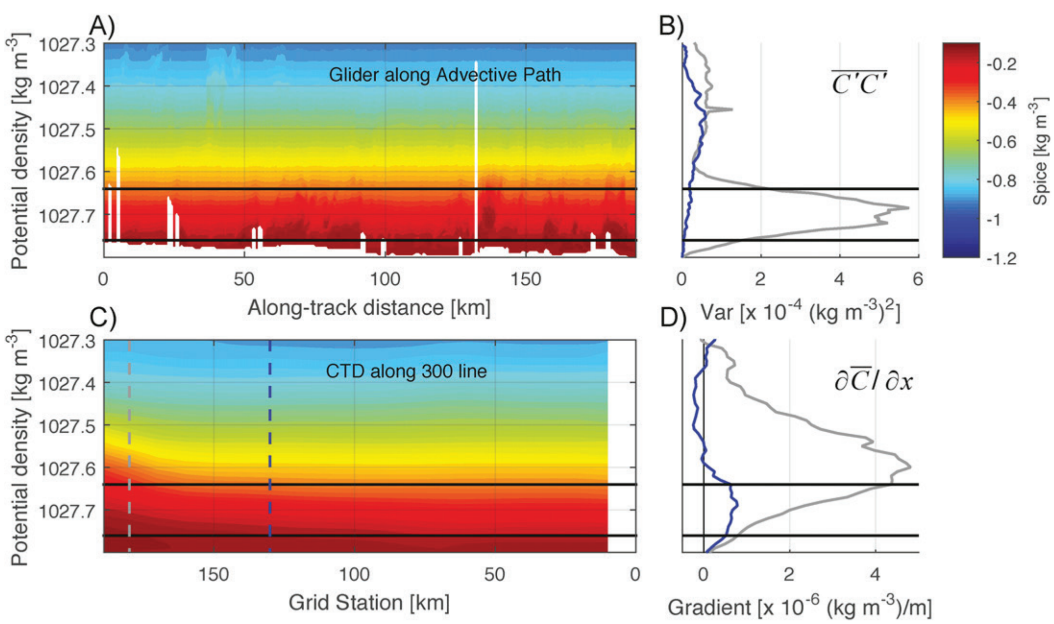

FIG. 14. (a) Spice C on isopycnals along Advective Path from glider. (b) Along-isopycnal variance of spice C (gray) and of high-pass-filtered spice C_{HP} (blue) for section in (a). (c) Cross-slope section of mean spice from climatological CTD data across the continental shelf at the 300 line. (d) Magnitude of the cross-slope spice gradient on isopycnals at the locations of the dashed lines in (c). In all panels σ_{shal} and σ_{deep} are indicated with black lines.

4) DISCUSSION

It is not obvious what causes the interleaving. Internal waves cannot provide enough temperature variance unless the lateral temperature gradient is on the larger end of those observed and the internal wave field is strongly biased toward inertial waves (which it somewhat is with $R_\omega = 9$). On the other hand, double diffusion, while qualitatively consistent with the vertical structure of the observations, tends to have slow growth rates. A more likely candidate appears to be stirring by the eddies of the cross-shelf temperature gradient within Marguerite Trough. Spice variance is largest at the eddy edges and its magnitude is consistent with the eddy sizes in accordance with mixing length theory. Thermohaline intrusions appear to be important for the decay of the eddies, particularly in their upper hemispheres, as cold neighboring water is brought inwards and warm slope water is ejected.

c. *Frictional spindown*

What appears to be cooling of the eddies may instead be redistribution of heat via a change in the buoyancy distribution of the eddy. Under the assumptions of a strictly vertical exchange of both mass and momentum, spindown of a geostrophically balanced along-front (or azimuthal) flow in the ocean interior leads to a secondary radial circulation that redistributes buoyancy so as to flatten isopycnals (Garrett 1982; Bormans 1992b). The potential vorticity equation takes the form of a diffusion equation in which the local time evolution of buoyancy B is balanced by a viscous spreading and a diapycnal diffusion of mass:

$$\frac{\partial B}{\partial t} = \frac{N^2}{f^2}\frac{\partial}{\partial r}\left(\nu\frac{\partial B}{\partial r}\right) + \frac{\partial}{\partial z}\left(K_z\frac{\partial B}{\partial z}\right). \tag{4.10}$$

Our data are incapable of being used to invert such a model, but we can make a few comments. The geostophic shear we calculate is evaluated at approximately the depth of the eddy core and is relative to the bottom, a depth range where we have previously shown there is strong potential for diapycnal mixing. It is possible that the turbulent mixing itself flattens isopycnals without the need for friction to reduce the azimuthal geostrophic flow. We do not know the Prandtl number $\mathrm{Pr} = \nu/K_z$ within these eddies, but it is generally thought to be of order 1. Assuming that it is 7 (canonical seawater value), an upper bound for a middepth value of the effective viscous spreading coefficient is of order $1\,\mathrm{m^2\,s^{-1}}$, which is comparable to the lateral diffusivity estimated in the previous section. There is insufficient evidence to confirm or refute any role of spindown in the eddies' decay.

5. Validation

Here we use a simple diffusion model informed by the results of the previous section to simulate the total heat loss of the eddy we tracked over crossings 1–5. We would like to emphasize that we do not expect to reproduce the small-scale structure of the eddy's cooling but instead aim to capture the bulk heat loss. The geometry of the first crossing gives us confidence that we passed directly through the eddy's center and through its entire diameter, therefore we set the initial condition as the hydrographic structure of the eddy as sampled on crossing 1. We identify the eddy's geographic center (x_1, y_1) and radius ($R_1 = 3.4\,\mathrm{km}$) as the mean and standard deviation, respectively, of a 2D Gaussian fit to the field of heat content per unit area integrated between σ_{shal} and σ_{deep}. We then assign each profile a radial distance from that center and grid the T and S on each isopycnal to construct a 3D field for the eddy. Outside of the eddy the domain is populated by the mCDW profile.

a. *Diffusion model*

We treat temperature and salinity as passive tracers and allow the eddy to diffuse in a domain $x = [-10\,\mathrm{km}, +10\,\mathrm{km}]$, $y = [-10\,\mathrm{km}, +10\,\mathrm{km}]$, and $z = [0\,\mathrm{m}, 480\,\mathrm{m}]$ with 250-m grid spacing in the horizontal and 2.5-m grid spacing in the vertical. The equation for temperature is

$$\left.\begin{aligned}
&\rho_0 c_p\frac{\partial T}{\partial t} = \rho_0 c_p K_h\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) + \rho_0 c_p\frac{\partial}{\partial z}\left[K_z(z)\frac{\partial T}{\partial z}\right],\\
&\frac{\partial T}{\partial z}(0) = \frac{\partial T}{\partial z}(-H) = 0,\\
&K_h = 3.2\,\mathrm{m^2\,s^{-1}},\\
&K_z(z) = \begin{cases} K_{\mathrm{top}} = 2.11\times10^{-5}\,\mathrm{m^2\,s^{-1}}, & z < 120\,\mathrm{m}\\ \text{log-linear increase between } K_{\mathrm{top}} \text{ and } K_{\mathrm{bot}}, & 120 \le z \le 400\,\mathrm{m}\\ K_{\mathrm{bot}} = 2.44\times10^{-3}\,\mathrm{m^2\,s^{-1}}, & z > 400\,\mathrm{m}\end{cases}
\end{aligned}\right\}, \tag{5.1}$$

and it is integrated for 4.5 days with a time step of 150 s using a finite-difference control volume approach. The diffusivity values are constant in time and are based on those parameterized in the previous section. The southern shelf composite K_z profile (Fig. 10) increases log linearly with depth from a value of $4.23 \times 10^{-6}\,\mathrm{m^2\,s^{-1}}$ at 120 m, however we found better results are achieved if we set K_{top} to be 5 times that value, which is within the reported 95% confidence interval.

b. Fit to data

We use a diffusion-only equation because the eddy's geographic coordinates $[x(t), y(t)]$ are additional unknowns. Therefore we assume that the eddy is advected by a depth-invariant current and seek an optimal $[x(\tau_i), y(\tau_i)]$ at each crossing i. We do this by performing a grid search by moving the modeled eddy to each location in a grid encompassing the glider track and then subsampling the modeled field along the glider track and calculating the depth-integrated heat content along the track. The position k that minimizes the root-mean-square (RMS) error between $Q^{\mathrm{obs}}(\tau_i)$ and $Q^{\mathrm{model},k}(\tau_i)$ defines the eddy center's location at time τ_i. On each crossing, there are a few profiles where thermohaline intrusions significantly attenuate that profile's heat per unit area and the presumed symmetry of the eddy and therefore they are excluded in the RMS fit (but are included when evaluating total along-track heat content).

To place error bars on our modeled heat content, we perturb the best fit eddy location by 1.2 km radially, again subsample the modeled field along the glider track, and then compute total along-track (x) and vertically (z) integrated heat content:

$$Q_{\mathrm{along}}(\tau_i) = \int_{x_{\mathrm{enter}}}^{x_{\mathrm{exit}}} \int_{z_{\sigma_{\mathrm{deep}}}}^{z_{\sigma_{\mathrm{shal}}}} \rho_0 c_p T_{\mathrm{anom}}(x, z, \tau_i)\, dz\, dx. \tag{5.2}$$

The spread in $Q_{\mathrm{along}}(\tau_i)$ provides a measure of uncertainty in the heat content of the best-fit eddy.

c. Results and interpretation

The best fit locations and modeled heat content are shown in Fig. 15. The predicted eddy track flows counter clockwise about the seamount east of Marguerite Trough (near 300.060), consistent with the mean flow, and the glider's excursion to the south confirms that this eddy did not go into Marguerite Bay. We are confident that the glider was indeed sampling the same eddy. Simulated particle trajectories (not shown) originating at $[x(\tau_1), y(\tau_1)]$ and using all possible 4-day sequences of the time-varying, depth-averaged current fields from Dinniman et al. (2011) confirm that parcels of water can follow the best-fit trajectory and can traverse the proposed distance traveled by the eddy over the total observation time.

In general, there is good agreement between the time series of observed and modeled along-track heat content (Fig. 15b). Particularly, the agreement is good near the edge of the eddy which contributes more to the integral of total heat content. There is a wide variety of intrusions, filimentation, and other submesoscale variability along the track. For example, the fourth crossing appears to skirt the eddy edge but contains a profile of water ejected from the eddy core. The second and third crossings appear to show the eddy core "split" by the cool layer that began penetrating the eddy during the first crossing. Obviously the model does not simulate these processes though it does seem capable of parameterizing their consequences. The total integrated heat contents fall within the range of perturbed model fits (Fig. 15c).

The results can be used to estimate the rate of heat loss of the eddy between crossings 1 and 5. The total heat content of the eddy during crossing 1 is easily obtained by integrating the model initial condition (itself a fit to the data) vertically between σ_{shal} and σ_{deep}, and then laterally out to R_1. At crossing 5, we obtain $Q_{\mathrm{max,chord}}$ and R_{chord} by fitting Eq. (2.1) to the data but to calculate the total heat content we need a cross section through the eddy center. Simple trigonometry shows that $R_{\mathrm{real}} = \sqrt{R_{\mathrm{chord}}^2 + D^2}$ and $Q_{\mathrm{max,real}} = Q_{\mathrm{max,chord}} \exp[+(D/R_{\mathrm{real}})^2]$, where D is the distance between the true eddy center and the chord-length center. Using $D = 2.5$ km (Fig. 15a), the total heat content is then obtained from Eq. (2.2) by using $Q_{\mathrm{max,real}}$ and R_{real} and integrating out to R_1. The initial and final heat contents are $Q_{\mathrm{tot}}(\tau_1) = 7.9 \times 10^{15}$ J and $Q_{\mathrm{tot}}(\tau_5) = 5.5 \times 10^{15}$ J, implying a cooling rate $\partial Q/\partial t = 7.0 \times 10^9\,\mathrm{J\,s^{-1}}$. It is worth noting that the modeled heat content on crossing 5 is 5.6×10^{15} J, only 2% greater than observed.

6. Discussions and conclusions

The first goal of this study was to understand the origin of UCDW eddies on the shelf. We conducted a linear stability analysis of the shelf-break current to show that its most unstable mode has a CDW-level amplitude maximum and an inverse wavenumber of 4.4 km. Glider observations confirmed that UCDW eddies on the shelf have diameters and crest-to-crest separation consistent with that metric and their anomalies are confined to the subpycnocline layer. The strong shear and weak stratification allow for sign changes in the interior potential vorticity gradient which cause instabilities smaller than the Rossby radius to persist

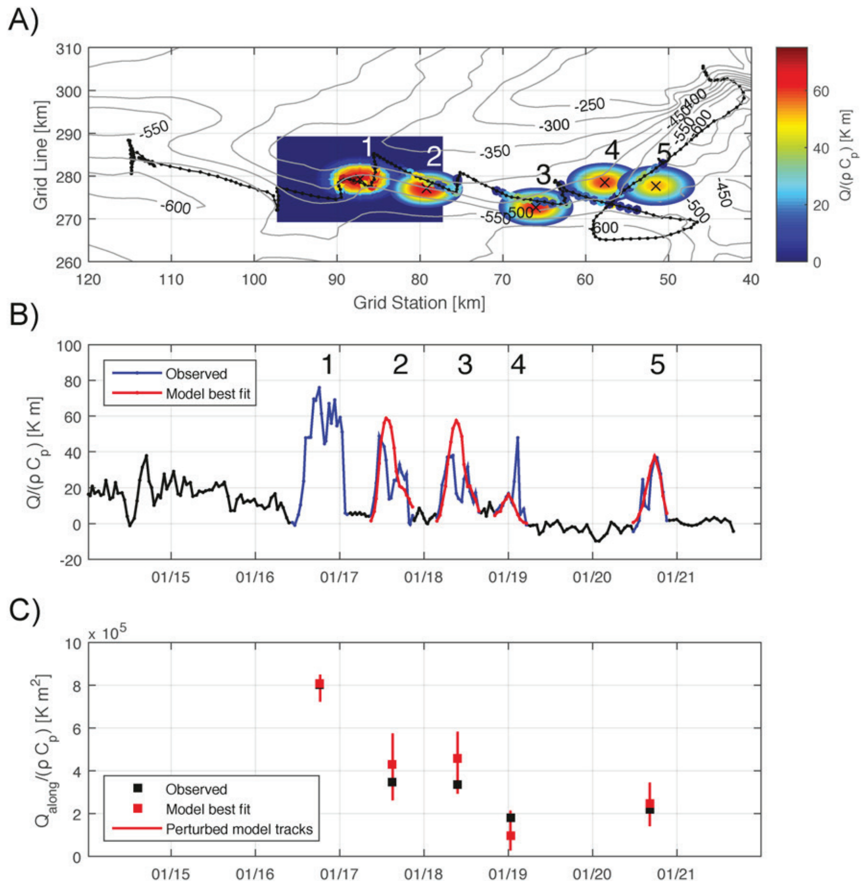

FIG. 15. Forward model results in comparison with glider data. (a) Glider track during the Tracking Stage (black line) where profiles containing the eddy are color coded by the vertically integrated heat content per unit area (dots). The contours are the diffusion model vertically integrated heat content per unit area at the time step of the crossing, situated at the geographic location that minimizes RMS error between the observed along-track series and the model field subsampled along the glider track. The first crossing shows the full model domain for scale. (b) Time series of observed (blue) and modeled (red) along-track heat content per unit area for each crossing of the eddy. (c) Time series of vertically and along-track-integrated heat content for each eddy. Observations are shown in black and the best fit model result is shown in red, along with error bars constructed by perturbing the model's best fit eddy location and then subsampling along the glider track and integrating.

even when Eady modes are suppressed by the bottom slope. This, in combination with the insensitivity to the planetary beta effect, suggests to us that similar UCDW eddies should be common around the Antarctic margins. However, we must be cautious with any broad extensions. While we have shown that either eastward or westward currents can support eddies, westward currents are often associated with the Antarctic Slope Front and very different stratification. The demonstrated sensitivity of eddy fluxes of CDW to other parameters that were not considered here, such as depth of the continental shelf or prominence of the Antarctic Slope Front (Stewart and Thompson 2015), restrict any generalizations and suggest eddy fluxes are still likely highly localized (Stewart et al. 2018) with one region of importance being the WAP.

The second goal of this study was to identify the major mixing processes that disperse eddy heat into surrounding water. Shipboard CTD and SADCP measurements were used to show cross-pycnocline diffusive fluxes should on average be $<1\ \mathrm{W\,m^{-2}}$ while fluxes below the eddy $T_{\max}$ should be an order of magnitude larger. CTD and glider profiles reveal that interleaving layers and thermohaline intrusions are ubiquitous, particularly in the lower pycnocline/eddy upper hemispheres where they link warm slope-type UCDW to the cooler waters within the adjacent water column's broad pycnocline. This water is most quickly

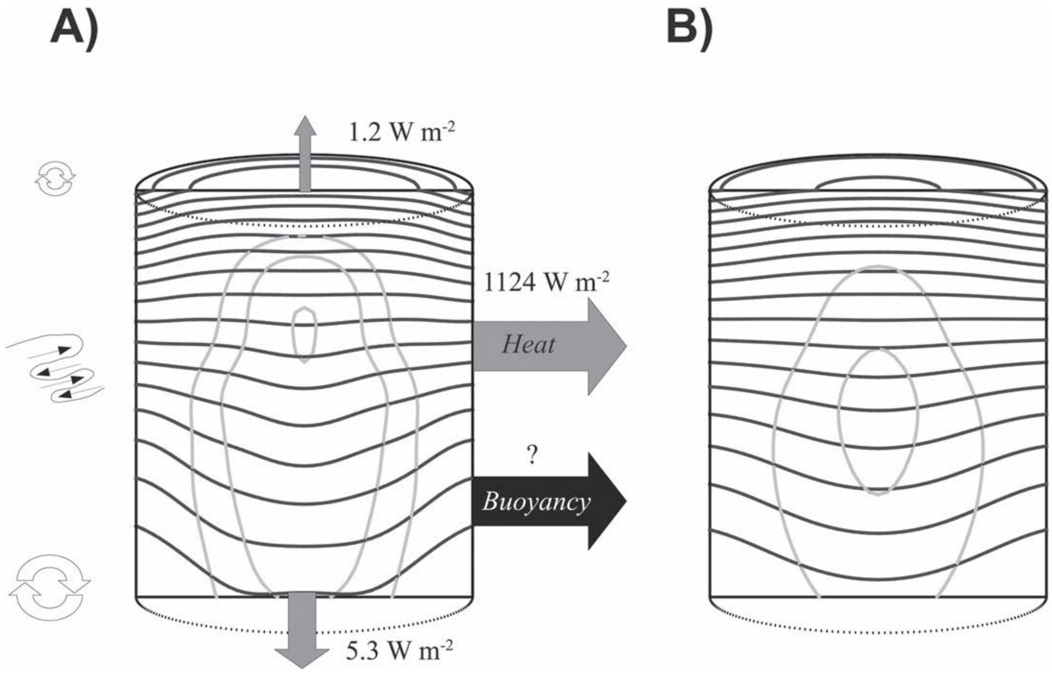

FIG. 16. Schematic summary of eddy heat loss processes and typical values for their fluxes based on the values in Table 1. The eddy is presented as a cylinder as in the integrated, averaged heat budget in the text. Isopycnals are shown as black lines, and three isotherms are shown as gray lines. (a) A schematic representation of the tracked eddy's initial condition and (b) schematic representation of the modeled eddy 4.5 days later. The same isolines are shown on each plot, suggesting that the temperature maximum is both eroded and mixed downward and that the geostrophic current is reduced. Lateral spreading of buoyancy by frictional spindown must occur, but its amount cannot be quantified with the glider data.

eroded over the Advective Path while the deeper, core $T_{\max}$ at ~250 m persists longer. The erosion of the core heat content per unit area is more apparent than that of the temperature maximum, implying erosion at the eddy boundaries and/or a redistribution of heat within the eddy interior. Consistent with this, high-pass-filtered spice variance is largest at the eddy edges.

The origin of the thermohaline intrusions is ambiguous. The magnitude of their thermal variance is larger than would be expected if due solely to internal wave shear, although this conclusion is highly dependent on the magnitude of the lateral temperature gradient across the eddy. In addition, thermal variance is largest above and just below the eddy core, both regions susceptible to double-diffusive instabilities. Instead, given the observed along-isopycnal spice variance, the mean spice gradient, and the size of the first-mode instability, a more plausible explanation for the origin of the interleaving layers may be stirring by the eddies themselves. A recent modeling study (Stewart et al. 2018) suggests that eddies may transfer heat across the Antarctic slope primarily by along-isopycnal stirring as opposed to advection by their overturning streamfunction. This also supports stirring as an explanation for the thermohaline variance.

The flexibility afforded by Slocum gliders allows for real-time, data-adaptive sampling. One of the novel aspects of this study is the collection of cross sections through an eddy as it traversed the shelf, providing a first estimate of the eddies' rate of cooling, which is consistent with that of a 3D diffusion model applied to the initial crossing. A lower limit on the time required to eliminate all heat relative to the mCDW profile within one radius from the eddy center is given by $Q_{\text{tot}}(\tau_1)/(\partial Q/\partial t) = 13.1$ days which assumes that the gradients are constant in time. Because lateral mixing dominates, an alternate cooling time is given by the solution to the two-dimensional diffusion equation with homogeneous lateral boundary conditions at infinity and a Gaussian initial condition of radius R. That solution implies that the heat content per unit area at the eddy center decreases as $R^2/(R^2 + 4K_h t)$. For the tracked eddy a 50% decrease is achieved after 10.3 days. For a typical eddy ($R = |\mathbf{k}_{\max}|^{-1}$), a 50% decrease takes 17.5 days.

We can synthesize these results with a heat budget integrated over a homogeneous eddy whose dimensions and gradients do not change in time:

$$\frac{1}{\rho_0 c_p}\frac{\partial Q_{\text{total}}}{\partial t} = 2\pi RHK_h \frac{\partial T}{\partial r}\bigg|_{r=R} + \pi R^2\left(K_z\frac{\partial T}{\partial z}\bigg|_{z=\text{top}} - K_z\frac{\partial T}{\partial z}\bigg|_{z=\text{bottom}}\right) + \varepsilon. \tag{6.1}$$

In this formulation, ε collects the mismatch between the left and right hand sides. It is meant to represent the effects of noise in the data but also captures the effects of processes that restructure the eddy. Because we only know $\partial Q/\partial t$ for the tracked eddy ($7.0 \times 10^9\,\mathrm{J\,s^{-1}}$), we balance the budget with that eddy's gradients and geometry averaged across crossings 1 and 5. For the tracked eddy, $R = 3.4\,\mathrm{km}$, $H = 188\,\mathrm{m}$, $\langle \partial T/\partial z|_{\text{top}}\rangle = 0.019°\,\mathrm{C\,m^{-1}}$, $\langle \partial T/\partial z|_{\text{bot}}\rangle = -0.0014°\,\mathrm{C\,m^{-1}}$, $\langle \partial T/\partial r|_{r=R}\rangle = 1.1 \times 10^{-4}\,°\mathrm{C\,m^{-1}}$, and the diffusivities are those used in the model, evaluated at the average depths of σ_{shal} and σ_{deep}. The balance implies the following conceptual model of eddy cooling. About 2% of initial heat loss occurs diapycnally through the permanent pycnocline; about 3% occurs diapycnally through the bottom and 95% occurs laterally. The lateral heat loss, which occurs in part through thermohaline intrusions, directly warms the surrounding pycnocline base and middepth waters. The diapycnal mixing through the bottom also works to flatten isopycnals at and below the $T_{\max}$ which reduces the azimuthal geostrophic current. The mismatch $\varepsilon/(\partial Q/\partial t) = 10\%$ is small, suggesting redistribution processes such as viscous spreading are of secondary importance compared to lateral mixing. To place this number in context, if the lateral diffusivity was increased from 3.2 to $3.6\,\mathrm{m^2\,s^{-1}}$ (which is within one standard error) then ε goes to zero. The budget is shown schematically in Fig. 16 with fluxes estimated for a more typical eddy (gradients and geometry from Table 1).

Importantly, a preference for the eddies to mix laterally and downward suggests that the eddies are good at redistributing heat rather than immediately venting it to the atmosphere. This sheltering has implications for the ability of intra and subpycnocline heat to persist and make its way shoreward toward marine-terminating glaciers even as the eddies themselves cease to remain coherent structures.

Acknowledgments. McKee and Martinson were supported by NSF Grants OPP-08-23101 and PLR-1440435; Schofield was supported by NSF Grant ANT-08-23101 and NASA Grant NNX14AL86G. Richard Iannuzzi processed the CTD and glider data, made Fig. 1, and provided valuable comments. We thank David Aragon and the Rutgers COOL group for deploying the glider and providing logistical support. We also thank Pat Caldwell at the JASADCP for culling and providing the SADCP data and Mike Dinniman for providing model current fields. We also acknowledge the captains and crews of the *L.M. Gould* and the *N.B. Palmer* for their efforts in acquiring many years of LTER data. Insightful comments from the editor and two anonymous reviewers greatly improved this manuscript. This is LDEO contribution 8310 and Palmer LTER contribution 620.

APPENDIX

The Garrett–Munk Spectrum on the WAP Continental Shelf

The Garrett–Munk (GM; Garrett and Munk 1975) spectrum provides an empirical description of the internal wave field in a flat-bottom open ocean away from boundaries and is frequently used to provide a statistical measure of internal wave variability in mixing parameterizations of nonlinear wave–wave interactions (e.g., G89). The GM spectrum ignores the presence of upper and lower boundaries and vertical structure in the wave field is manifested through a series of modal structures. Two fundamental parameters that scale the spectrum are a nondimensional energy E (canonically 6.3×10^{-5}) and a stratification depth b (canonically 1300 m). The GM shear spectrum is

$$\Phi_{\text{shear}} = \frac{Eb^3}{2\pi j_*}\left(\frac{N_0}{N}\right)\frac{\beta^2}{(1+\beta/\beta_*)^2}, \tag{A.1}$$

where β is the vertical wavenumber ($\mathrm{rad\,m^{-1}}$), $\beta_* = (\pi j_*/b)(N/N_0)$ is a reference wavenumber, $N_0 = 0.0052\ \mathrm{rad\,s^{-1}}$ is the canonical reference stratification, and $j_* = 3$ is the canonical mode number. A roll-off of -1 is imposed at wavenumbers greater than $\beta_c = 0.2\pi\ \mathrm{rad\,m^{-1}}$.

On the WAP continental shelf with typical bottom depths of ~400 m, the nondimensional energy E and the stratification scale b are likely quite different from canonical values (Levine 2002). Here we maintain the GM functional form (thus neglecting vertical boundaries) but adjust E and b in accordance with the environment of the WAP. One way to do so (section 4c of Levine 2002) is to first estimate the product $N_0 b$ from the observed stratification $N(z)$ and then to estimate the energy density in the internal wave band. We estimate $N(z)$ by first computing an average density profile from all summertime (January and February) Shelf CTD casts. For all casts, the depths of a set of evenly spaced isopycnals are calculated via linear interpolation and each isopycnal is assigned its mean depth. The resulting potential density profile is then interpolated to an 8-m grid and finite-differenced in order to obtain a profile of mean $N(z)$. The product $N_0 b$, which scales the wavenumber bandwidth, is defined as

$$N_0 b = \int_{404\,\mathrm{m}}^{24\,\mathrm{m}} N(z)\,dz = 1.5\,\mathrm{m\,s^{-1}}, \tag{A.2}$$

so that $b = 288\,\mathrm{m}$. The profile of mean N squared is shown in Fig. 9a. The lower integration bound is chosen as an average depth of all shelf stations and the upper integration bound is chosen as a typical seasonal mixed layer depth since overturns in the averaged density profile become apparent shallower than that [because the depth of the seasonal mixed layer varies regionally and interannually, the mean $N(z)$ profile is quasi-exponential with no apparent seasonal mixed layer]. Parameters N_0 and j_* are left at their canonical values.

To estimate the nondimensional energy density, we first estimate the kinetic energy density KE via baroclinic energy spectra from the moored current meter data of Martinson and McKee (2012). Their current meter data generally sample once per hour, however in 2007 they have one year-long record at site 300.100 that sampled once every 20 min with two current meters spanning the permanent pycnocline (one each nominally at $T_{\min}$ and $T_{\max}$). We define the barotropic current as the average of the two records and subtract that out. Then, the spectrum of the residual baroclinic current at each depth is calculated via squaring the Fourier transform of the complex time series, is averaged in the vertical, and is integrated over $[f, N_0]$. While the Nyquist frequency for this sampling is $0.5N_0$, the -2 roll-off in the internal wave band reveals that most of the contribution to the integral comes from the lower portion of the band. The depth average of the two integrated spectra times 1/2 yields the kinetic energy density (KE) and the nondimensional energy density is given by

$$E = \mathrm{KE}/(N_0 b)^2 = 3.0 \times 10^{-4}. \tag{A.3}$$

We now consider how the modified GM spectrum translates to parameterized diffusivities. Dissipation in the G89 model is given by

$$\varepsilon = \left[1.96\left(\frac{1.67}{\pi}\right) j_*^2 b^2 N_0^2 E^2 f_0 \operatorname{acosh}(N_0/f_0)\right]\left(\frac{N^2}{N_0^2}\right)\left(\frac{S^4}{S_{\mathrm{GM}}^4}\right)$$
$$= \varepsilon_0 \left(\frac{N^2}{N_0^2}\right)\left(\frac{S^4}{S_{\mathrm{GM}}^4}\right), \tag{A.4}$$

where the constant ε_0 is derived from wave–wave interactions in the GM energy flux spectrum. The assumption of a steady turbulent kinetic energy balance and a constant mixing ratio yields the relation for the diffusivity

$$K_z = \frac{\Gamma\varepsilon_0}{N^2}\left(\frac{N^2}{N_0^2}\right)\left(\frac{S^4}{S_{\mathrm{GM}}^4}\right) = K_0\left(\frac{S^4}{S_{\mathrm{GM}}^4}\right) \tag{A.5}$$

as presented in the text [but here without the corrections h and j; Eqs. (4.4) and (4.5)]. Under the canonical GM spectrum, $K_0 = 5.0 \times 10^{-6}\,\mathrm{m^2\,s^{-1}}$ whereas for the local parameters derived above $K_0 = 5.6 \times 10^{-6}\,\mathrm{m^2\,s^{-1}}$, which is a small difference. In addition, compared to shear variances using canonical GM parameters, integrated shear variances using the corrected GM parameters yield diffusivities that are generally up to a factor of 2 greater in the upper water column but almost equal near the $T_{\max}$. Given that the G89 method is demonstrated to be accurate within a factor of 2, all of this suggests that the improvements afforded by the corrected GM spectrum are small.

The *OceanGliders* program started in 2016 to support active coordination and enhancement of global glider activity. *OceanGliders* contributes to the international efforts of the Global Ocean Observation System (GOOS) for Climate, Ocean Health, and Operational Services. It brings together marine scientists and engineers operating gliders around the world: (1) to observe the long-term physical, biogeochemical, and biological ocean processes and phenomena that are relevant for societal applications; and, (2) to contribute to the GOOS through real-time and delayed mode data dissemination. The *OceanGliders* program is distributed across national and regional observing systems and significantly contributes to integrated, multi-scale and multi-platform sampling strategies. *OceanGliders* shares best practices, requirements, and scientific knowledge needed for glider operations, data collection and analysis. It also monitors global glider activity and supports the dissemination of glider data through regional and global databases, in real-time and delayed modes, facilitating data access to the wider community. *OceanGliders* currently supports national, regional and global initiatives to maintain and expand the capabilities and application of gliders to meet key global challenges such as improved measurement of ocean boundary currents, water transformation and storm forecast.

Keywords: *in situ* ocean observing systems, gliders, boundary currents, storms, water transformation, ocean data management, autonomous oceanic platforms, GOOS

INTRODUCTION

The ocean is an important component of the global earth system influencing the global/regional climate, weather, ecosystems, living resources and biodiversity. The ocean plays a major role in many human activities including coastal protection, tourism, search and rescue, defense and security, shipping, aquaculture and fisheries, offshore industry and marine renewable energy. Ocean observation serves to enable us to better understand ocean functions and to meet the societal needs related to these activities. The Intergovernmental Oceanographic Commission (IOC of UNESCO) developed the Global Ocean Observing System (GOOS) more than two decades ago to coordinate the different national efforts in terms of sustained ocean observations throughout the world and to maximize the societal benefits of ocean observations. The GOOS has three observation panels for the development of observing strategies for climate, biogeochemistry and biology/ecosystems and the Observation Coordination group (OCG) of the World Meteorological Organization (WMO)/Intergovernmental Oceanographic Commission (IOC) Joint Commission on Oceanography and Marine Meteorology (JCOMM) for technical coordination of on-going observations. GOOS also serves as the ocean component of the Global Climate Observing system (GCOS). It is implemented through GOOS Regional Alliances and supported by a wide range of bodies, such as the Committee on Earth Observing Satellites (CEOS), the Partnership for Observation of the Global Ocean (POGO) and the GEO Blue Planet initiative.

The OceanObs'99 conference stimulated the first design of the GOOS and 10 years later, the OceanObs'09 conference assessed the progress made in implementing the GOOS. At that time, an international consensus was reached on how the GOOS should continue to evolve. Discussions around the GOOS highlighted the tremendous potential value for physical, biogeochemical, and biological observations, particularly in the transition between the open ocean and the coastal environment, which is a key area for societal issues, economical applications and at the same time is a prime area for autonomous underwater glider (Davis et al., 2002) observations. Gliders were considered in this global framework from the very beginning. Developed in the 1980–1990s (Lee and Rudnick, 2018), they arose from the vision that a network of small, intelligent, mobile and cheap observing platforms could fill sampling gaps left by the other ocean observing platforms (Stommel, 1989). This idea was first discussed at OceanObs'99 (see Conference Statement[1]), when the technology was immature, and further developed at OceanObs'09, when the technology was still maturing but poised to make a substantial contribution to global ocean observing (Testor et al., 2010). It was agreed that gliders could fill important gaps left by other observing systems and thus greatly enhance the GOOS if fully integrated into the system, and recommendations were made for the next decade.

Progress Over the Last Decade

Since OceanObs'09, autonomous underwater gliders have reached a mature state and are now operated routinely. They offer persistent fine resolution observations in the coastal and open ocean, even at high latitudes (at least during summer months). Typically, gliders profile from the surface to the bottom, or to 200–1,000 m depth, taking 0.5–6 h to complete a cycle from the surface to depth and back. During that time they travel 0.5–6 km horizontally at speeds of about 1 km/h, even during very severe weather conditions. Deployments of about a year are now possible, with deployments of 3–6 months now routine, and survey tracks extending over 1,000s kilometers. Sensors on gliders measure physical variables such as pressure, temperature, salinity, currents, turbulence and wind speed (Cauchy et al., 2018), biological variables relevant to phytoplankton and zooplankton, and ecologically important chemical variables such as dissolved oxygen, irradiance, carbon dioxide, pH (Saba et al., 2018), nitrate and hydrocarbon. Gliders have been developed to sample under-sea ice and ice shelves (Webster et al., 2015; Nelson et al., 2016; Lee et al., 2017), to recover data from other deep instruments via acoustic telemetry and send them to land while at the surface (Send et al., 2013), to detect acoustic tags on fishes (Oliver et al., 2013, 2017) and marine mammals. Improved gliders have reached depths of up to 6,000 m (Osse and Eriksen, 2007). All these improvements greatly open up the range of possible applications.

Their unique sampling capacities (high resolution and long term) are especially suitable for some key oceanic phenomena. They have yielded major scientific breakthroughs, revealing new insights into ocean physical, biogeochemical and biological processes. In particular, there are new results on (1) high latitudes oceanography, air-sea-ice interactions and intermediate/deep convection, (2) the variability of boundary currents, (3) (sub)mesoscale processes, (4) phytoplankton phenology and biogeochemistry, (5) higher trophic levels and biology, (6) shallow and marginal seas, (7) climate and variability of the water column, (8) internal waves, turbulence, tides, diffusivity and vertical mixing, and (9) particles fluxes and sedimentology (see **Table 1**).

Glider data are used for many applications in ocean physics, chemistry and biology (Rudnick, 2016). Glider data management by the scientific community has made data available to the public in real time for classical measured variables. Ocean numerical modeling and forecast activities already benefit from these data (**Table 1**). Models of ocean circulation, particularly for regional and coastal domains, have benefited from glider data in terms of validation and data assimilation, particularly in regional and coastal models. Glider data can improve hurricane intensity forecast models and has led to major results in ocean forecasting, weather forecasting including hurricane intensity, climatologies, and state estimates.

Underwater gliders will enable us to enter a new era of ocean observation and state estimates more effectively, meeting the needs of society and marine researchers. Gliders are a vital component in the portfolio of ocean observing platforms for most of the national ocean observation agencies. These agencies have invested in developing glider observing capability, and there are now about 400–500 gliders in the world actively being used to better observe the ocean (it is difficult to have exact numbers but based on our community knowledge we estimate ∼250 gliders in the USA; ∼100 in Europe; ∼50 in China; ∼30 in Australia; ∼30 in Canada; 9 in Mexico; 9 in South Korea; 5 in South Africa; 3 in Israel; 3 in Peru; 2 in New Zealand; 2 in India, 2 in Taiwan, etc.). Glider technology has also been used by the private sector during the last decade for applications in pollution events, defense, environment, and the offshore industry (Fragoso et al., 2016).

The Evolution of a Glider Observing Community-OceanGliders

Today, underwater gliders are operated by many teams around the world that have developed end-to-end systems able to steer their gliders and collect their data through their own facilities and Iridium satellite-based communications. Glider deployments are challenging because they must be managed in real-time throughout their deployment with the two-way communications needed for active piloting by the different operating teams. Glider technology requires a high level of expertise on the scientific and technological aspects in order to effectively operate the vehicles. Thanks to networking, coordination and capacity-building, training, liaison between providers and users, advocacy, and provision of expert advice, the global glider community has become more organized, grown rapidly, and responded to some of the system challenges. The idea for a glider community emerged in October 2005 at the first "EGO (Everyone's Gliding Observatories) Workshop and Glider School" and since then, collaborations have further developed. EGO Workshops and Glider Schools have been organized on an annual basis, to present and discuss scientific and technological issues, and to train and engage new users and countries worldwide. The formation of a user group and global coordination has improved glider operational reliability and data management, and resulted in improved glider monitoring, ocean observing and developments of the glider platform. Over the last decade, this coordination

activity has also developed nationally and regionally. Many national facilities have been established to serve their national communities such as the IMOS (Integrated Marine Observing System) Ocean Gliders facility, Ocean Gliders Canada, GMOG (Grupo de Monitoreo Oceanográfico con Gliders) in Mexico, MARS (Marine Autonomous and Robotic Systems) in the UK, Norwegian National Facility for Ocean Gliders (NorGliders) in Norway, "Parc National de Gliders" in France, etc. Glider groups have also been set up for coordination within integrated ocean observation initiatives such as the Integrated Ocean Observing System (IOOS), the Integrated Marine Observing System (IMOS) and the European Ocean Observing System (EOOS)/EuroGOOS. There are now several levels of coordination and this greatly facilitates scientific and technological exchanges between glider operators and users, in academia and industry.

Building on this diverse community, the *OceanGliders* program started in September 2016 at the 7th EGO conference. It was set up in recognition of the maturity of the glider systems and their potential role in the GOOS in coming years. The *OceanGliders* program as a component of the GOOS was approved by the Joint WMO-IOC Technical Commission for Oceanography and Marine Meteorology (JCOMM) at their 5th Intergovernmental Session in October 2017 and the *OceanGliders* Steering Team reports to OCG. Here we review the progress made in implementing a glider component of the GOOS, one of the key recommendations from OceanObs'09, present the recently established program and components, and offer a vision for the coming decade.

MOVING FROM THE REGIONAL TO THE GLOBAL

The progress of gliders in moving from a developing to a mature technology is exemplified by the programs that have been run continuously for over 10 years, for example, in the California Current (Adams et al., 2016; Rudnick et al., 2017), and the Solomon Sea (Davis et al., 2012). Long-term observations lasting several years are becoming widespread (Heslop et al., 2012; Schaeffer et al., 2016a; Yu et al., 2017; Du Plessis et al., 2019). The capability to sustain these programs relies on the improved dependability of gliders (Brito et al., 2014; Rudnick et al., 2016a; Brito and Griffiths, 2018) and the experience, skill and confidence of the operators. The success of these projects can be summarized in the likelihood of a glider completing a desired mission, and the fraction of the time that a glider is in the water. Typical success rates of 0.9 have been achieved by experienced teams. The delivery of data from gliders in real time has become routine, with main glider data assembly centers in Europe (EGO/Coriolis[2]), Australia (IMOS[3]), and the USA (IOOS[4]).

Underwater gliders play a special role in observing systems designed to support regional modeling activities, because gliders generate many profiles at controlled locations. The potential for glider development was recognized quite early on, leading to the influential Autonomous Ocean Sampling Network (Ramp et al., 2009). Glider data are often used with models for two purposes: (1) verification, meaning to evaluate model output for fidelity to the ocean; and/or, (2) assimilation, the use of data to constrain model output (Edwards et al., 2015; Hayes et al., 2019). Models can either (1) forecast ocean variables in advance of any access to data for verification; or (2) hindcast to deliver state estimates that use data to create a complete set of ocean variables. Many combinations of using glider data for verification or assimilation of forecast or hindcast models have been tried in many regions around the world. For example, off California, Kurapov et al. (2017) used glider data (Rudnick et al., 2017) to verify a forecast model, while Chao et al. (2018) assimilated the same glider data to create forecasts. Temperature and salinity data from these gliders were assimilated into a state estimate (Todd et al., 2011a, 2012; Zaba et al., 2018), while velocity data were not assimilated so they could be used for verification. In the Mediterranean, Dobricic et al. (2010) showed the large-scale impact of the repetition of a glider section and in particular when depth-average currents were also assimilated while Mourre and Chiggiato (2014) and Onken (2017) assimilated glider data for a forecast and verified against data from a ship survey. A state estimate of the tropical Pacific (Verdy et al., 2017) was verified against withheld glider observations on either side of the Pacific basin. These examples illustrate the character of recent work. Ongoing work is expected to improve regional observing modeling in the coming decade.

Underwater gliders are especially well-suited for sustained, fine-spatial-resolution observations near the ocean boundaries. They allow cross-front measurements to help resolve mesoscale/sub-mesoscale fronts and associated shear-driven instabilities in both the coastal and open ocean. The long times for deployments of gliders are possible because they move slowly (10s cm/s) and because energy lost to drag is proportional to the cube of the speed through water. Gliders must profile continuously in order to make way through water, so fine resolution in the order of a few kilometers is common. Gliders can be deployed and recovered from small boats, thereby minimizing costs and allowing flexible operation. Sustained, fine-resolution operations near boundaries are ideal for monitoring the regional effects of climate variability. Gliders fill the gap between the coast and the open ocean, as tracks of thousands of kilometers are typical, making traversing the 200 nautical mile Exclusive Economic Zone practical. Gliders could revolutionize regional oceanographic observing just as Argo did for observing the open ocean over the last two decades.

OceanGliders Terms of Reference

The international *OceanGliders* program was created as a component of the GOOS with the broad goals of strengthening the glider community (users, scientists, engineers, operators, manufacturers) and facilitating the sustained worldwide use of gliders for the benefit of society and science[5]. An initial structure and set of governance rules were agreed upon, as well as more detailed ways to maintain and develop the program, briefly summarized in **Table 2**. Because of their proven ability to fill gaps and needs in the existing observation system, gliders are on the cusp of a transition from isolated, regional use by a few expert teams, to widespread use around the globe by coordinated groups with a wider range of applications. The glider community has realized the many benefits of sharing expertise, best practices, data, and even infrastructure components among existing and new members. Providing a global program, in which new ideas can be discussed and coordinated for larger-scale adoption, will turn regional efforts into integrated global efforts. This fits perfectly into the GOOS mission to promote feasible, high-impact observing programs.

Data Management

OceanGliders targets high-impact, societally-relevant, science-based observing through a number of initial scientific Task Teams (*OceanGliders* TT). They are developed in the following section, but one Task Team in particular relates to the smooth, coordinated functioning of each TT with each other and with the rest of the GOOS: the data management TT. This team aims to address the needs of long-term observation aspects of data management, benefiting the wider community, supporting and encouraging scientists designing and executing process studies, as well as engineers developing new gliders, sensors, and computing

TABLE 2 | Summary of *OceanGliders* terms of reference and objectives.

Purpose	To provide scientific leadership to promote and strengthen the glider community and facilitate their sustained use globally in order to respond to the integrated requirements of the Global Ocean Observing system (GOOS). Oversee the development and implementation of a global-scale glider array for observing key regions of the ocean on the long term, based on national and regional projects (https://www.ego-network.org/dokuwiki/lib/exe/fetch.php?media=public:gst:glider-st_tor.pdf)
Membership	Anyone willing to contribute to the different Task Teams is considered as a member, keeping in mind the focus on developing sustained glider activity and the "Framework for Ocean Observing."
Steering Team	Reflect and represent the sustained glider activity and to drive *OceanGliders* toward its goal of filling gaps in GOOS/GCOS
Exec Committee	Chair, co-Chair, Task Teams Leaders and GOOS advisor
Task Teams	Design network, define targets for Task Teams missions (optimum strategy)
	Define science implementation plans
	Describe scientific requirements and societal requirements
	Describe the global costs and cost-effectiveness
	Define the contribution of Task Teams in a multi-platform system designed to address scientific and societal issues, including unique roles of gliders
Meetings	Annual Steering Committee meetings

technologies to participate in metadata and data management. Data management implies not only data repositories of a certain standard, but the guidance and coordination in the development of new standards and best practices (Pearlman et al., 2019) for data collection, processing, and quality control. Data management requires metadata and its description, storage, and access. One of the benefits of coordination will be improved and sustained quality control of glider data.

Network Monitoring and Data Dissemination

One main goal for glider operators is to make data publicly available and in particular to publish data in near-real time on the GTS (Global Telecommunication System) and in CF (Climate and Forecast) compliant formats for operational services. They provide their metadata and data to a Data Assembly Center (DAC) in charge of the data management and linked to a Global Data Assembly Center (GDAC) for further dissemination and archive. Three *de facto* GDACs are currently operating: Australia (IMOS), Europe and partners (EGO/Coriolis), and the United States (IOOS). Each GDAC has adopted similar strategies and conventions: CF-compliant NetCDF observation file formats can be uploaded by operators, and public sites and tools are provided for downloading and visualization. There are minor differences in formats, and the implementation of tools for raw file conversion, discovery, download and visualization varies widely. Numerous regional and local efforts have developed important tools but this has made it painfully obvious that coordination is needed for global-scale visibility and availability of ocean observations of known quality control. Initial efforts by IMOS, EGO/Coriolis and IOOS at collecting daily glider data illustrate some of the extent of glider activity worldwide over the past decade (**Figures 1**, **2**). This also represents the commitments from glider teams that have fed these systems, showing most of the glider deployments carried out so far in the world. The next step of unifying and providing data seamlessly from any region through one portal must be simpler. Already, the three GDACs have shared detailed information on how to upload, discover, download, and visualize using their tools. Simplifications have been made to provide easy access among the GDACs. This information will be centralized as in **Figure 3** and accessible on the *OceanGliders* website www.oceangliders.org and will be an important tool to monitor global glider activity and promote its objectives.

The first dedicated global glider data management meeting has stimulated further developments (Genova, Italy, 17–19 September, 2018). Besides sharing expertise and latest developments at the regional level, this meeting produced a global consensus about how glider data can be made more useful to society, considering both historical and near real time data sets, now and in the future. Short-term goals include: setting up a solution to access all glider data in a single format; define indices for glider activity monitoring; handling the real time and delayed mode quality controls and assessments at the global level. Further development and sharing of best practices on data and metadata management are key for the *OceanGliders* Data Management Task Team. To that end, there is now a new central directory at www.oceanbestpractices.net, hosted by IODE, for *OceanGliders*.

Glider-specific tools have been developed at the GDAC and regional/institutional (or DAC) level to complement the other elements of the GOOS. The unique trajectory character of glider data, and of the wide range of metadata can cause these tools to be quite complex. Even the familiar concepts of "cruise," "mission," "transect," and "profile" do not adequately describe the nature of glider flight and programmable behavior in real time.

There are too many to exhaustively list here, but notable examples include: GliderScope[6] (Hanson et al., 2017), IOOS[7], EGO GFCP[8], NorGliders GliderPage[9], SOCIB[10] (Troupin et al., 2015), MARS[11], and GANDALF[12]. Going forward, standardized data and metadata interfaces will benefit the future development of such tools and enable easier, global access to the full set of quality-controlled glider data and metadata [e.g., the Sensor Web Enablement framework and associated standards (Bröring et al., 2017)].

Emerging Requirements

Glider data management will need to encompass developments within the glider networks, the GOOS and outside of the oceanographic domain in order to anticipate future changes in global data management. The implementation of Findable-Accessible-Interoperable-Reusable (FAIR) data principles is a

common theme in environmental data management and will place demands for development on glider data infrastructure (Tanhua et al., 2019). The integration of data from different networks within the GOOS and the implementation of new Essential Ocean Variables (EOVs) are also emerging as requirements. Furthermore, additional demands on data management will emerge with such as automated piloting (e.g., Chang et al., 2015; Smedstad et al., 2015) and operational glider network monitoring technologies.

ADDRESSING GLOBAL OBSERVING NEEDS

The *OceanGliders* group met to discuss possible areas of focus and beyond the central need for improved data management, identified three key areas of focus for the developing program. These areas of interest were organized into Task Teams (TT) whose goals are to address the societal needs for ocean data and to entrain the community into discussions around the role of gliders in meeting these needs. It is expected that the mission-based TTs will organically develop by organizing the different initiatives into integrated and coordinated global efforts.

Boundary Currents

Society experiences changes in the global ocean at the ocean's boundaries. These boundary regions are the nexus of societal use of the ocean for fisheries, transportation, and recreation. The boundary regions are also where the intense ocean currents are key to the transport of mass, heat, salt, biogeochemical variables and plankton. In the large ocean basins, the subtropical western boundary currents dominate the surface poleward transport of warm water or equatorward transport of cold water at depth and are major drivers of climate variability. Subtropical eastern boundary currents are often upwelling systems that comprise some of the most biologically productive regions in the world and host the world's Oxygen Minimum Zones (OMZ). Subpolar eastern boundary currents induce significant poleward heat transport in the downwelling eastern part of the subpolar gyres. Boundary currents in marginal seas provide the major means of exchange with the open ocean and impact regional ecosystems. Finally, the communication between the coast and open ocean is regulated by the boundary currents that flow along the continental slopes, affecting ecosystems, flood levels, erosion and commercial activity. To summarize, there is a great need for sustained observations of these highly dynamic boundary current regions.

Underwater gliders are particularly effective at measuring and monitoring subsurface biogeochemical fields that are both key to marine ecosystem productivity and involved in some of the most pressing ocean challenges like ocean acidification and hypoxia. For instance, glider capabilities are well-suited to sample the upwelling source waters transported to the edge of the continental shelf by eastern boundary currents. Recent studies in the Pacific and Atlantic reveal details of the spatial structure and time evolution of, for example, low-oxygen zones in such regions (Pierce et al., 2012; Pietri et al., 2013; Adams et al., 2016; Pizarro et al., 2016; Thomsen et al., 2016; Karstensen et al., 2017).

From their earliest conception, underwater gliders were viewed as components of observing/modeling systems, and progress over the past decade has proven the efficacy of this approach. The data provided by underwater gliders are a natural match for regional models of coastal ocean circulation. These regional models are necessary, as the currents and water properties in the coastal ocean vary on the relatively small scales

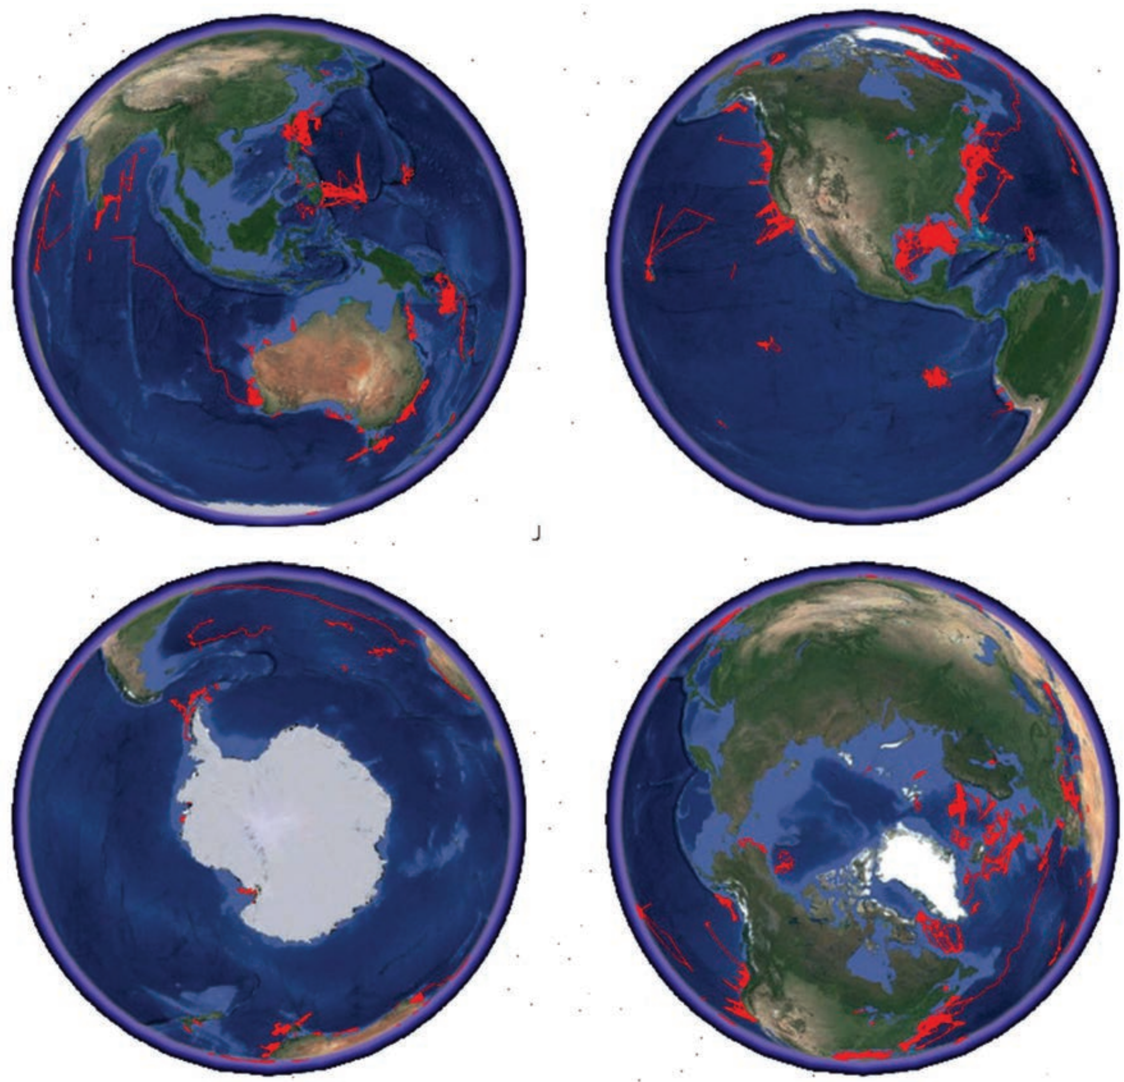

FIGURE 2 | Gliders tracks of past deployments until October 2018 (OceanObs'19 submissions), as can be viewed using google-earth from different locations.

set by topography. Accurate forecasting depends on initialization on these small scales, which can be satisfied by a network of gliders.

The most widespread application of sustained glider programs has been in boundary currents. These efforts range from the significant western boundary currents, to the highly productive eastern boundary upwelling systems, to regionally important boundary currents in marginal seas. Initial targets are often the mean and variability of velocity, temperature, and salinity, and now moving to include biogeochemical and biological variables. As the sustained time series increase in length, interannual climate variability is resolved. The remarkable increase in sustained glider observations in the last 10 years is summarized below and illustrated by **Figures 4–6**.

Sustained projects in the Atlantic include observations on the western, eastern and northern boundaries of the North Atlantic. The marginal seas of the Atlantic, including the Mediterranean and the Gulf of Mexico are also home to long-term observations.

- The Davis Strait was observed repeatedly during 2005–2014 to quantify the exchange between the Arctic Ocean/Baffin Bay and the subpolar North Atlantic (**Figure 5A**; Beszczynska-Möller et al., 2011; Curry et al., 2014; Webster et al., 2015). Although this effort succeeded in collecting year-round observations across the seasonally ice-covered strait, challenging logistics, harsh operating conditions and funding prevented continuous occupation of the section over the entire 2005–2014 period.
- The warm water paths of the North Atlantic Current over the Rockall-Hatton Plateau at 58°N are being observed using repeat glider sections between 15 and 21°W as part of OSNAP since 2014 (**Figure 5E**; Houpert et al., 2018; Lozier et al., 2019).

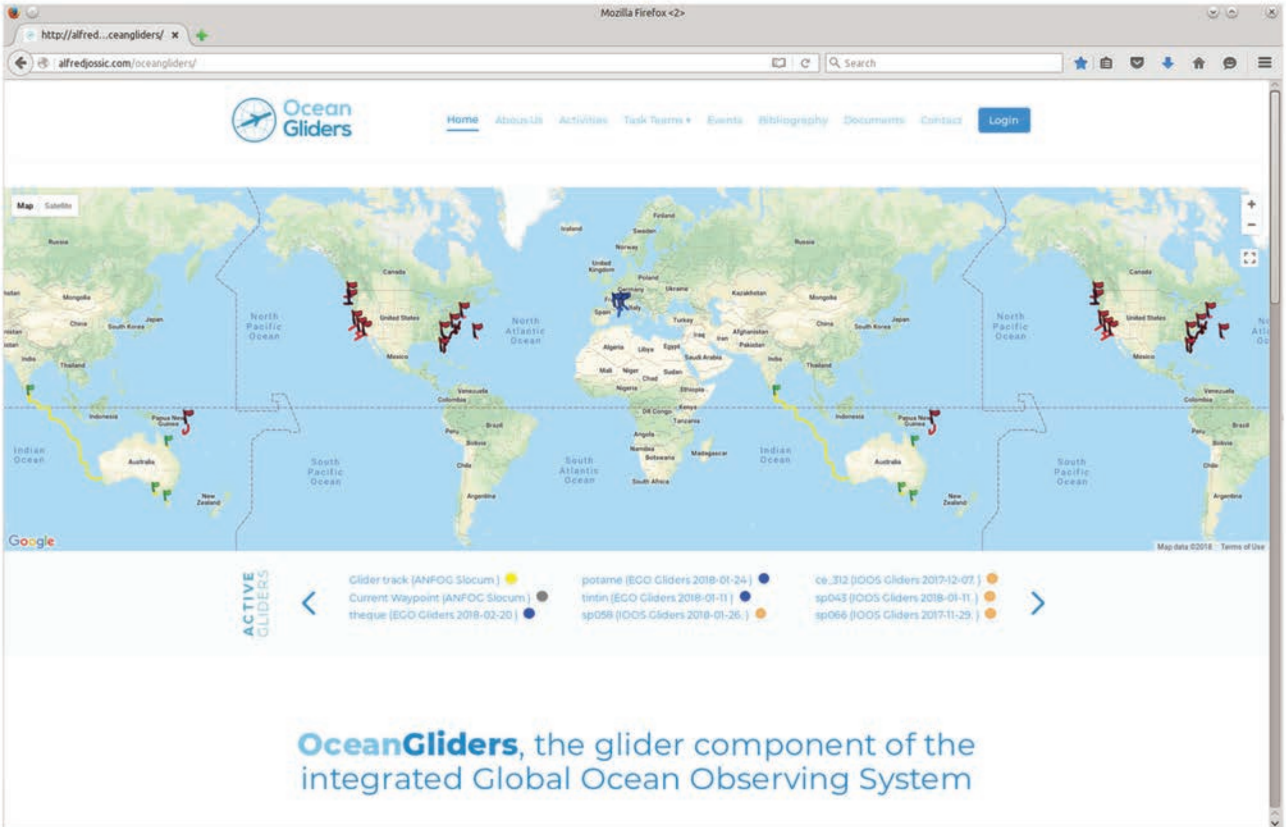

FIGURE 3 | The global active glider fleet trajectory map, updated daily (from http://anfog.ecm.uwa.edu.au/index.php?page=global_gliders, accessed 23 August, 2018).

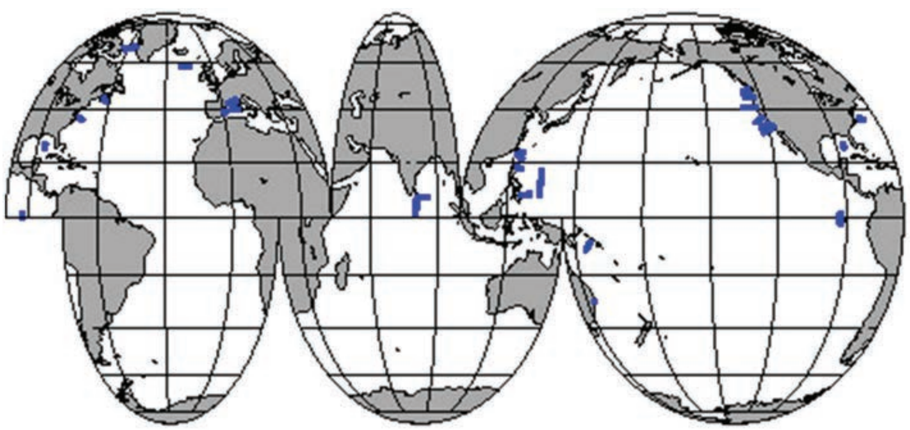

FIGURE 4 | Sustained observations of boundary currents of duration from at least one to over a dozen years. Mean sections of absolute geostrophic velocity are a unique product of underwater gliders, calculated by combining geostrophic shear with directly measured depth-average velocity. These sections at the locations in this figure are shown in **Figures 5**, **6**.

- The Nova Scotia Current was observed during 2011–2014 by repeat glider sections as part of the Ocean Tracking Network (**Figure 5B**; Dever et al., 2016) and re-established by Fisheries and Oceans Canada in 2018 as part of its monitoring programs.
- Along the East Coast of the United States, a program of routine glider surveys across the Gulf Stream is underway. Commanded to steer across strong currents of the western boundary current, gliders are able to occupy cross-Gulf Stream transects as they are advected downstream (**Figure 5C**; Todd

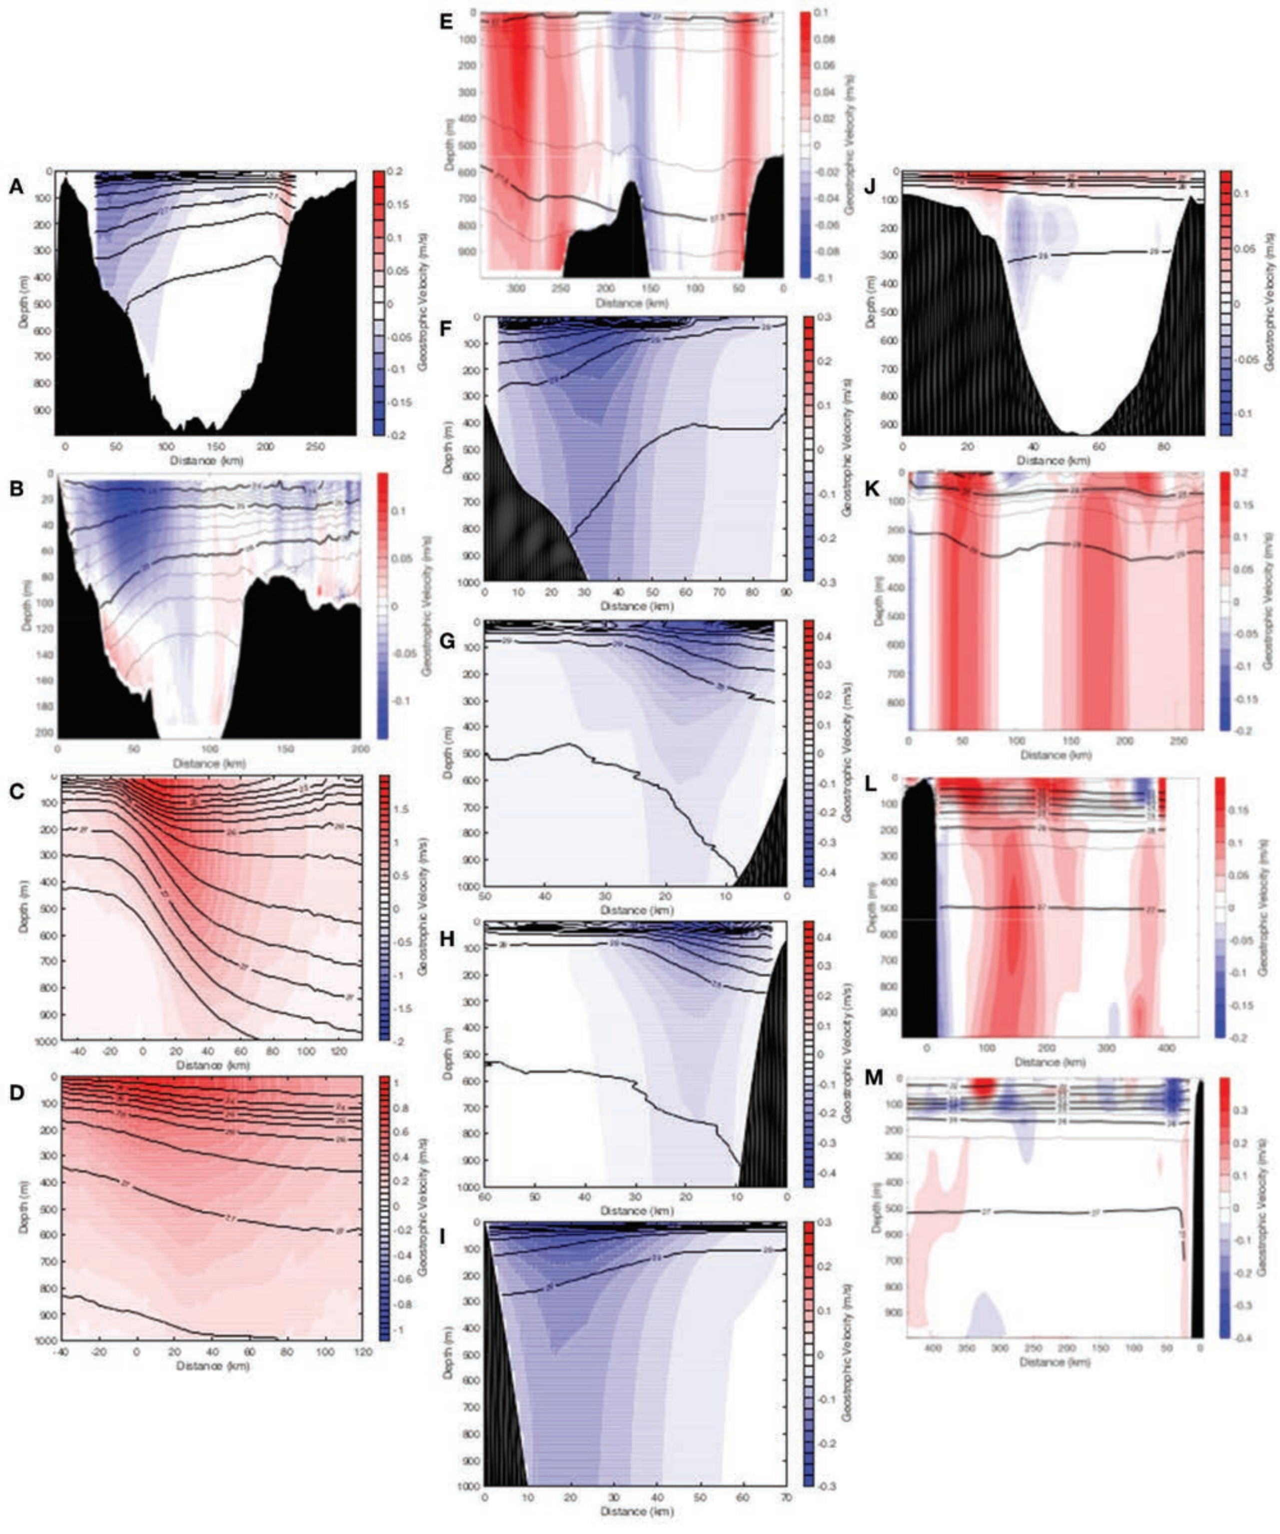

FIGURE 5 | Mean sections of geostrophic velocity from the Atlantic, Mediterranean and Indian Ocean. Sections in the Atlantic include **(A)** the Davis Strait, **(B)** the Nova Scotia Current off the east coast of Canada, **(C)** the Gulf Stream off the eastern US coast, **(D)** the Gulf of Mexico Loop Current, and **(E)** the North Atlantic Current west of the UK. Sections in the Northern Current System of the Mediterranean Sea are **(F–I)** along the southern coast of France, **(J)** between the Spanish coast and the island of Ibiza, and **(K)** between Sardinia Island and Menorca. In the Indian Ocean, sections are off the **(L)** east and **(M)** south coast of Sri Lanka. The sections are oriented generally west to east or south to north, and positive geostrophic velocity is primarily northward or eastward.

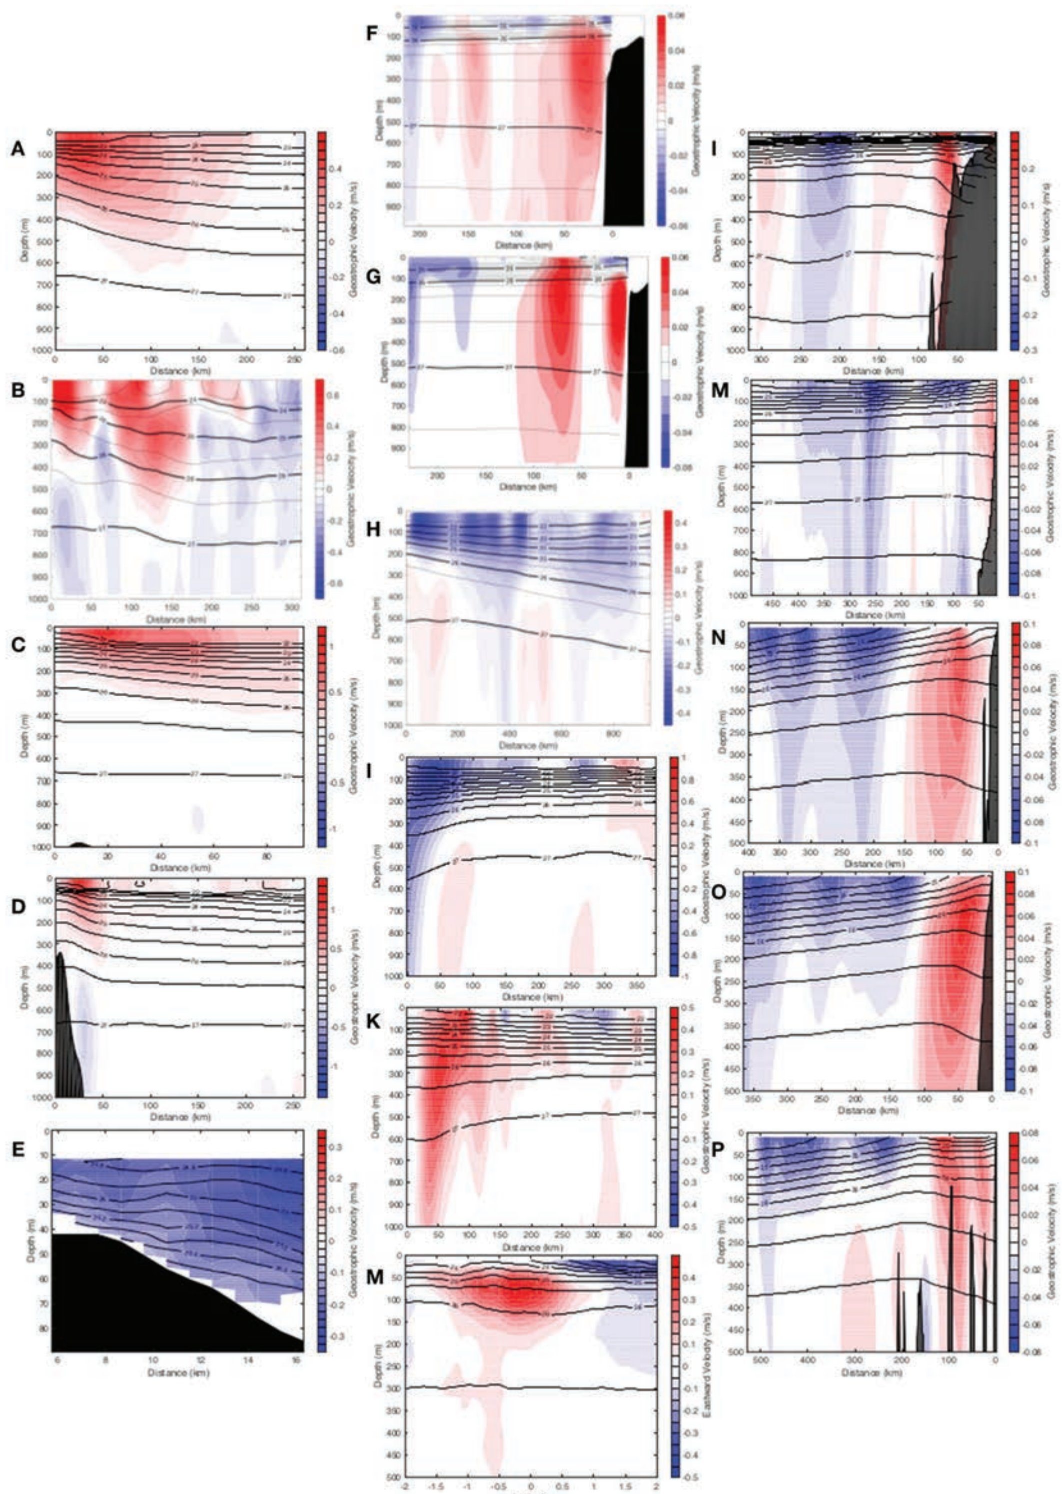

FIGURE 6 | Mean sections of geostrophic velocity from the Pacific. Sections in the western Pacific include the Kuroshio offshore of **(A,B)** Taiwan and **(C,D)** Luzon, and in **(E)** the East Australian Current, **(H)** the North Equatorial Current, **(I)** the Mindanao Current, and **(J)** the New Guinea Coastal Current of the Solomon Sea. Sections in the eastern Pacific include **(F,G)** two off Washington, **(L)** one off Oregon and four off the California coast at **(M)** Trinidad Head, **(N)** Monterey Bay, **(O)** Point Conception, and **(P)** Dana Point. A mean section across the equator at 93°W off the Galapagos **(K)** was measured by acoustic Doppler profilers, as geostrophy fails at the equator. The sections are oriented generally west to east or south to north, and positive velocity is primarily northward or eastward.

et al., 2016, 2018; Todd, 2017; Todd and Locke-Wynn, 2017; Gula et al., 2019).

- The Gulf of Mexico Loop Current was observed starting in 2007, and continuously during 2011–2014 with a focus on mean structure, eddies and separation processes (**Figure 5D**; Rudnick et al., 2015; Todd et al., 2016). Along-gradient glider trajectories of mesoscale eddies ubiquitous in the central and western Gulf of Mexico have been repeatedly carried out since May 2016 to present as a component of a quasi-continuous (90% of time) monitoring program conducted by GMOG.
- European Slope Current at 56.5N as part of the sustained Ellett Line program. Gliders have been occupying this section in winter since 2009, and several times per year since 2015 (Sherwin et al., 2015).
- In the Western Mediterranean, repeat glider transects have been conducted to monitor the variability of the Northern Current System, over 10 years in the north of the basin (**Figures 5E–H**; Testor et al., 2018), for 6 years at a circulation "choke" point (**Figure 5I**; Heslop et al., 2012), for 8 years at the Mallorca Channel (Barceló-Llul et al., 2019) and more recently between Sardinia and Balearic Islands (**Figure 5J**) and between Mallorca Island and the African coast (Cotroneo et al., 2016; Aulicino et al., 2018).
- The Norwegian Atlantic Current Observatory has undertaken long term glider monitoring across 2 transects over 4 years, monitoring northward flow to the Arctic regions (Høydalsvik et al., 2013). Gliders have been used to monitor the topographic steering of warm Atlantic waters toward Arctic tidewater glaciers on the west Spitsbergen margin (Fraser et al., 2018).
- Since 2012, gliders have been deployed in the Subantarctic Zone of the South Atlantic each year, as part of the Southern Ocean Seasonal Cycle Experiments (SOSCEx; Swart et al., 2012). Deployment have covered all seasons except late austral autumn to assess bio-physical interactions from sub seasonal to seasonal scales (Du Plessis, 2015; Swart et al., 2015; Thomalla et al., 2015; Little et al., 2018; Du Plessis et al., 2019).
- Repeated sections were carried out off Cape Verde Islands as part of the Collaborative Research Center 754 (DFG; Oschlies et al., 2018), Senegal (Kolodziejczyk et al., 2018) and Angola, primarily to study the OMZ.

Projects in the Indian Ocean range from the Bay of Bengal to the currents that connect to the Southern Ocean:

- Gliders in the Bay of Bengal off the east and south coasts of Sri Lanka (**Figures 5K,L**; Lee et al., 2016).
- Repeated sections in the Agulhas Current since 2017 as part of Gliders IN the Agulahas (GINA, Krug et al., 2018) following the Shelf Agulhas Glider Experiment (SAGE) in 2015. Initial results include observations of cyclones on the inshore edge of the current (Krug et al., 2017).
- Many cross sections of the Leeuwin Current, the poleward flowing eastern boundary current in the southern Indian Ocean (Pattiaratchi et al., 2017).

Projects in the Pacific include sustained observations in the eastern boundary current of the North Pacific, and both the midlatitude and low-latitude western boundary currents of the North and South Pacific:

- The Kuroshio off Taiwan (**Figures 6A–D**; Lien et al., 2014; Yang et al., 2015), the North Equatorial Current north of Palau (**Figure 6H**; Schönau and Rudnick, 2015) and the Mindanao Current off the Philippines (**Figure 6I**; Schönau and Rudnick, 2017) were occupied continuously from 2007 to 2014 to quantify transports and water masses as part of the project Origins of the Kuroshio and Mindanao Current (OKMC). Observations began again in 2017 with a line off Taiwan.
- Repeated sections across Solomon Sea were made for nearly a decade to monitor the low latitude western boundary current that feeds the Pacific equatorial current system from the Southern Hemisphere (**Figure 6J**; Davis et al., 2012).
- The California Underwater Glider Network has occupied three lines in the California Current System for the past decade with a primary goal of monitoring the regional effect of climate variability as caused by El Niño (**Figures 6N–P**; Rudnick et al., 2017). A fourth line off northern California has been occupied for 2 years (**Figure 6M**).
- The inshore edge of the East Australian Current (EAC) has had repeated sections run since 2010 (**Figure 6E**) to observe the separation of the current, and the momentum balance at that point (Schaeffer and Roughan, 2015), the hydrographic structure of the current (Schaeffer et al., 2016a), the biogeochemistry (Schaeffer et al., 2016b).
- Sections across the California Current, immediately south of the West Wind Drift bifurcation region, were occupied continuously from 2003 to 2009, and then annually, for 6–9 months per year, from 2010 to 2015 (**Figures 6F,G**). These observations provide data to advance the understanding of the regional response to climate variability and California Undercurrent Eddies (Pelland et al., 2013).
- The Ocean Observatories Initiative began occupying 5 sections off Oregon and Washington, starting in 2014 to address the influence of climate variability on eastern boundary ecosystems. One of these lines, off Oregon, has been occupied continuously since spring 2006 (**Figure 6L**; Mazzini et al., 2014).
- Repeated sections off Peru started in 2008 (Pietri et al., 2013) to study the Humbolt system.
- Repeated sections off Chile (Pizarro et al., 2016) primarily to study the OMZ.
- Repeated sections in the Coral Sea adjacent to the north Queensland coast (Australia) have been used to estimate boundary current transport (Ridgway and Godfrey, 2015).
- The Equatorial Current System was observed during 2013–2016 using acoustic Doppler profilers (Todd et al., 2017; **Figure 6H**), as geostrophy fails at the equator. These measurements were undertaken as part of the Repeat Observations by Gliders in the Equatorial Region (ROGER) program (Rudnick, 2016).
- Glider transects at 37.9°N across the East Korean Warm Current along the Korean Peninsula have been conducted since 2017.

Underwater gliders can measure absolute geostrophic velocity. The geostrophic shear may be calculated from glider sections by estimating the horizontal gradient of density. This shear is referenced to the depth-average velocity that is calculated by dead reckoning between navigational fixes at the beginning and end of dives. This absolute, depth-dependent geostrophic velocity normal to the glider section allows calculation of the transport of mass, heat and salt. These transports are the fundamental quantities needed for baseline monitoring of boundary currents. Much work has been done to quantify the scales resolved and the accuracy of the velocity. For example, high frequency motions, such as internal waves, are projected into spatial variability in a glider section, with the result that horizontal wavelengths longer than 30 km are resolved in midlatitudes (Rudnick and Cole, 2011). The accuracy of the depth-average velocity, is of order 0.01 ms^{-1}, as inferred in early design studies, and confirmed by decades of observations (Rudnick et al., 2018). The sustained observations have produced several estimates of the boundary currents (**Figures 4–6**).

The goal of the *OceanGliders* Boundary Ocean Observing Network (BOON) is to provide coordination for a global observing program. Because boundary currents invariably reside in EEZs, their observation must depend on regional efforts respectful of the coastal countries. The goal of BOON is to sustain observations year-round. The result will be a global network of regional networks that monitor boundary current variability across international borders to the world's benefit.

The *OceanGliders* BOON complements existing ocean observing networks. Argo has transformed ocean science with its global coverage. BOON connects Argo's observations of the open ocean with the coastal ocean by operating the transects that are required to monitor boundary currents. BOON expands the footprint of site-specific moorings of OceanSites by repeated sections that may connect to mooring locations. Repeated surveys by ships form the backbone for many existing regional efforts, in some cases going back decades. BOON will step change our ability to observe boundary current variability in real-time, across all seasons and in difficult conditions and locations, building on the historical record and improving temporal and spatial resolution by overlapping with these ship surveys. BOON will identify gaps in the observation of boundary currents, with the goal of filling them by the most appropriate technology (Todd et al., 2019).

Storms

Tropical and extra-tropical storms are among the most destructive natural events on Earth. Tropical storms cause an average of 10,000 deaths per year and will potentially cost the global economy more than $9.7 trillion over the next century. Growing coastal populations, urbanization, and rising sea levels magnify our vulnerabilities to storms, escalating the need for more accurate storm tracking, intensity and impact forecasts. Tropical storm tracking forecasting has shown steady improvement over the past 25 years due, in part, to the improvements in the global atmospheric forecast ensembles. But similar improvements in tropical storm intensity forecasts have lagged, in part due to the paucity of upper ocean data defining its pre-storm heat content, the inability of operational ocean models to forecast with sufficient accuracy the rapid changes in upper ocean heat content in conditions of extreme forcing, and the uncertainty in the processes that influence the transfer of heat between the ocean and atmosphere. Tropical storm impacts, such as wind and storm surge, require accurate tracking and intensity forecasts.

Gliders have been the critical observing system element for two study areas in particular, one focused on an area of potential rapid intensification surrounding the Caribbean Islands, and another in the Mid Atlantic Bight where rapid intensity reductions have challenged forecasters.

In the tropical Atlantic and Caribbean Sea, early research carried out by NOAA/AOML, NOAA/NHC, and University of Miami scientists has demonstrated that the upper ocean is linked to hurricane intensification and/or weakening provided that the appropriate atmospheric conditions are present (Shay et al., 2000). For example, several studies have shown how major hurricanes, including Hurricane *Katrina* (2005), rapidly intensified while traveling over a warm Loop Current and Eddy feature in the Gulf of Mexico (Mainelli et al., 2008). Studies carried out for other Atlantic hurricanes have shown the close link between the upper ocean heat content and the intensity changes observed in Cat 3 and above hurricanes. Since this link has been established in this region, efforts are now geared toward improving hurricane intensification forecasts of numerical operational and experimental models to produce a correct representation of the upper ocean density (temperature and salinity) structure. For example, recent research has shown that the appropriate initialization of the ocean component within the HYCOM-HWRF intensity forecast model has improved the representation of the upper ocean while reducing the error of the intensity forecast of Hurricane *Gonzalo* (2014) by almost 50% (Dong et al., 2017; **Figure 7**). In this case, underwater glider data were critical to improving the hurricane forecast because they were the only ocean observations that captured the salinity-stratified barrier layer that inhibited the mixing of colder subsurface waters and subsequent upper ocean cooling ultimately allowing for hurricane intensification (Domingues et al., 2015).

NOAA OAR research has established the relationship between hurricane intensity and the Mid Atlantic's two-layer water column. The missing essential ocean feature is the unseen bottom Cold Pool. This vast (1,000 km long × 100 km wide) cold water mass (∼10°C) lies below a thin warm layer (>28°C) during the Atlantic hurricane season and is unobservable by satellites. By deploying autonomous underwater gliders ahead of Mid Atlantic land-falling hurricanes, the Cold Pool was mapped and its evolution monitored, leading to the discovery of rapid storm induced mixing that cooled the ocean ahead-of-eye-center by up to 11°C (Glenn et al., 2016). This new ahead-of-eye-center cooling process was shown to be region-wide in multiple hurricanes (Seroka et al., 2017) and is responsible for over 75% of the observed storm-driven cooling in the Mid Atlantic since 1985 (Glenn et al., 2016). Furthermore, the cooling of the surface ocean by the entrainment of the sub-surface Cold Pool was the missing component required to accurately forecast

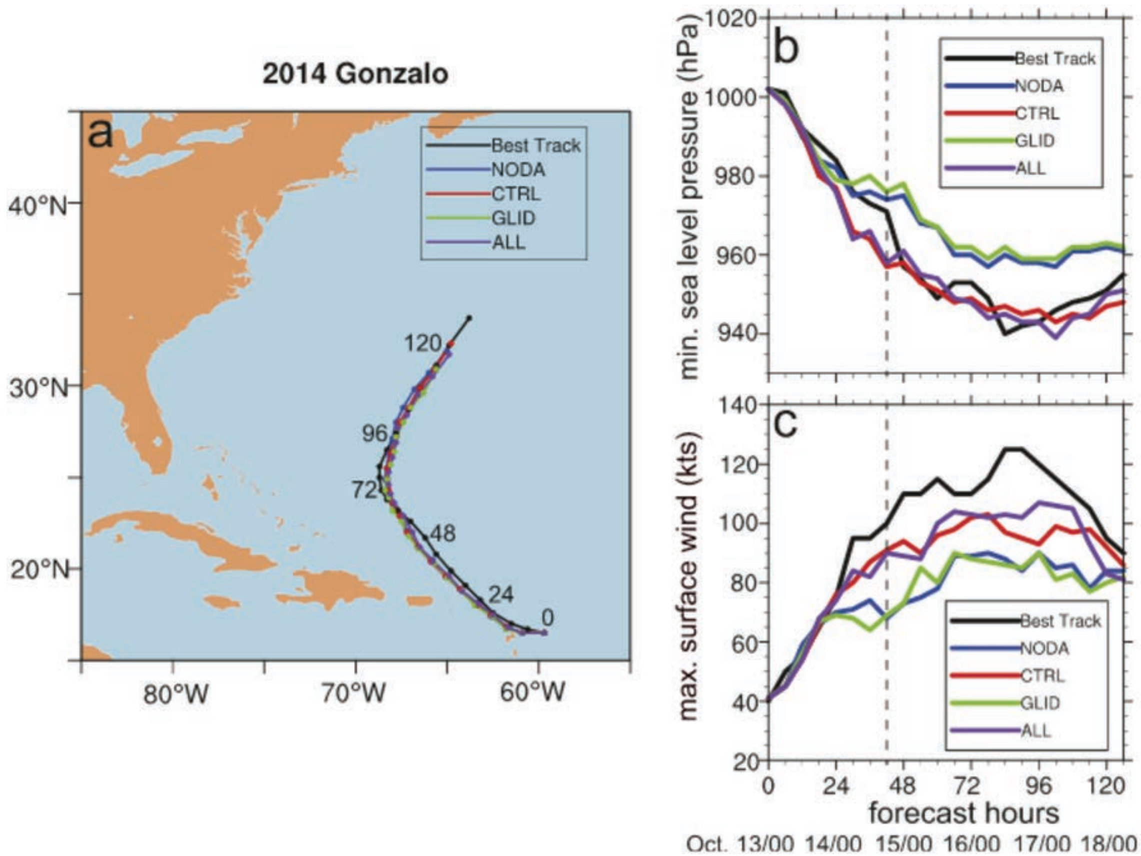

FIGURE 7 | (a) Hurricane Gonzalo track forecast, **(b)** minimum sea level pressure (center pressure), and **(c)** maximum wind forecasts, along with the best track. Gliders improve hurricane forecast. The dashed line denotes the track location closest to the glider at 0000 UTC 13 Oct 2014. (Figure 12 from Dong et al., 2017).

the rapid de-intensification of Hurricane *Irene* (Seroka et al., 2016). In stark contrast, gliders deployed ahead of Superstorm *Sandy* revealed a different Cold Pool response and impact on intensity. The onshore track, large wind field, and slow approach forced the Cold Pool more than 70 km offshore. This removed the bottom Cold Pool water and resulted in limited surface cooling and little storm weakening ahead of Sandy's historic storm surge in the region (Miles et al., 2017). The warm surface layer and the bottom Cold Pool, and their rapid evolution during hurricanes, must be well-resolved to reduce the uncertainty of hurricane intensity predictions. This can only be accomplished with underwater gliders reporting whatever the sea conditions are, and real-time subsurface profiles over the GTS, since operational ocean models cut off satellite altimeter data assimilation for water depths <150 m, leaving satellite Sea Surface Temperature (SST) as the only operational data contribution on continental shelves.

Picket lines of subsurface gliders sustained for the hurricane season in areas of rapid intensity change where identified as the most critical addition to the integrated ocean observations required to improve the ocean component of coupled ocean-atmosphere forecast models. A U.S. collaborative effort between NOAA, Navy, NSF, Industry and Academia implemented the hurricane glider picket line concept for the first time during the 2018 hurricane season. Data flow from individual glider operators to the GTS was coordinated through the U.S. IOOS Glider Data Assembly Center (DAC). The system was tested in September when 3 hurricanes were simultaneously present in the North Atlantic, each with gliders deployed in their path. This included Hurricane *Florence*, a category 4 storm at its peak that impacted the eastern seaboard of the US (**Figure 8**). The glider data transmitted over the GTS were used as input to the operational Ocean Heat Content maps that were used to help with NHC forecast intensity decisions.

OceanGliders supports the development of sustained glider observations to address hurricane issues worldwide as well as additional ones related to extra-tropical storms. Extra-tropical storms, also referred to as mid-latitude cyclones, are large scale (>1,000 km) low pressure weather systems that occur in middle and high latitudes and are associated with frontal systems. The wind speeds of these storms can be as high as those associated with tropical storms but their impacts last longer because of their greater spatial extent. Due to the large-scale features, extra-tropical storms are well-represented in atmospheric models. Hence, ocean gliders have mainly contributed to understanding the impacts of the storms on the ocean and coastal environments, particularly in terms of changes to the heat content (e.g., rapid

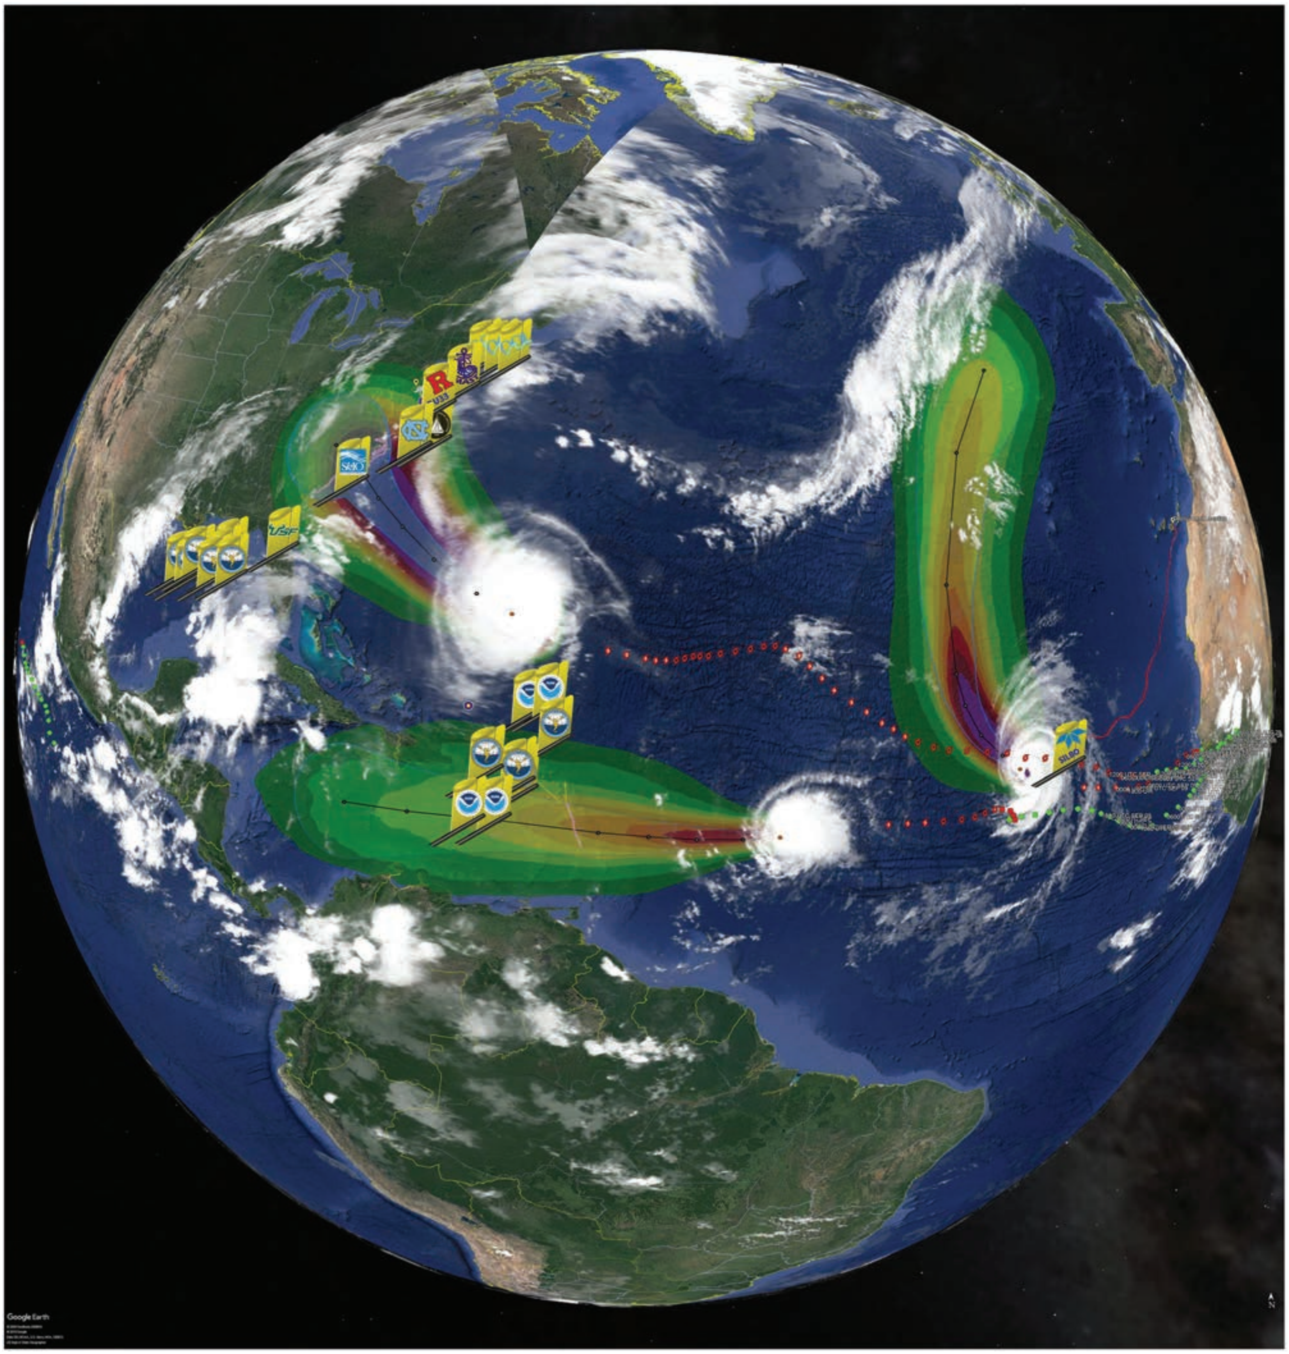

FIGURE 8 | Hurricane Florence, Isaac and Helene cloudtops (left to right) on September 11, 2018, with NHC best tracks behind each hurricane, NHC probability of tropical storm force winds ahead of each hurricane, and the tails of the diverse fleet of ocean glider in the picket lines transmitting upper ocean data in near-real time to forecasters.

cooling), its feedback on storm intensity, sediment resuspension and transport processes, and ecosystem response.

Ocean gliders are complementary to other storm sampling systems in their ability to relatively rapidly profile the upper ocean and transmit data to land even during the most severe storm conditions (Domingues et al., 2019). They provide unique datasets for studies of rapid upper ocean evolution and high-value profile data for assimilation in both operational forecast and research models before, during and after storms. Ocean glider measurements have revealed rapid changes in the distribution of water properties (temperature, salinity), and suspended sediment and chlorophyll (proxy for phytoplankton

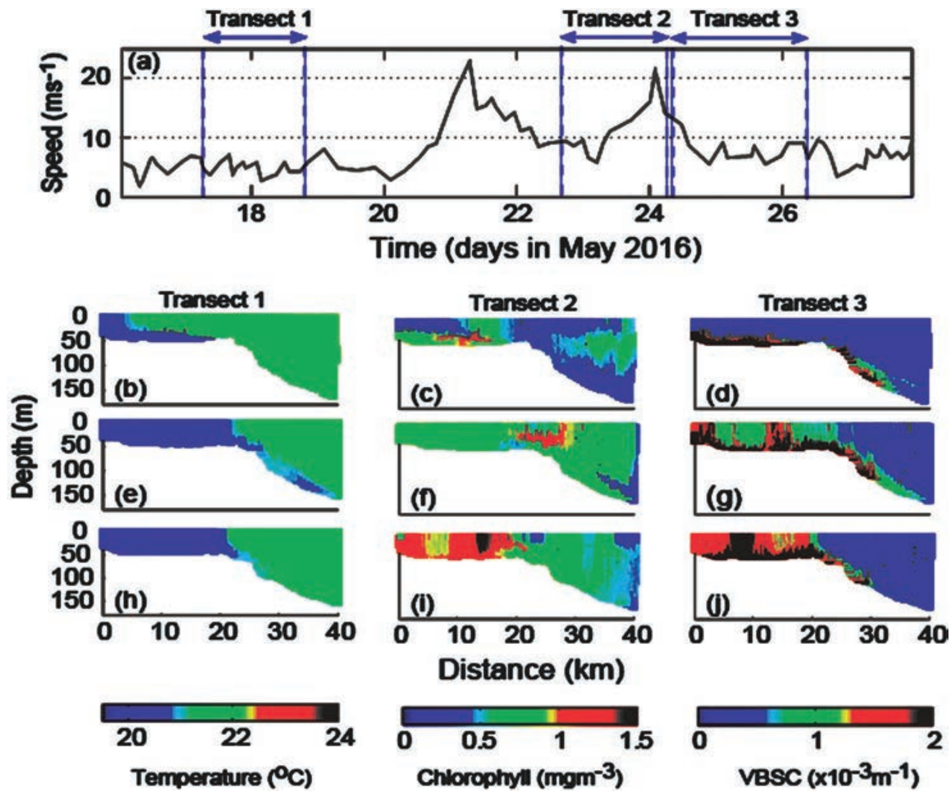

FIGURE 9 | (a) Wind speed and direction at Rottnest Island, south-west Australia. The vertical dashed lines represent timing of the ocean glider transects; Ocean glider vertical cross-sections of: **(b,e,h)** temperature (°C); **(c,f,i)** chlorophyll (mg·m^{-3}); and, **(d,g,j)** backscatter (x10^{-3}m^{-1}) across the Rottnest continental shelf. The time series of wind indicate calm winds (speeds ~5 m·s^{-1}) followed by two winter storms (speeds >20 m·s^{-1}). The wind speeds reduced to ~7 m·s^{-1} on 23 May before increasing again to >20 m·s^{-1}. There were 3 cross-shore ocean glider transects during this period. During the calm period (17–18 May 2016), a well-mixed water column with cooler (~20°C) water was present on the inner-shelf region to 5 km from the coast. Seaward of 5 km, a dense shelf water cascade (DSWC, Pattiaratchi et al., 2011) was present and extended along the sea bed to the shelf break. On the inner shelf, chlorophyll concentrations and backscatter values were higher within the DSWC and low in the surface layer. The two storms vertically mixed the continental shelf resulting in a well-mixed water column, increased suspended sediment elevated chlorophyll concentrations (modified from Chen et al., in review).

biomass) concentrations. Gliders with turbulence packages are being used to quantify the strength of storm driven mixing and its relevance in supporting prolonged phytoplankton production (Swart et al., 2015; Nicholson et al., 2016) as also highlighted by data collected on the inner continental shelf along the Rottnest continental shelf in south-west Australia (**Figure 9**).

Water Transformation

Physical, chemical, and biological properties are imported, redistributed, mixed and exported in substantial amounts by the oceanic circulation and processes. Any attempt to understand, model, and predict the evolution of the global and regional climates and marine ecosystems must include observations of their variability and their local and remote sensitivities to external changes. Indeed, fluctuation in any aspect is to lead to changes in the others, with the potential for feedback loops between them. While average conditions of the oceanic circulation and processes have been studied and assessed, little is known about the shifts in the system because of difficulties in observing water transformation phenomena directly and determining their (physical, chemical, biological) impacts.

Water transformation processes occur at relatively small scales and high frequencies not presently addressed by the GOOS. They are critical phenomena, however, that need to be assessed to better understand and model the evolution of the global/regional oceans, and in particular, their deep reservoirs of heat, salt, nutrients, etc. We do not know how these ocean processes influence change in these water properties. To fill this gap, the *OceanGliders* program proposes the long term and sustained observation of these phenomena with gliders whose unique capabilities (including under ice operations) and versatility allow the monitoring of such processes, in combination with other observing techniques, with sufficient accuracy. *OceanGliders* aims to address the two following global needs in ocean observations, by considering several key regions where water transformation processes that are important for the global (physical, chemical and biological) ocean occur.

Open Sea and Shelf Water Formation

Much of what is known about the oceanic circulation derives from the fundamental concept of water mass. The global/regional ocean is composed of a limited number of water masses that are formed (or transformed) in particular regions because of favorable local conditions (atmospheric regimes, stratification, topography, general circulation and major currents interactions) that can trigger buoyancy changes and the vertical mixing of the resident water masses in the surface and/or bottom boundary layers. Due to preconditioning effects (bottom topography, atmospheric forcing, stratification) the water formation processes lead to large mixed patches (100s km) presenting quasi-homogeneous (physical, chemical and biological) properties, and intermediate (100s of m, shelf/slope bottom) or sometimes deep (1–2 km, bottom) mixed layer depths, or thick (100s of m) bottom boundary layers.

The buoyancy decrease can be due to strong air-sea interactions (Swart et al., 2015; Houpert et al., 2016), sea ice and polynya formation in winter (Queste et al., 2015; Schofield et al., 2015), rough bottom topography (Beaird et al., 2013; Ruan et al., 2017), and major current instabilities (Schaeffer and Roughan, 2015). The water formation processes are common in winter in the subpolar gyres and high latitudes leading to the formation of the open ocean and shelf waters (Pattiaratchi et al., 2011; Durrieu de Madron et al., 2013; Bourrin et al., 2015; Peterson et al., 2017—**Figure 9**). It is so-called deep convection in few areas in the world where the mixing can reach great depths and ventilate the deep layers of the ocean due to peculiar and regional conditions (Testor et al., 2018). Later, in spring, these regions restratify, while the new water masses spread (or cascade on the ocean bottom) and mix with their surroundings. During this phase, intense blooms occur as the vertical mixing brought a large amount of nutrients in the euphotic layer and this can be sustained for a while by restratification processes (Queste et al., 2015; Schofield et al., 2015; Mayot et al., 2017), while the impacts on the benthic ecosystems can be important because of resuspended sediments. Mixing due to rough topography can also occur in overflow regions (Antarctic, Mediterranean, Denmark Strait) leading to the formation of new water masses and sediment resuspension (Durrieu de Madron et al., 2013, 2017; Venables et al., 2017) and through upwelling dynamics. The ice edge, presently in retreat toward the shelf, is a region of particular interest for water mass transformation, and gliders are ideal tools for exploring the marginal ice zone, as demonstrated in studies close to Greenland (Lee and Thomson, 2017; Våge et al., 2018).

These processes lead to the formation of water masses that move (together with their properties) through the oceanic basins interacting at the large scale with other water masses. This mixing can "buffer" or "memorize" climatic (physical, biogeochemical and biological) signals for long periods of time, until these water masses are mixed again vertically in the following years/decades/centuries, possibly far away (1,000s of km) from their formation areas. This water mass transformations can lead to rapid changes in the ocean, both locally and in remote places (Schroeder et al., 2017; Bosse et al., 2018).

Presently the large-scale formation of mode waters in winter is relatively well-covered by the present GOOS, but not by other open sea and shelf water mass formations that are more constrained by the regional scale. These processes are critical to the ventilation of the ocean and the evolution of the marine ecosystem, and this limits our understanding of the present state and evolution of the ocean and marine ecosystem. They occur sometimes in local patches on the shelf and in open sea, and on an intermittent basis, and are consequently not well resolved (temporally and spatially) at present. In addition, they generally result from different oceanic and atmospheric factors that encompass at least a year, owing to preconditioning effects (Durrieu de Madron et al., 2011; Bosse et al., 2018). This implies that sustained *in-situ* observing efforts must often be carried out in relatively large areas throughout the year to fully grasp the phenomena, with efforts occurring at a high frequency, and with high horizontal resolution to resolve the features that are involved. Moreover, in case of strong air-sea interactions in winter/spring, it is challenging to carry out traditional *in situ* measurements due to severe conditions at sea, for example winter convection in the Labrador Sea (deYoung et al., 2018). The observation of such phenomena remained a challenge until the use of autonomous underwater gliders, in combination with more classical ocean observing techniques. Much progress has been made during the last decade thanks to these relatively new platforms as demonstrated by many new publications on that subject (see introduction) and has led to a paradigm shift for deep convection (**Figure 10**). *OceanGliders* supports initiatives to fill these observational gaps in regions of water mass transformation in the coastal and open ocean.

Mesoscale and Submesoscale Phenomena

Mesoscale eddies (10–100 km horiz.) occur throughout the ocean and are not well-resolved by the present GOOS, particularly their vertical structure. They are responsible for large fluxes of energy and matter in the ocean. Depending on whether they rotate cyclonically or anticyclonically, they can be rich or poor in nutrients and can provide favorable or unfavorable conditions for phytoplankton and other organisms. They can be surface constrained, centered at intermediate depths or even extend down to the bottom (even the abyssal plain) and resuspend sea-floor sediments (Durrieu de Madron et al., 2017). Between their cores and their surroundings, temperature can vary by several degrees and practical salinity by 1 g/kg or more, while biogeochemical properties such as oxygen saturation can vary from 0 to 100% and pH by more than 1 (Bosse et al., 2017; Karstensen et al., 2017—**Figure 11**).

Mesoscale eddies can have a sub-surface expression, typical of the water mass composing their cores, and some are undetectable by satellite which makes their observation a challenge. They can be very coherent and dissipate mainly through very small-scale processes (diffusion, microturbulence) making their lifetimes extend to months or even years (Yu et al., 2017). They are able to transport the physical, biogeochemical, and biological properties of the waters composing their cores over great distances (1,000s km) after their formation before they finally dissipate (Fan et al., 2013; Pelland et al., 2013; Bosse et al., 2015, 2016, 2017; Meunier et al., 2018a). They can dissipate due to dramatic events like vertical mixing driven by atmospheric forcing reaching into their cores or by interactions with other eddies, currents or topography. Their properties, particularly their biological ones, can also change drastically throughout their lifetime due to such

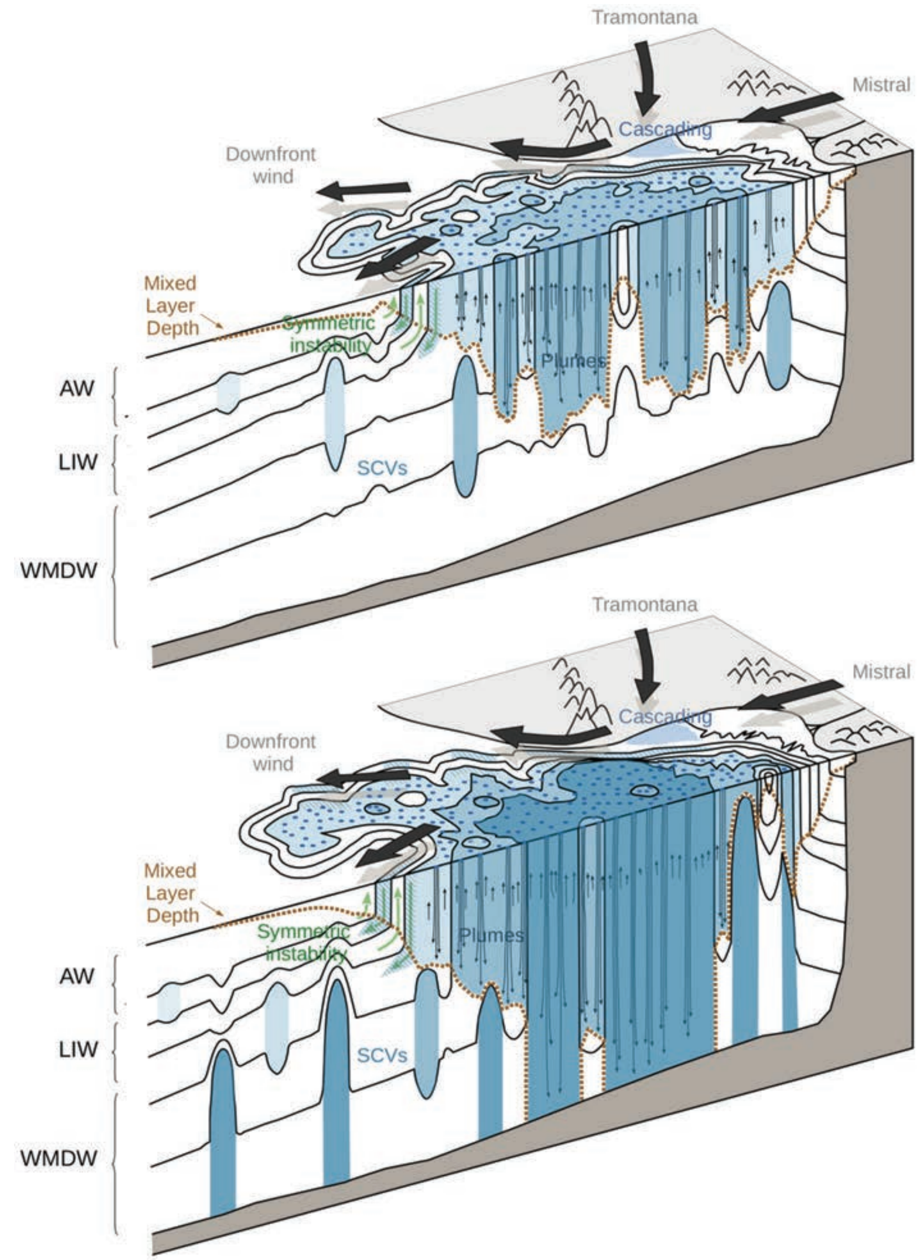

FIGURE 10 | Schematic diagram of the evolution of the convection area during the violent mixing phase in a period of 1–2 weeks. Underlying stratification/outcrop is shown by selected isopycnals (continuous black lines). The volume of fluid just mixed by convection is shaded and color coded according to potential density classes. (Figure 13 from Testor et al., 2018). Numerous glider deployments have allowed to objectively map the (physical and biogeochemical) evolution of the deep convection area on a 10-days basis for quantitative estimates while high resolution measurements allowed to investigate the small scale processes at stake.

external factors (McClatchie et al., 2012; Ainley et al., 2015; Villar et al., 2015; Durrieu de Madron et al., 2017). The impact of such factors on the properties of the eddy cores clearly depends on their vertical structure which in turn, depends on the oceanic (and atmospheric) conditions at their formation.

Mesoscale eddies can be formed through vertical mixing (due to air-sea-ice interactions or induced by rough topography, major current barotropic/baroclinic instabilities and/or detachments from the boundary circulation due to the continental slope curvature (Caldeira et al., 2014) and/or other effects like upwelling (Bosse et al., 2015). Mesoscale eddies can be classified according to their formation mechanism because they present similar characteristics and core properties. It has been shown that a number of different types of eddies (Loop Current Eddies, Agulhas rings, Dead Zone Eddies, Gulf Stream rings, Meddies, Suddies, Weddies, Algerian/Sardinian Eddies, deep

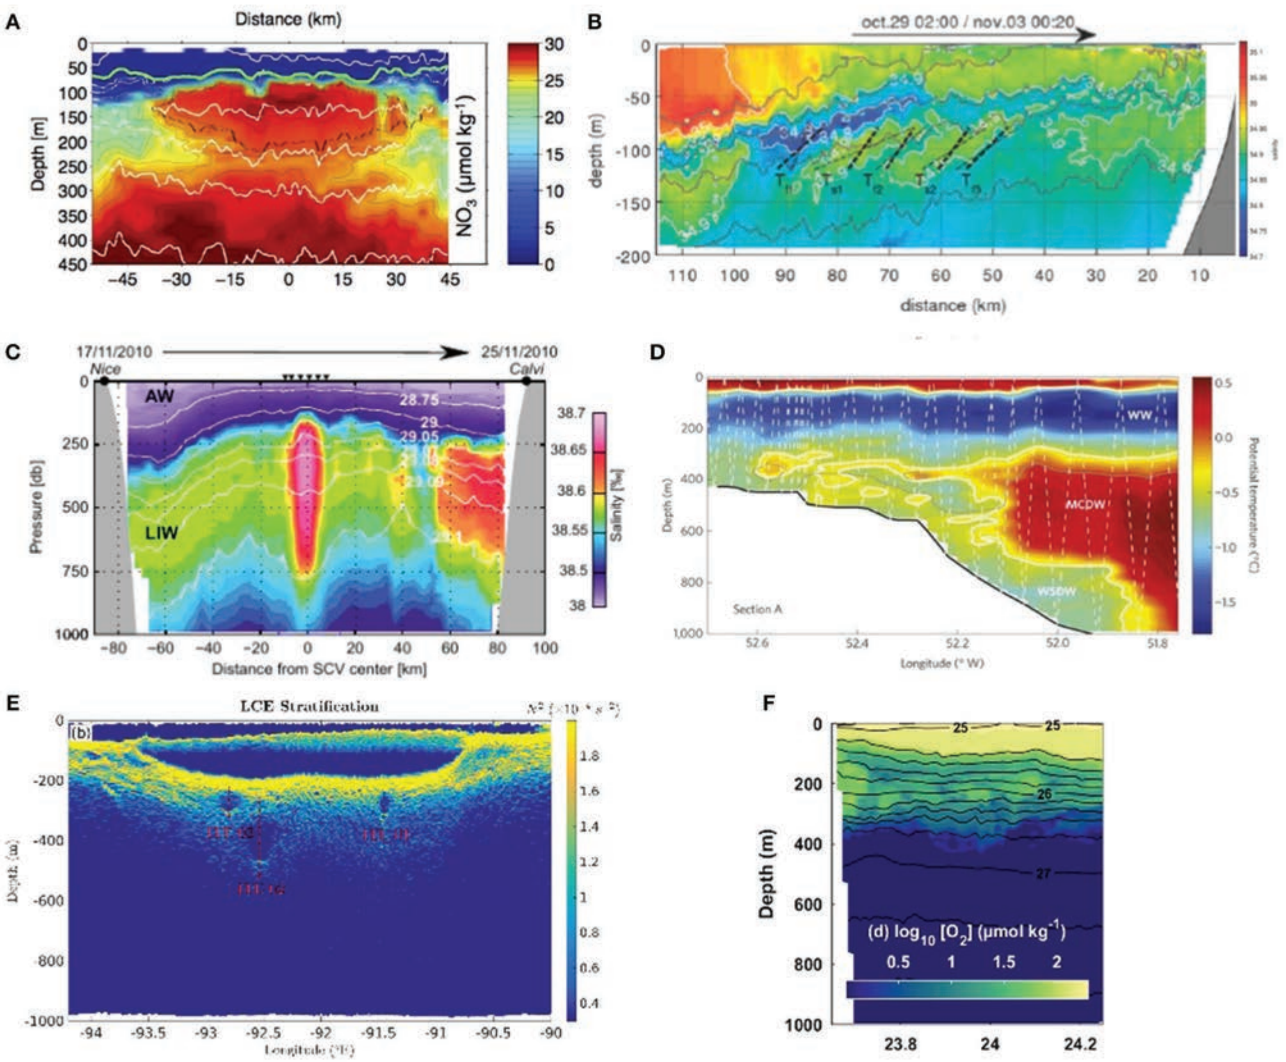

FIGURE 11 | Some highlights of (sub)mesoscale oceanic processes revealed by gliders that have been identified as important for the functioning of the physical, chemical and biological ocean: **(A)** Vertical section across a Dead Zone Eddy (DZE) showing its lens-like structure in nitrate concentrations (from Figure 7 of Karstensen et al., 2017); **(B)** Vertical section of salinity across the upwelling front off Peru (from Figure 7 of Pietri et al., 2013); **(C)** Vertical section across a SCV "Suddy" (from Figure 2 of Bosse et al., 2015); **(D)** Vertical section across the shelf of Antarctica peninsula (from Figure 1 of Thompson et al., 2014); **(E)** Vertical section across a LCE showing intrathermocline eddies (ITE) within (from Figure 11 of Meunier et al., 2018b); **(F)** Vertical section of dissolved oxygen in the Persian Gulf (from Figure 2 of Queste et al., 2013).

convection SCVs, ITEs…) can have a great impact on the ocean circulation/ecosystem state and evolution through their particular structures and transport mechanisms. Other fine scale processes are clearly involved in the ocean mixing, like microturbulence (Fer et al., 2014; Palmer et al., 2015; Schultze et al., 2017) or frontogenesis, filamentation due to stirring or symmetric instability (**Figure 11** and Ruiz et al., 2012; Thompson et al., 2014, 2016; Thomsen et al., 2016; Pietri et al., 2013; Brannigan et al., 2017; Buffett et al., 2017; Du Plessis et al., 2017; Pascual et al., 2017; Kolodziejczyk et al., 2018) that can lead to significant vertical velocities and fluxes. However, the extent and variability of their impact over long periods of time still needs to be assessed. The "mesoscale" dynamics and associated "submesoscale" features are important contributors to the ocean state and are of crucial importance for biogeochemical and biological processes in the ocean. Gliders offer a new high-resolution lens for observing the full seasonal cycle, a dominant mode of the earth system, in their ability to observe the physical-biological coupling at sub-seasonal and sub-mesoscale (Martin et al., 2009; Swart et al., 2012, 2015; Monteiro et al., 2015; Thomalla et al., 2015; Du Plessis et al., 2017).

It is difficult for an *in situ* ocean observing system to capture all these important but relatively small circulation features, but a regular (annual) statistical assessment of the numbers and properties (and impact) of the main families of eddies and smaller processes can be achieved through subsurface, continuous and sustained glider observations of sufficient horizontal resolution. The time and space resolution of the glider sampling, for a variety of different sensors, make gliders essential observing platforms for studies and continuous assessments of the role of (sub)mesoscale processes in the ocean circulation and ecosystem. Over the last decade, a remarkable number of articles on (sub)mesoscale dynamics and smaller scale mixing processes based on underwater glider data and their impact on biogeochemistry and biology has been published (see introduction). The importance of Submesoscale Coherent Vortices (SCV), filaments along fronts and around mesoscale eddies, and induced vertical movement, has been demonstrated from ground truth and their impact can now be monitored on the long term in key regions with gliders (Hristova et al., 2014; Bosse et al., 2016; Yu et al., 2017).

Underwater gliders do sample the vertical structure of the ocean in an unprecedented way, with high resolution along the horizontal over long periods of time. Gliders also transmit the observational data in near real-time. This remote access to observational data that resolves the (sub)mesoscale can improve forecasting the ocean dynamics, biogeochemistry and ecosystem. The glider data is a perfect match for assimilation in regional/coastal numerical models, providing ocean state estimates at small scales with increased accuracy benefiting societal applications. Gliders can map the subsurface ocean at high resolution and provide powerful tools for monitoring previously inaccessible ecological processes. *OceanGliders* promotes and supports all physical, biogeochemical and biological studies focusing on these small-scale processes and encourages long-term continuation of these studies. The anomalies caused by these (sub)mesoscale variabilities exceed by one order of magnitude those attributed to changes in large scale circulation and marine ecosystem variability brought about by a warming planet, as assessed by the IPCC (Bates et al., 2018) and must be considered to further our understanding and monitoring of the physical, biogeochemical and biological ocean.

END-USER BENEFITS

In section Addressing global observing needs, we have detailed the unique "oceanographic" monitoring space that gliders occupy. Here we describe how this translates to benefit for the end users of a fully integrated observing system, i.e., what key roles (primary and supporting) a global sustained glider network can play in delivering services for both science and society.

Gliders can make sustained observations at high resolution, bringing temporal and spatial scales, hourly to sub seasonal and from 10 m to 1,000 km's, relevant for a number of key ocean processes within economic reach. They are navigable and can be directed to sample ocean phenomena in real-time and with a fleet of gliders monitoring can be continuous, if required, and operational. Glider sensor payloads are expanding and their unique role in acoustic monitoring is already being exploited. They can sample in extreme conditions and to increasing depths, from surface to 6,000 m depth.

Gliders require pilots; however navigation is increasingly automated as a result of advances in platform reliability, community experience and piloting support tools. Glider observations require careful data processing protocols, an area that is being actively resolved, with tools and services emerging, and standard products from several deployments (e.g., gridded sections, geostrophic currents, etc.) that could be more accessible to non-expert users, many of which are from the *OceanGliders* community. Although gliders are relatively "slow" samplers, this is not an impediment to providing sampling capability at key space and time scales for the global observing system.

Gliders are uniquely poised to deliver sustained and responsive observations to the GOOS in the following areas:

- Connecting coast to open ocean: key for monitoring the regional effects of climate variability, and of processes (circulation, currents, upwelling) that have an impact on regional ecosystems.
- Boundary current monitoring: key to the transport of heat, salt, biogeochemical variables (nutrients) and plankton, they influence ecosystems and therefore variability in ocean productivity, and impact flood levels, erosion and commercial activity.
- The observation of ocean state variables at a high density in time and space in order to gain insight into the variability/statistical distribution of these variables locally given the turbulent nature of ocean flows.
- Surface to deep profiles in extreme conditions: observing ocean structure that affects the strength of violent storms (e.g., hurricanes) and of violent ocean mixing.
- Sustained observations in the polar regions where ship persistence is challenging due to ice and harsh conditions.
- Fast deployment and real-time navigation enabling delivery of vital information for environmental disaster management.

Looking at these key sampling capabilities under the GOOS theme areas of climate, operational services and ocean health, it is clear that sustained glider monitoring, as part of a fully integrated global ocean observing system, delivers a range of benefits.

Climate

- Monitoring boundary currents delivers knowledge on sub-seasonal variability and long-term trends that affect climate, leading to improved climate prediction. This information is used for adaptation to climatic change.
- Sustained 3D observations of deep and shelf water formation, a key component of our climate and ocean circulation system, provide knowledge to assess deep storage of heat, salt, nutrients and carbon sequestration. They uniquely can aid our understanding of variability in water formation and the impact of this on the global ocean budgets.
- Monitoring the subsurface development of climate oscillations (e.g., el Niño) aid prediction, support advanced warning capability and improved parameterization of climate patterns that affect seasonal forecasts.

Operational Services

- Monitoring lines across key coast-to-open ocean transects (often boundary current regions) increase the accuracy of regional ocean forecasts, which have economic impact (e.g., offshore wind, powerful eddies that affect oil platform drilling, flood hazard warnings, abundance and location of commercial

species) supporting reanalysis and prediction models, good for getting real time data back to inform the next modeling cycle.
- Glider deployments in the path of hurricanes and violent storms (tropical and extratropical) provide *in situ* water profiles of ocean structure and heat/salt content assimilated real-time into models, significantly increasing the accuracy of the storm intensity prediction, which is vital to regional government and emergency services.
- Speedy deployments of gliders at pollution events, provide simultaneous data on ocean circulation and pollutants, either to track the pollutants or to improve ocean forecasts by providing data for assimilation. This supports decision making by better disaster management services and thus can reduce environmental impact.
- Speedy and flexible deployments of gliders can enable co-located measurements with other air/ocean observing systems, which are key for advancing scientific understanding of marine biogeochemical-physical interactions and/or air-sea flux interactions across the oceanic surface. These can also help provide precious data points for future coupled data assimilation methods under active consideration for balanced initialization of coupled earth system models.
- Sustained ocean sound monitoring delivers real time information on key marine mammal species, for ship avoidance decisions. Increasingly, this is a must for conservation of populations as new shipping routes increasingly intersect with marine mammal habitats.
- Monitoring boundary currents or water transformation in key areas delivers knowledge on ocean changes, both sub-seasonal variability and long-term trends, that affect climate. Real-time information on these key components of the global circulation better constrain models and are used, for example, to increase the accuracy of forecasts for coastal regions.

Ocean Health

- Sustained transects from coastal to open ocean, including boundary currents and water transformation areas, are key for monitoring the regional effects of ocean variability on regional ecosystems. Physical, chemical and biological information from these sections improves understanding of ecosystem response to environmental stressors (e.g., low dissolved oxygen, ocean acidification), aids regional ecosystem management and can provide ocean health monitoring indicators.
- Sustained acoustic (fish tags, passive acoustics for mammals, active acoustics for zooplankton) and video monitoring from coast to open ocean, deliver information assessing distributions and stocks as well as behaviors of marine organisms and response to environmental conditions that enables improved physical/ecosystem modeling, prediction, and resource management.

THE WAY FORWARD

At present, global glider operations are still at the pilot stage and are not fully developed. There are some regional operations, e.g., the repeated glider transects off the west coast of the United States, that are well-established and fully operational but full coordination of glider missions at the regional, basin or global scale, as discussed, remain in the planning stages. There has been enough activity to prove that we have the capability to conduct such operations but the development of clear scientific and operational goals for the proposed network remains under discussion. Indeed, this white paper is a contribution to that discussion and is meant to further stimulate consideration of the potential opportunities to fill gaps in the present networks of global ocean sampling.

Further developments should be framed with clear measurement goals and analysis of the appropriate technological solutions to address the observational challenges. There are now many different options to address the three themes of the GOOS: Climate, Operational Services and Ocean Health, including autonomous surface and underwater craft, drifters, subsurface moorings, ships of opportunity and research ships and satellite systems. All of the options should be considered to determine which solution, or mix of platforms, best meets the observational goals. We have some of the tools needed for this analysis but also need to work together as a community to optimize the design of the global observing system.

Ocean gliders, and other autonomous marine vehicles, are evolving and improving at a remarkable pace. Their endurance, related to battery capacity and sensor performance, continues to improve, as does their range of operations in both the coastal and open sea environments. It is now possible to sample the deep ocean with gliders, with developments that will enable us to routinely reach depths of 6,000 m, while missions of many months or longer are now routine. There is also a growing range of private companies building these systems providing a wider range of options. This diversity shows the wide interest in these platforms and builds our confidence in their further development and availability, which is a key aspect of sustainability. Performance in extreme conditions, such as winter conditions, and navigation under sea-ice, is improving, and there are very few places on the planet where they cannot operate. Autonomy continues to develop, while full operational independence is still quite a few years away. As with many new platforms, in the first few years enormous effort is required to setup and deploy them. After two decades of operation, the learning curve for new users is not as steep as it was because of technological improvements and because the global community supports new users. Internationally, the *OceanGliders* program will help the glider community focus on the GOOS requirements. It builds on several long-term glider observational programs that exist in Europe, Australia, Canada, the United States, Mexico, Peru, Chile, South Africa, New Zealand, etc. Further development and coordination among these initiatives, and new ones that form, will provide support for coordinated global operations.

Global observing systems have shifted from a primarily physical focus to expanded measurements, spanning biological and biogeochemical variables. Essential Ocean Variables (EOV) within the GOOS now span a wide range, including biogeochemistry, biology and ecosystems. There has been a lot of progress in developing such sensors for gliders, for example, fluorometers for measuring phytoplankton have been in development for a long-time. So too have active/passive multi-frequency acoustic sensors been deployed on gliders to measure oceanic currents, surface wind intensity, zooplankton, and to detect acoustic small/large fish tags, marine mammals, sharks etc. Other sensors include imagery, as well as nitrate, oxygen and pH, carbon dioxide sensors, and various optical sensors to detect light, backscatter, attenuation, particles, harmful algal blooms and ocean acidification. However, the battery capacity of the gliders still limits the total range of sensors that can be deployed on a single vehicle. It is clear that further battery and sensor developments will enable a wider range of possibilities and demonstrate that the platform has potential for making an even wider range of observations than at the moment.

Data from ocean gliders are presently being used in operational ocean models and operational weather forecast models. The data are typically streamed in real-time through the GTS and are then available to all operational users. They have been used in research or pre-operational systems and improved weather forecast modeling and operational global and regional ocean forecasts such as Mercator Ocean, FOAM (Met Office), MFS (Mediterranean Forecasting System), BLUELink (Bureau of Meteorology, Australia), CONCEPTS (Fisheries and Oceans, Environment and Climate Change Canada and Department of National Defence, Canada), HYCOM/NCODA (USA), NAVOCEANO (US Naval Oceanographic Office), REMO (Brazil), TOPAZ/NERSC (Norway). Observation impact studies show the value of sub-surface hydrographic observations, such as those from gliders, in improving prediction. Moreover, data products can be created, such as data aggregations and mean fields, that are easily usable for model validation and assessment. In this paper we have presented plans to deploy gliders in the waters near hurricanes, in ocean boundary currents and in key areas of water transformation. Data from such deployments could provide critical information to improve the performance of ocean forecast models as ocean dynamics in such regions remains a modeling challenge for the next decade. Improved prediction at sub-seasonal to seasonal (S2S) scales requires use of ensembles (or super-ensembles) including those from ocean models. These ensembles can also provide a good representation of quantified uncertainty in time and space which could be targeted by future flexible positioning of underwater gliders in real-time or near real-time. Having a large network of gliders, potentially with different sensor packages and/or different measurement goals, will lead to piloting challenges on a day-to-day basis for individuals. Eventually the sampling patterns might be autonomously determined through use of data-assimilating models, remote sensing products, and other *in situ* measurements.

The increasing operational interest in gliders and glider teams' capability suggests that the applications mentioned in section End-user benefits could all become operationally routine within a decade. Looking further ahead there is much capacity for the use of gliders to expand, particularly in relation to ocean health and human pressures.

We envision that:

- Increase in sensor capability of gliders will increase their use for early warning of environmental stress or pollution (Verfuss et al., 2019), for example to manage compliance areas of ecosystem sensitivity.
- The weather/modeling community may invest in gliders in key ocean areas to support improved prediction, perhaps with artificial intelligence, smart models autopiloting the gliders in real-time in the regions of greatest uncertainty.
- Deep gliders will deliver the same insight on deep variability of currents, water mass, heat, salt, biogeochemical and biological variables, fundamentally changing our ability to model deep flow and thus climate scale predictions and seasonal forecasts. They will also be our cost-effective eyes and ears on the deep, policing infringement of deep mining and reporting on deep ecosystem health.
- Increasing battery life, introducing novel energy sources, and improving solutions to bio-fouling, will lower costs and extend glider operation time. This will allow for the monitoring of open ocean areas at low cost (there will still be a need to deploy them from small boats).
- International consortia will share sites for recovery/deployment, facilities for refurbishment, and even pilots to optimize operations worldwide and reduce the costs of operation and the loss probability.
- The cost of the gliders will decline as their numbers increase and the number of users worldwide increase.
- The glider's payload space will increase enabling them to carry a wider range of sensors and/or a different battery configuration.

In considering the application of gliders to problems such as boundary currents, water transformations or storms, a careful analysis of the measurement challenge should include consideration of other approaches to ocean observation. Gliders have strengths and limitations, as do all platforms and sensors, and both should be taken into account when designing an observing solution to address critical gaps in our global ocean observing strategy. Formal design exercises must be carried out with the other components of the GOOS considering its 3 themes: Climate, Operational Services and Ocean Health. Such design studies must consider all the societal benefits and needs of GOOS applications, including human impact, ecosystem, biodiversity and pollution assessments as well as sustainable management and marine hazard response (cf. GOOS strategic mapping[13]).

Numerical simulation experiments, using sophisticated coupled ocean-atmosphere models to determine the best mix of platforms and the tradeoffs in ocean sampling that result from deploying different systems should be carried out. However, this must be done while keeping a critical eye on the model's performances and this must not be the only basis when producing a design. While gliders may fill a critical role for a particular system, for example a particular boundary current, it

[13]http://www.goosocean.org/index.php?option=com_content&view=article&id=120&Itemid=277

may still be the case that a mix of moorings, drifters and other platforms would provide the best observational solution because of logistical constraints. It could be that biological requirements balance the needs of operational services, in a particular region in terms of resources optimization or the contrary, and so on.

The *OceanGliders* program can contribute to societal development and sustainability, and there are many examples of this potential already being achieved. These can be exemplified by activities that contribute toward achieving the United Nations Sustainable Development Goals (SDGs)[14], of which SDG2 (Zero Hunger), SDG13 (Climate Action) and SDG14 (Life Below Water) are arguably most germane. Examples of glider networks making such contributions include deployments in climatically sensitive regions that are also important breeding and nursery grounds for foodwebs, and the focus of a significant fishing industry. Sustained glider missions in these areas conducted as part of whole-ecosystem research programs provide the underpinning scientific knowledge for ecosystems-based fishery management. Glider networks provide enhanced data collection and improved transfer of knowledge to policymakers, so as to support such societally-relevant sustainability activities.

It is important to consider the targeted phenomena, their space/time scales and EOV since they will impose requirements in terms of sampling. The different *OceanGliders* TT will define what "operational" means for them. The Boundary Currents TT requirements of sampling the seasonal cycle implies that "operational" means having gliders in water year-round, while Storms requirements imply having gliders in the water only during the storm periods, and Water Transformation requirements could be year-round or focus only on the winter/summer period depending on the water transformation phenomenon that is considered. Other requirements will emerge as the program develops with TT on biogeochemistry or polar regions for instance.

The world ocean will change. We need to assess those changes appropriately and must not underestimate what could be done with gliders. Without doubt, there will be more end-user engagements, new technologies on board, more connectivity, more sensors, more gliders and more users to address that. The flexibility of gliders allows complementarity, and this is an asset for their integration in the GOOS. The challenge for the next decade will be to build a GOOS glider component that will help the GOOS reach the right balance between its different components to deliver products for societal benefits and applications, through the monitoring of the required oceanic phenomena and EOV.

VISION

Our vision is for a mature sustained global glider observing network by 2030. It will not only support regional, sustained operational deployment of gliders serving the present societal needs around operational services, ocean health and climate, but also solely allow new ocean observing applications in this framework. The outstanding capacity of gliders to play a role as an agent of integration, across scales, from the coast to the open ocean, and from physics to biology, needs to be used to enhance the GOOS, integrating with its other components (*in situ* and satellites). These global glider operations will likely have different schedules of operation, carry different sensors, and serve different needs but will have a shared support system through the *OceanGliders* program that will allow them to work together efficiently, to govern and support the system, coordinating global glider operations and ensuring that the needs of society for ocean data are best met.

OceanGliders will support global standards and best practices to ensure that the operations and the data delivered can be monitored at the global scale. Improved data interfaces and standardized data will ensure quality-controlled data are easily found and effectively used. By 2030 one should be able to effortlessly, perhaps unknowingly, find and acquire quality-controlled physical, biogeochemical and biological data from gliders alongside an already huge range of earth observations and use them to address scientific, commercial, or policy initiatives. Attaining our vision would ensure that the value of observations to society will never be lost, indeed, will increase over time as they are used and reused and in new ways not originally imagined.

Here, we have identified three key areas for the *OceanGliders* program to focus on: Boundary Currents, Storms and Water Transformation. These represent interests heard from the glider and user community, but we expect more to develop, as the *OceanGliders* program matures. Moving forward, *OceanGliders* will have, together with a wide range or stakeholders and participants, to conduct a value-chain assessment to explore further needs of users to ensure that the network continues to be fit-for-purpose, as discussed in the Framework on Ocean Observing. Through this paper, we have sought to demonstrate, through exploration of some key thematic examples, the opportunities and potential benefits of coordinated deployment of ocean gliders to fill some key gaps in the existing ocean observation system. The precise form of such activity requires a comprehensive and integrated analysis of the needs for observation, that is the most broadly defined societal needs, and an assessment of the different approaches to observation, just one of which is ocean gliders. Such an assessment will have to address needs related to the three key thematic areas of the GOOS: Ocean health, Operational services and Climate.

In his seminal paper, Stommel (1989), foresaw an operational fleet of 300–550 gliders at any time evolving in the world ocean to support the GOOS by 2025. Only a substantial increase in global resources would yield such an outcome by 2030. We propose a more modest implementation of the *OceanGliders* global program for the next decade. Sustained observations of boundary currents are perhaps the most established capability of gliders relevant to the GOOS. A sensible goal is to have continuously 100 gliders in a sustained Boundary Ocean Observing Network within the next 10 years, with some additional gliders addressing Storms and Water Transformation issues where and when this fleet would not already do so. We are confident that operation of such a fleet of 100 gliders is achievable. Further development will rely on capacity building and would be driven by a combination

[14]https://sustainabledevelopment.un.org/?menu=1300

of need and demonstrated benefit of the glider program. We have presented results from 25 boundary current sections sustained for a minimum of 1 year, and for as long as 12 years. While not all these 25 sections are currently sustained, the proof that they are operable has been made. An increase in this sampling by a factor of 4 is a relatively reasonable worldwide goal. The operational cost to keep one glider in the water for 1 year is approximately $200K, thus 100 gliders would cost $20M per year, a relatively affordable cost for a global component of the GOOS.

AUTHOR CONTRIBUTIONS

The editorial team for this paper (PT, BY, DR, SG, DHa, CL, CP, KHi, EH, and VT) has collected the contributions of the other co-authors and coordinated the writing of the paper.

ACKNOWLEDGMENTS

The editorial team would like to recognize the support of the global glider community to this paper. Our requests for data and information were met with enthusiasm and welcome contributions from around the globe, clearly demonstrating to us a point made in this paper that there are many active and dedicated teams of glider operators and users. We should also acknowledge the support that OceanGliders has received from the WMO/IOC JCOMM-OCG and JCOMMOPS that have allowed this program to develop, encouraging us to articulate a vision for the role of gliders in the GOOS. We acknowledge support from the EU Horizon 2020 AtlantOS project funded under grant agreement No. 633211 and gratefully acknowledge the many agencies and programs that have supported underwater gliders: AlterEco, ANR, CFI, CIGOM, CLASS Ellet Array, CNES, CNRS/INSU, CONACyT, CSIRO, DEFRA, DFG/SFB-754, DFO, DGA, DSTL, ERC, FCO, FP7, and H2020 Europen Commission, HIMIOFoTS, Ifremer, IMOS, IMS, IOOS, IPEV, IRD, Israel MOST, JSPS, MEOPAR, NASA, NAVOCEANO (Navy), NERC, NFR, NJDEP, NOAA, NRC, NRL, NSF, NSERC, ONR, OSNAP, Taiwan MOST, SANAP-NRF, SENER, SIMS, Shell Exploration and Production Company, Sorbonne Université, SSB, UKRI, UNSW, Vettleson, Wallenberg Academy Fellowship, and WWF.

Coastal and ocean acidification can alter ocean biogeochemistry, with ecological consequences that may result in economic and cultural losses. Yet few time series and high resolution spatial and temporal measurements exist to track the existence and movement of water low in pH and/or carbonate saturation. Past acidification monitoring efforts have either low spatial resolution (mooring) or high cost and low temporal and spatial resolution (research cruises). We developed the first integrated glider platform and sensor system for sampling pH throughout the water column of the coastal ocean. A deep ISFET (Ion Sensitive Field Effect Transistor)-based pH sensor system was modified and integrated into a Slocum glider, tank tested in natural seawater to determine sensor conditioning time under different scenarios, and validated *in situ* during deployments in the U.S. Northeast Shelf (NES). Comparative results between glider pH and pH measured spectrophotometrically from discrete seawater samples indicate that the glider pH sensor is capable of accuracy of 0.011 pH units or better for several weeks throughout the water column in the coastal ocean, with a precision of 0.005 pH units or better. Furthermore, simultaneous measurements from multiple sensors on the same glider enabled salinity-based estimates of total alkalinity (A_T) and aragonite saturation state (Ω_{Arag}). During the Spring 2018 Mid-Atlantic deployment, glider pH and derived A_T/Ω_{Arag} data along the cross-shelf transect revealed higher pH and Ω_{Arag} associated with the depth of chlorophyll and oxygen maxima and a warmer, saltier water mass. Lowest pH and Ω_{Arag} occurred in bottom waters of the middle shelf and slope, and nearshore following a period of heavy precipitation. Biofouling was revealed to be the primary limitation of this sensor during a summer deployment, whereby offsets in pH and A_T increased dramatically. Advances in anti-fouling coatings and the ability to routinely clean and swap out sensors can address this challenge. The data presented here demonstrate the ability for gliders to routinely provide high resolution water column data on regional scales that can be applied to acidification monitoring efforts in other coastal regions.

INTRODUCTION

Ocean acidification (OA) has presented great research challenges and has significant societal ramifications that range from economic losses due to the decreased survival of commercially important organisms to the ecological consequences associated with altered ecosystems (Cooley et al., 2009; Doney, 2010). Particular areas of the coastal ocean are more susceptible to sustained, large increases in carbon dioxide (CO_2), including those in upwelling zones (Feely et al., 2008, 2010a), bays (Thomsen et al., 2010), and areas with high riverine and/or eutrophication influence (Salisbury et al., 2008; Cai et al., 2011). Yet few observations exist to track upwelling and movement of low pH water.

Past OA monitoring efforts have been limited to surface buoys equipped with sensors that measure pH and/or $p\mathrm{CO}_2$ (the concentration of CO_2 in seawater measured as partial pressure of the gas), flow-through $p\mathrm{CO}_2$ systems utilized by research vessels, and water column sampling during large field campaigns (e.g., U.S. Joint Ocean Global Flux Study, Bermuda Atlantic Time Series, Hawaiian Ocean Times Series) with low spatial resolution (mooring) or with low temporal resolution and high cost (research cruises). Only a fraction of these efforts include the U.S. continental shelves (e.g., Gulf of Mexico Ecosystems and Carbon Cycle Cruises [GOMECC], East Coast Ocean Acidification [ECOA] cruises) (Jiang et al., 2008; Wang et al., 2013, 2017; Wanninkhof et al., 2015), commercially important coastal regions where finfish, lobster, and wild stocks of shellfish are present (Hales et al., 2005; Feely et al., 2008; Vandemark et al., 2011; Xue et al., 2016). Furthermore, very few sampling locations (spatial and temporal scale) include more than one of the four measureable carbonate chemistry parameters (pH; dissolved inorganic carbon concentration, or DIC; total alkalinity, or A_T; and $p\mathrm{CO}_2$). At least two out of the four are necessary in order to fully characterize the marine carbonate system, including determinations of aragonite saturation state (Ω_{Arag}), an approximate measure of whether calcium carbonate (in the form of aragonite) will dissolve or precipitate in calcifying organisms (Lee et al., 2006; Cai et al., 2010; Johnson, 2010; Wang et al., 2013).

The recent development of sensors for *in situ* measurements of seawater pH has resulted in a growing number of autonomous pH monitoring stations in the United States (Seidel et al., 2008; Martz et al., 2010). New pH sensors that can rapidly respond to pH change and also withstand higher pressure (depth) show great value in monitoring coastal systems. A Deep-Sea ISFET (Ion Sensitive Field Effect Transistor) profiling pH sensor was recently developed by Monterey Bay Aquarium Research Institute (MBARI) and Honeywell and has been successful in collecting high quality data on a depth-profiling mooring (Johnson et al., 2009, 2016; Martz et al., 2010). These recent measurements in the open and coastal ocean have shown that the pH varies greatly in time and space, reflecting complex circulation patterns that are likely due to the influence of low pH deep water through mixing and the intrusion of low pH, fresh and/or estuarine water (Dore et al., 2009; Byrne et al., 2010; Hofmann et al., 2011; Yu et al., 2011). Earlier, an innovative approach of combined *in situ* pumping and shipboard measurements of $p\mathrm{CO}_2$ also demonstrated rapid spatial variations of the CO_2 system in the upwelling margin offshore Oregon, United States (Hales et al., 2005). These fluctuations may lead to large ecological and economic impacts, thus reinforcing the need for reliable high-resolution observations of the full water column.

Significant improvements could be immediately achieved with the implementation of a real-time monitoring network that quantifies the spatial location, duration, and transport of the low pH/Ω_{Arag} water in coastal regions (Feely et al., 2010b; Martz et al., 2010). The spatial, temporal, and depth resolution achieved from Teledyne Webb Slocum glider data far exceeds that from traditional sampling from ships and moorings (Rudnick et al., 2004; Schofield et al., 2007). These systems can sample in depths as shallow as 4 meters and as deep as 1000 m and have been used in a broad range of challenging environments including near ice shelves in the Antarctic, beneath hurricanes and coastal storms, and on river dominated continental shelves. Recent calls for a national (Baltes et al., 2014) and international observational network for OA identified underwater gliders as a potential pH monitoring instrument that "could resolve shorter space-time scale variability of the upper ocean" (Feely et al., 2010b; Martz et al., 2010). A variety of sensors have successfully been mounted on Slocum gliders. To date, however, no direct measurements of ocean pH have been collected by pH sensors integrated into these gliders.

We present here the recent development of the first integrated glider platform and sensor system for collecting pH data in the water column of the coastal ocean on a regional scale. Specifically, we modified and integrated a deep-depth rated version of the ISFET-based pH sensor system (Johnson et al., 2009, 2016; Martz et al., 2010), into a Slocum G2 glider science bay. In addition to pH, the glider is equipped with sensors that provided profiles of conductivity, temperature, depth, spectral backscatter, chlorophyll fluorescence, and dissolved oxygen (DO) that enabled the mapping of ocean pH against the other variables and the calculation of A_T and Ω_{Arag}. Here, we describe the performance of the new sensor from seawater tank tests and from the first *in situ* deployments within the U.S. Northeast Shelf (NES), one of the nation's most economically valuable coastal fishing regions. Water column pH measurements in this region are sorely lacking; hence, the glider deployments presented here deliver a much-needed full characterization of water column pH dynamics in this coastal region from the nearshore to the shelf-break and demonstrate the application of glider-based acidification monitoring in other coastal regions.

EXPERIMENTAL SECTION

pH Sensor Integration

The deep ISFET-based pH sensor was modified by Sea-Bird Scientific, and its integration into a Slocum Webb G2 glider (200 m) was a coordinated effort between Rutgers, Sea-Bird Scientific, and Teledyne Webb Research. To optimize the performance of the pH sensor for use on a glider Sea-Bird Scientific significantly modified the original design of Deep-Sea DuraFET, and ISFET-based sensor developed by MBARI (Johnson et al., 2016). Given the light sensitivity of the sensor and desire to be closely coupled with CTD (conductivity, temperature, depth) data acquisition, the deep ISFET-based sensor was reconfigured by Sea-Bird Scientific to fit into the existing rectangular glider CTD port utilizing a shared pumped system to pull seawater in past both the pH and CTD sensor elements (**Figure 1A**). Prior to integration with the glider CTD, the deep ISFET-based pH sensor was calibrated in a custom temperature-controlled pressure vessel filled with 0.01 N HCl over the range of 5–35°C and 0–3000 psi (Johnson et al., 2016). After the temperature and pressure calibration was completed, the pH sensor was integrated with the glider SBE41CP pumped CTD and conditioned in natural seawater for 1 week (Johnson et al., 2016). Based on the laboratory data collected at Sea-Bird Scientific the current specifications for the glider-based Deep-Sea DuraFET pH sensor are ±0.05 pH units in accuracy and ±0.001 pH units in precision. The resulting streamlined version utilizes the same mounting form factor as the SBE41CP pumped CTD, the standard model presently installed in Slocum gliders. Teledyne Webb Research facilitated the integration of the new deep ISFET pH/CTD unit into a standard glider science bay hull section (**Figure 1B**). This standalone science bay was also outfitted with a Sea-Bird Scientific ECO puck (BB2FL) configured for simultaneous fluorescence, CDOM, and optical backscatter measurements, and complimented the existing Aanderaa optode integrated into the aft of the glider for measuring DO. Teledyne Webb Research environmentally cycled (pressure and temperature), bench tested, and performed in-water tests on the completed assembly prior to deployment. A proglet was written for the glider science processor to ingest, store, and make available the data at each surface interval.

After the sensor calibrations and pre-deployment tests were completed by Sea-Bird Scientific and Teledyne Webb Research, the science sensor bay was assembled into the glider (**Figure 1C**) and placed in a natural seawater tank at Rutgers University for a minimum of 1 week at room temperature and pressure in order for the pH sensor to condition to seawater off the coast of Atlantic City, New Jersey (Bresnahan et al., 2014; Johnson et al., 2016).

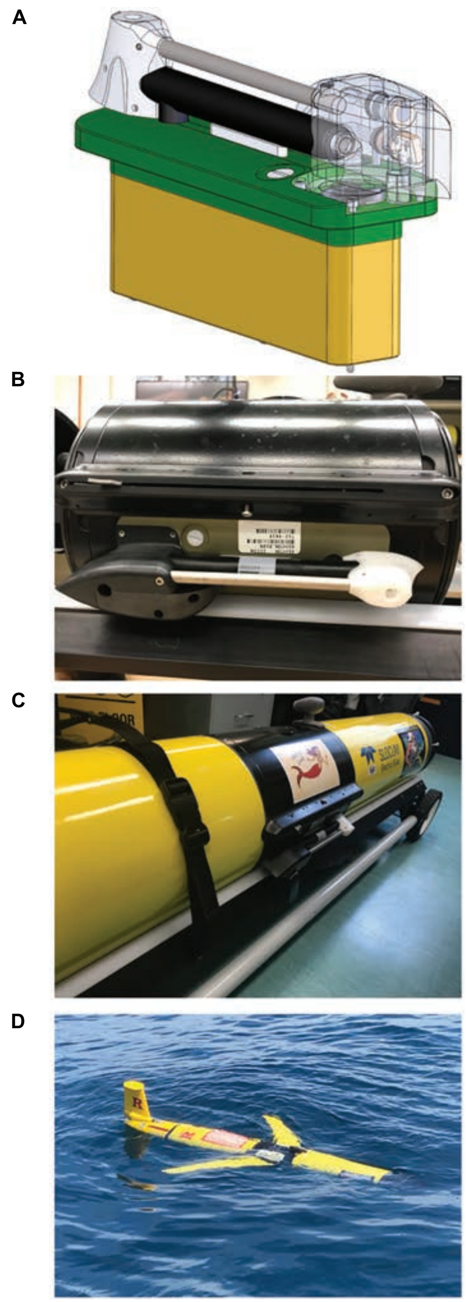

FIGURE 1 | DeepISFET-based pH sensor integration into a glider. Deep ISFET-based pH sensor integrated with pumped CTD **(A)**, Coupled pH and CTD integrated into a standalone science bay **(B)**, completely assembled in the glider **(C)**, and deployed in the Mid-Atlantic **(D)**.

pH Data Analysis

pH_{total} was calculated using the glider-measured reference voltage, pressure, sea water temperature, salinity, and sensor-specific calibration coefficients. Calculations were completed in Matlab (Johnson et al., 2017), and the code is provided in the **Supplementary Material**. The final equation used to calculate pH (below) was derived and modified from previous efforts

(Khoo et al., 1977; Millero, 1983; Dickson et al., 2007; Martz et al., 2010; Johnson et al., 2016):

$$pH_{total} = \frac{V_{ref} - k_0 - k_2 * t - f(p)}{S_{nernst}} + \log(Cl_T) + 2 * \log(\gamma HCl)_{T,P} - \log\left(1 + \frac{S_T}{K_{STP}}\right) - \log\left(\frac{1000 - 1.005 * S}{1000}\right)$$

Where:

$$S_{nernst} = \frac{R * T * \ln(10)}{F}$$

$$\log(\gamma HCl)_{T,P} = \log(\gamma HCl)_T + \left(\frac{V_{HCl^*p}}{\ln(10)\,RT}\right)/2$$

R is the universal gas constant = 8.314472 J/(mol*K);
t is the temperature in °C;
T is the temperature in K;
S is salinity in psu;
P is the pressure in dbar;
p is the pressure in bar;
F is the Faraday constant = 96485.3415 C/mol;
k_0 is the cell standard potential offset;
k_2 is the cell standard temperature slope;
$f(p)$ is the sensor pressure response function;
V_{ref} is the reference voltage;
V_{HCl} is the partial molar volume of HCl;
Cl_T is total chloride;
$(\gamma HCl)_T$ is the HCl activity coefficient at T;
$(\gamma HCl)_{T,P}$ is the HCl activity coefficient at T and p;
S_T is total sulfide;
K_{STP} is the acid dissociation constant of $HSO_{4,T\&P}$.

Tank Tests to Determine Sensor Conditioning Time

We conducted a series of tests October 17-November 6, 2018 to determine ISFET sensor conditioning time (**Figure 2A**). First, the glider was placed in a tank filled with natural seawater collected from nearshore waters near Atlantic City, NJ, United States. The pH/CTD sensors were immediately turned on with data continuously recording and transmitting in real-time using a Freewave modem linked to Teledyne Webb Slocum Fleet Mission Control software. This test defined the time required of an "off the shelf" pH sensor to condition or equilibrate to local seawater. A second set of tests investigated the response of the pH sensor to various wet/dry exposure time frames, representing scenarios wherein the sensor may be kept dry for periods of a few hours to days, such as during local, overnight, or distant transit from the laboratory facility to the field prior to a deployment (**Figures 2B–E**). Specifically, the second set of tests determined conditioning period after: (1) the glider was turned off for 2 h while the pH sensor remained submerged in the tank, then turned back on (**Figure 2B**); (2) the glider was removed from the tank and the pH sensor dried for 3 h, then the glider was placed back in the tank and turned on (**Figure 2C**); (3) the glider was removed from the tank and the pH sensor dried for 1 day then the glider was placed back in the tank and turned on (**Figure 2D**); and (4) the glider was removed from the tank and the pH sensor dried for 3 days then the glider was placed back in the tank and turned on (**Figure 2E**). The pH sensor was considered conditioned for each set of tests after the pH measurements stabilized with minimum drift (±0.0001 pH units hour^{-1} or ±0.003 pH units day^{-1}).

During the tank tests, discrete seawater samples were collected from the tank next to the glider at least three times daily and measured immediately on a spectrophotometric pH system set up next to the seawater tank. Accuracy of the glider pH sensor was determined as the pH measurement offset between glider pH and pH measured spectrophotometrically after the pH glider sensor was conditioned.

First Glider Deployments

After the sensor integration, factory calibration, testing, and conditioning was complete, we tested the capability of the glider sensor package in two deployments in coastal waters along the U.S. Northeast Shelf. Slocum gliders operate by increasing and decreasing volume with a buoyancy pump to dive and climb in repeat sawtooth sampling patterns. Wings, a pitch battery, and the shape of the glider body result in forward motion with an aft rudder and internal compass maintaining a pre-programed heading while underwater. At pre-programed surface intervals the glider acquires new location information, downloads new mission parameters, and sends back real time data. The glider, RU30, used in this study was a coastal glider with a 200 m rated pump. Coastal gliders profile vertically at 10–15 cm s^{-1} and travel horizontally at speeds of ∼20 km day^{-1}. Science sensors sample at 0.5 Hz resulting in measurements at every 20–30 cm intervals vertically.

We first deployed the glider on May 2, 2018 ∼9 km off the coast of Atlantic City, NJ (17 m water depth) (**Figures 1D, 3**, magenta track). This glider was powered by alkaline battery pack which supports a typical deployment for 3–4 weeks. Upon deployment, we conducted a CTD hydrographic profile and several individual casts with a 5 L Niskin bottle to sample discrete seawater samples for validating the sensor (see below) while the glider was conducting dives 50–100 m from the vessel. Once water sampling was completed, the glider was sent toward its next offshore waypoint to begin its cross-shelf transect. The glider completed a full cross-shelf transect in 20 days, and was recovered on May 22, 2018 ∼24 km off the coast of Atlantic City, NJ (25 m water depth). A subset of the full glider datasets were sent to shore in near real time via Iridium satellite cell phone located in the glider tail. After each glider sampling segment the glider surfaces, inflates an air bladder in the tail section, and connects to shore via iridium satellite cell phone. These datasets included all science variables necessary to calculate pH. This allowed for initial data quality checks while the glider was deployed, and ensured that if the glider was lost critical science data was still collected. After the glider was recovered, the full datasets were downloaded from the science memory cards stored onboard and are the datasets used throughout this publication. We have made

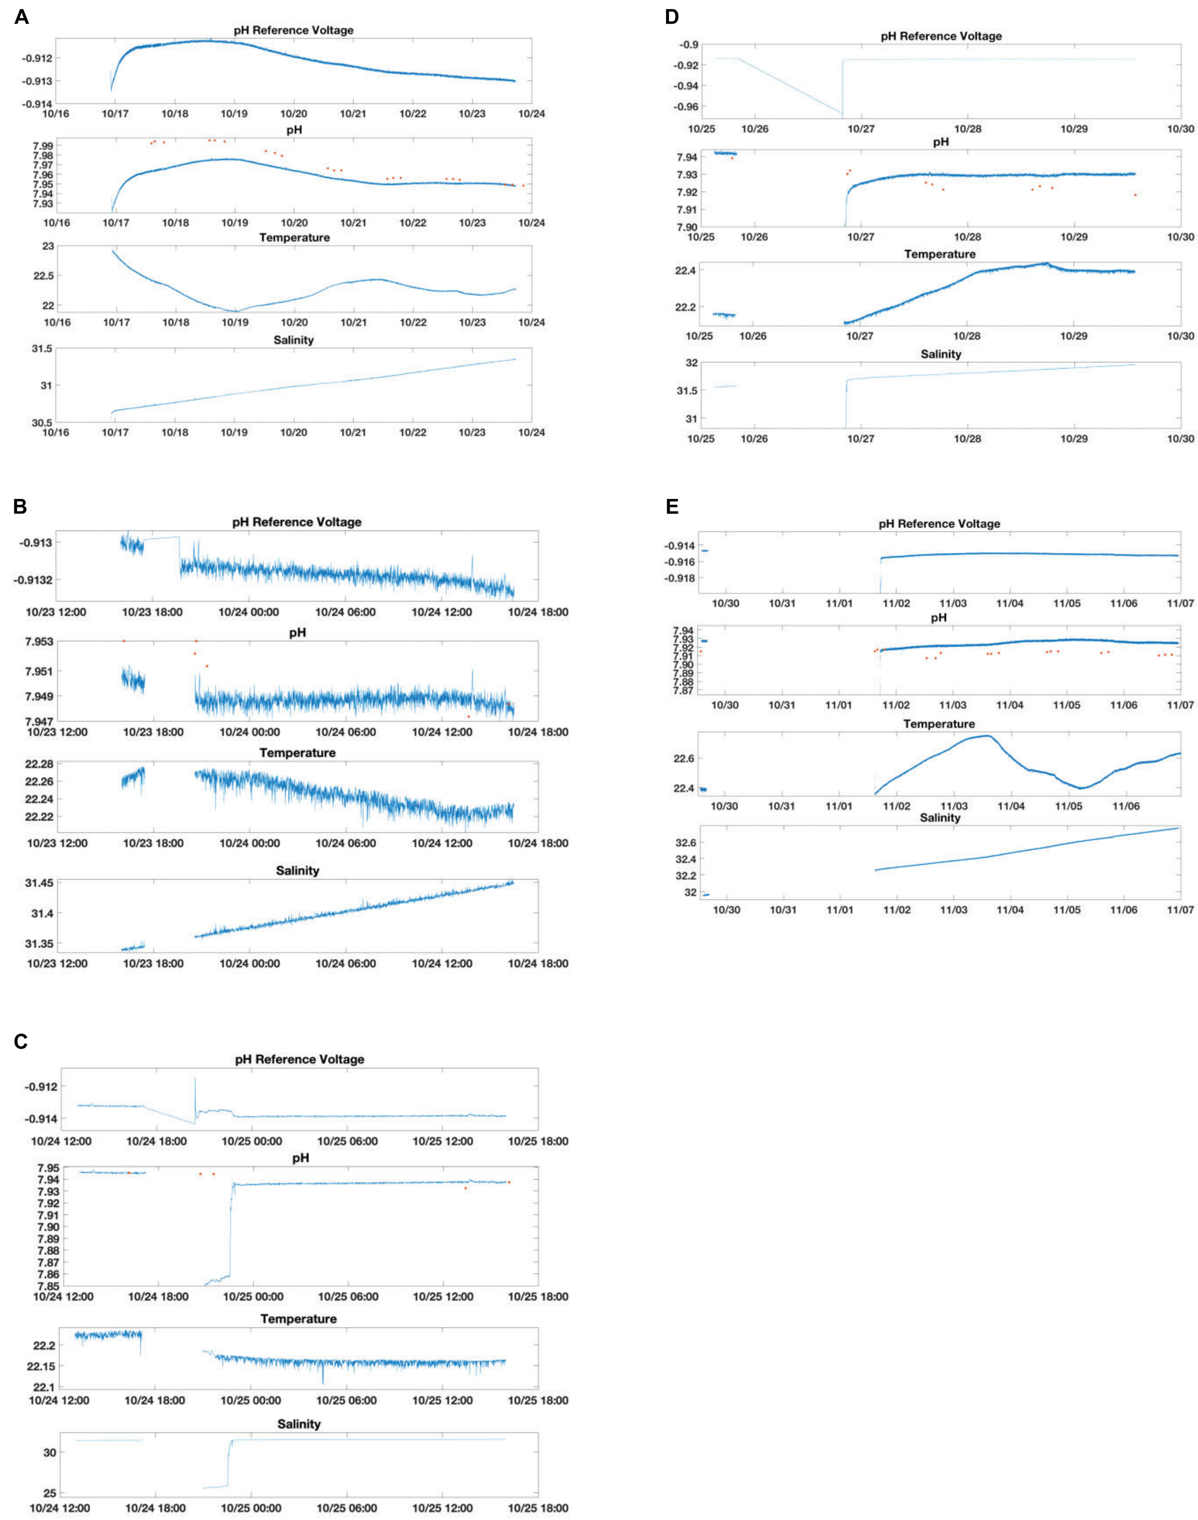

FIGURE 2 | Glider pH and discrete (spectrophotometric) pH tank test conditioning experiments. Data shown includes pH reference voltage measurements, calculated pH, temperature and salinity over time (month/day, for longer conditioning periods; month/day time, for shorter conditioning periods). The glider was placed in a saltwater tank and the pH/CTD sensor was turned on to determine times for initial conditioning from a sensor "off the shelf" **(A)**; conditioning after pH/CTD sensor turned off for 3 h while submerged in tank then turned back on **(B)**; conditioning after glider removed from tank and sensor dry for 2 h then placed back in the tank and turned on **(C)**; conditioning after glider removed from tank and sensor dry for 1 day then placed back in the tank and turned on **(D)**; conditioning after glider removed from tank and sensor dry for 3 days then placed back in the tank and turned on **(E)**. Data gaps represent the dry/off period.

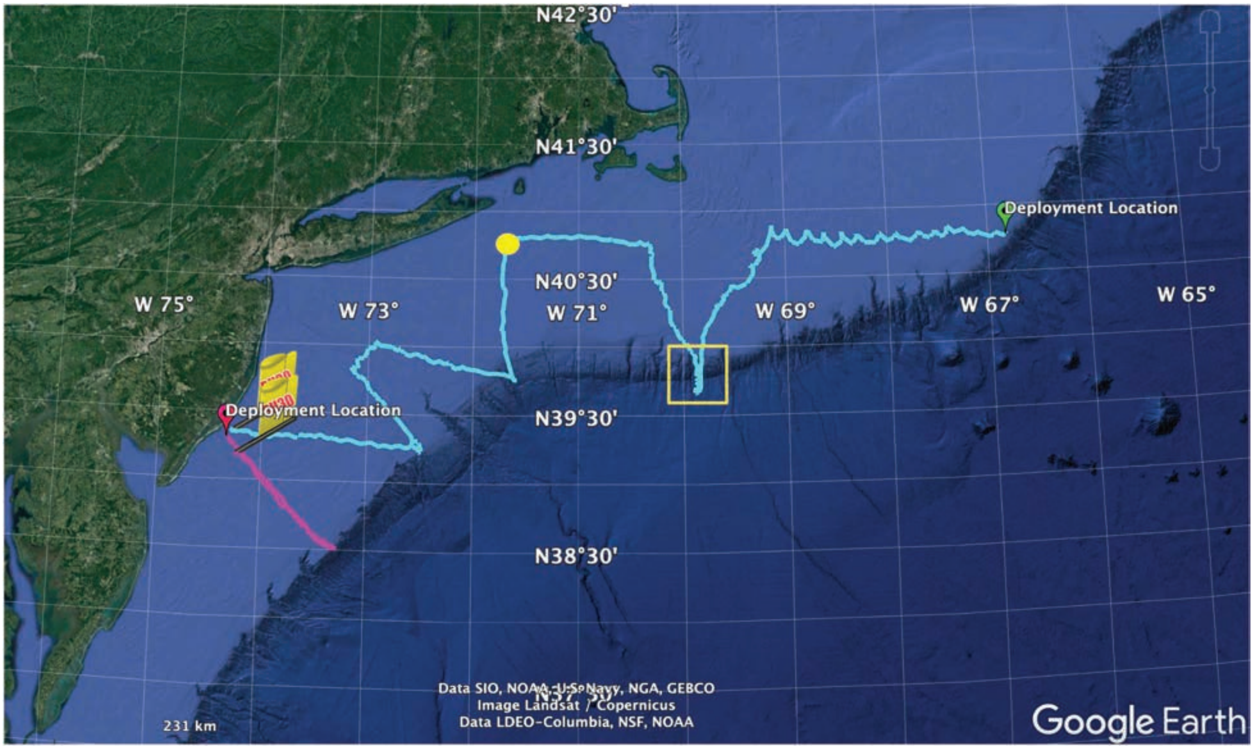

FIGURE 3 | Map showing location of first pH glider deployments. For the first deployment (magenta track), the glider was deployed off the coast of Atlantic City, New Jersey on May 2, 2018 and took measurements of pH and other variables from nearshore to the continental shelf break and back where it was recovered on May 22, 2018. For the second deployment (cyan track), the glider was deployed east of Georges Bank on July 5, 2018 and took measurements of pH and other variables during its transit until it was recovered off the coast of Atlantic City on August 28, 2018. During this deployment the glider was entrained into a warm core ring for nearly 5 days (yellow box). Concerned about biofouling due to this extended period in warm water, we intercepted the glider south of Montauk, NJ, United States on July 31, 2018 (yellow dot) to clean and re-deploy the glider and collect additional discrete water samples for sensor validation.

the glider variable data available and openly accessible on the ERDDAP server. The delayed mode time-series that contains all of the data as present in the source data files is accessible at: http://slocum-data.marine.rutgers.edu/erddap/tabledap/ru30-20180502T1355-trajectory-raw-delayed.html. The raw profile dataset that contains the data but broken up by glider profiles (not a time-series) is accessible at: http://slocum-data.marine.rutgers.edu/erddap/tabledap/ru30-20180502T1355-profile-raw-delayed.html. The science dataset that contains only scientifically relevant variables is accessible at: http://slocum-data.marine.rutgers.edu/erddap/tabledap/ru30-20180502T1355-profile-sci-delayed.html. Glider data processing, including analyses for sensor time lag corrections (below), was conducted using Slocum Power Tools available at: https://github.com/kerfoot/spt.

A second glider deployment occurred on the eastern edge of Georges Bank on July 5, 2018 (**Figure 3**, cyan track). This glider was powered by a lithium battery pack (configuration was 78 DD cells in a three series) which supports a typical deployment for nearly 60 days. At the time of this deployment, discrete seawater samples were collected in surface waters within 5 m from the pH/CTD glider sensor. After which the glider was sent west over Georges Bank. During a 4–5 days period (July 18–22), the glider was entrained in a warm core ring on the shelf break in waters off southern New England (**Figure 3**, yellow box). Concerned about biofouling due to this extended period in warm water, we intercepted the glider south of Montauk, NJ on July 31, 2018 (**Figure 3**, yellow dot) to clean the glider and collect additional discrete water samples for sensor validation. The glider was moderately biofouled and included biofouling inside the sensor intake (**Figure 4**). The glider and sensor were cleaned as much as possible by flushing with seawater and using brushes and cloth, but we were unable to remove biofouling in the far reaches of the internal sensor surfaces. The glider was re-deployed and continued on its transit where it was recovered off the coast of Atlantic City, NJ, United States on August 28, 2018. Due the evidence of biofouling during this summer deployment, we do not present here the full datasets and only report biofouling impacts on pH measurements and derived A_T.

Sensor Time Lag Corrections

Thermal lag corrections were applied to conductivity measurements prior to calculating pH. In a standard Sea-Bird CTD temperature is measured outside of the conductivity cell while conductivity is measured inside of the cell resulting in a mismatch in the measurements then used to calculate salinity, density, and subsequently pH (Garau et al., 2011). Thermal lag typically results in incorrect salinity and density estimates

FIGURE 4 | Biofouling on the glider deep ISFET-based pH sensor after 26 days during the July–August, 2018 deployment. The glider was intercepted, cleaned, and re-deployed south of Montauk, NJ, United States on July 31, 2018.

when the glider profiles through sharp interfaces. To address the thermal lag, temperature and conductivity data were binned in 0.25 m increments. Sequential temperature and conductivity profile pairs (one upcast and one downcast) were averaged together and the average profile was interpolated back to the original sampling depths. Salinity was calculated based on the corrected temperature and conductivity profiles.

Reference voltage and derived pH measurements exhibited a time lag during deployment, identified as skewed shifts in upcast and downcast measured (reference electrode) and derived pH (**Figures 5A,B**). To correct this lag, we first identified all upcast/downcast pairs (where there is an upcast followed by a downcast during the deployment). To determine the time shift that best matches the location of the clines, in this case typically a halocline, in an upcast and subsequent downcast, each pair was run through iterations of time shifts from 0 to 120 s at 5 s intervals. Optimal time shift was identified as the shift that minimized the difference of reference voltage in the two arms of the inverse V trajectory (upcast and subsequent downcast). We plotted optimal time shift for each upcast/downcast pair over time (**Figure 5C**) and optimal time shifts throughout full deployment as a histogram to determine shift peaks over time (**Figure 5D**). We observed 2 peaks during the May 2018 deployment, so one shift (47 s) was applied to first 1/3 of the deployment and a second shift (30 s) was applied to the last 2/3 (**Figures 5A,B**). July had 3 peaks (46, 81, 104 s) which were applied to those corresponding sections of deployment (data not shown).

Total Alkalinity Estimations and Aragonite Saturation State Calculations

To complement our glider pH measurements and to fully resolve the carbonate system, A_T was estimated from simultaneous glider salinity measurements. A_T exhibits near-conservative behavior with respect to salinity in the Atlantic along the east coast of the United States (Cai et al., 2010; Wang et al., 2013). To estimate A_T, we used the following linear regression equation, determined from the salinity-A_T relationship at three cross-shelf transects along the U.S NES (Massachusetts, New Jersey, and Delaware) sampled during the ECOA-1 cruise (summer 2015) (total 170 pairs of A_T and salinity data, $R^2 = 0.99$).

$$A_T = 50.04^* x + 564.08$$

Where x is salinity.

Final carbonate system parameters, including Ω_{Arag}, were calculated in Matlab using CO2SYS (van Heuven et al., 2011), with glider measured temperature, salinity, pressure, and pH and glider-derived salinity-based A_T as inputs. We used total pH scale (mol/kg-SW), K1 and K2 constants (Mehrbach et al., 1973) with refits (Dickson and Millero, 1987), and the acid dissociation constant of $KHSO_4$ in seawater (Dickson, 1990).

Quality Assurance and Quality Control (QA/QC)

The hydrographic (CTD) and DO data collected during the glider missions follows the QA/QC procedures outlined in an approved EPA Quality Assurance Project Plan (QAPP) that was developed specifically for glider observations of DO along the New Jersey coast (Kohut et al., 2014). The procedures include pre- and post-deployment steps for each sensor to ensure data quality for each deployment. Beyond these common measurements, the science bay of the glider was outfitted with an ECO puck and the profiling deep ISFET-based pH sensor. QA/QC procedures for each sensor are described in detail below.

CTD

The hydrographic data for each mission was sampled with a pumped CTD specifically engineered for this glider. Based on manufacturer specifications, the CTD was factory calibrated by SeaBird Scientific upon completion of the CTD-pH sensor integration. The QAPP requires a two-tier approach to verify the temperature and conductivity data from the glider CTD (Kohut et al., 2014). The first-tier test is a pre- and post-deployment verification between the glider CTD and a factory calibrated Sea-Bird-19 CTD in our ballast tank at Rutgers University in New Brunswick, NJ, United States. The second-tier test is an *in situ* verification at both the deployment and recovery of the glider. For each deployment and recovery, we lowered a manufacturer calibrated SeaBird-19 CTD to compare to the concurrent glider profile. This second-tier test gives an *in situ* comparison within the hydrographic conditions of the mission.

Aanderaa Optode

The DO data was sampled with an optical sensor unit manufactured by Aanderra Instruments called an optode. Like the CTD, we deployed a glider optode that is factory calibrated at least once per year. In addition to these annual calibrations, we also completed pre- and post- deployment verifications. To do this we compared optode observations to concurrent Winkler titrations of a sample at both 0

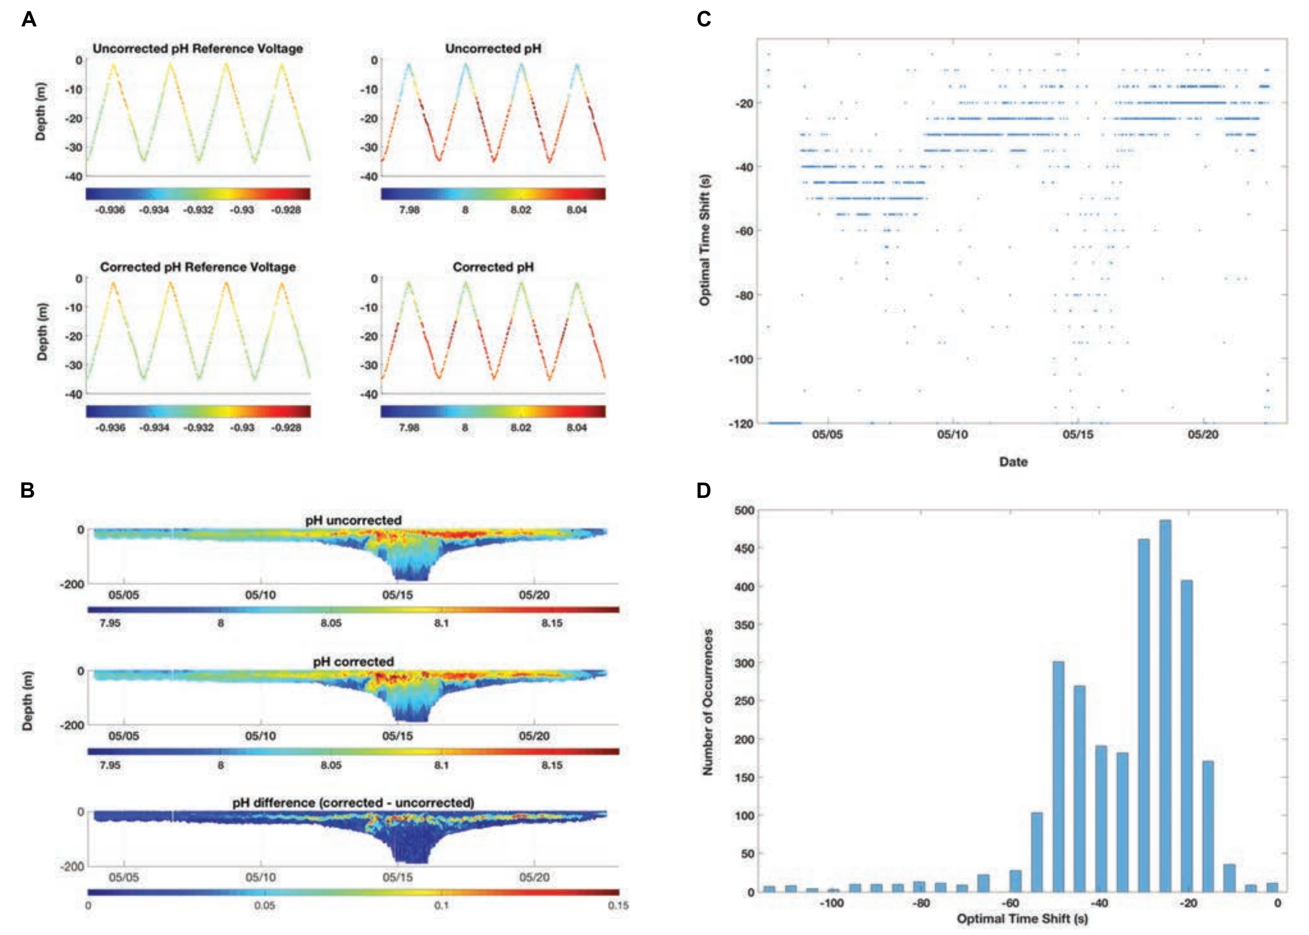

FIGURE 5 | pH response time lag corrections. Optimal time shift was identified as the shift that minimized the difference of reference voltage in the two arms of the inverse V trajectory (upcast and subsequent downcast). Example segments of uncorrected and corrected time lag observed in glider pH reference voltage and calculated pH data during the May 2018 deployment are shown in panel **(A)**. The time lag correction adjusted the measurements of pH reference voltage (left columns), and hence the calculations of pH (right columns). These were expanded to include uncorrected [top], corrected [middle], and the difference between the corrected and uncorrected pH [bottom] for the full May 2018 deployment **(B)**. The optimal time shift observed for upcast and downcast pairs over time **(C)** and the histogram of optimal time shifts **(D)** during the May deployment are presented here. Peaks were applied to shift time of pH reference voltage readings in order to minimize separation between glider up and downcasts.

and 100% saturation. The verification for this deployment met the QAPP requirement that all optode measurements are within 5% saturation of the results of the Winkler titrations for both the 0 and 100% saturation samples (Kohut et al., 2014).

BB2FL ECO Puck

The puck we deployed was standard factory calibration from WET Labs (recommended every 1–2 years for pucks in gliders).

Profiling Deep ISFET-Based pH Sensor

We followed Best Practices for autonomous pH measurements with the DuraFET, including the recommended rigorous calibration and ground truthing procedure (Bresnahan et al., 2014; Martz et al., 2015; Johnson et al., 2016). Using a 5 L Niskin bottle aboard the vessel during deployment and recovery, replicate water samples were collected near the glider from multiple depths (0.5 m, depth of thermocline, and 2 m from bottom; see **Table 1**). During this 1–2 h sampling procedure, the glider sampled the water column near the vessel. Water samples were collected for pH, DIC, and A_T analysis from the Niskin bottle into two 250 mL borosilicate glass bottles for a specific depth, with one bottle for DIC and A_T and another bottle for pH. Sampling involved overflow of seawater for at least one to two volumes, after which bottles were gently filled completely to avoid gas exchange with surrounding air. One mL of sample was removed to create a small headspace to allow for seawater expansion. The sample was then poisoned with 50 μL of saturated mercuric chloride, sealed with a pre-greased glass stopper and rubber band, and stored in a cool, dark location until analysis at Cai's laboratory (University of Delaware). Discrete sample pH was measured spectrophotometrically at 25° Celsius on the total

At glider deployment (May 2) and recovery (May 22), water samples were collected from various depths using a 5 L Niskin bottle, preserved, and returned to the laboratory for determination of pH, A_T, and Dissolved Inorganic Carbon (DIC). During this 1–2 h water sampling procedure, the glider sampled the water column in proximity to the vessel. Values displayed here are replicate discrete pH measurements (corrected for in situ temperature and salinity) and glider pH measurements averaged at each sample depth (±0.5 m) over the sampling period. Additionally, glider A_T (μmol kg^{-1}) was calculated using a linear regression determined from the salinity-A_T relationship at three cross-shelf transects along the U.S Northeast Shelf (Massachusetts, New Jersey, and Delaware) sampled during the ECOA-1 cruise (summer 2015).

pH scale using purified M-Cresol Purple purchased from R. Byrne at the University of South Florida (Clayton and Byrne, 1993; Liu et al., 2011). Cai's lab has built a spec-pH unit similar to the Dickson Lab (Carter et al., 2013). The accuracy of pH data was verified against *Tris* buffers (Millero, 1986; DelValls and Dickson, 1998) purchased from Andrew Dickson at UCSD Scripps Institute of Oceanography and through joining inter-laboratory comparisons. A_T titrations were performed using open cell Gran titration and Apollo Scitech A_T titrator AS-ALK2 following previously described methods (Cai et al., 2010; Huang et al., 2012; Chen et al., 2015). DIC was measured using an Apollo Scitech DIC analyzer AS-C3, which acidifies a small volume of seawater (1.0 mL) and quantifies the released CO_2 with a LI-7000 Non-Dispersive InfraRed analyzer (Huang et al., 2012; Chen et al., 2015). Precision of A_T and DIC are better than ±0.1%. Measurements of A_T and DIC were quality controlled using CRMs obtained from Andrew Dickson at UCSD Scripps Institute of Oceanography. The internal consistency was first evaluated among DIC, A_T, and pH using the Excel version of CO2SYS (Pierrot et al., 2006). Then we conducted temperature correction for the measured pH values to the *in situ* conditions using the same Excel version of CO2SYS the guidelines for input (analysis) and output (*in situ*) temperature, a total pH scale (mol/kg-SW), K_1 and K_2 constants (Mehrbach et al., 1973) with refits (Dickson and Millero, 1987), and the acidity constant of $KHSO_4$ in seawater (Dickson, 1990). These discrete samples were compared to the glider deep ISFET pH measurements. Discrete pH and A_T measurements collected during this work are available below and in the **Supplementary Material**. Final carbonate system parameters on the discrete water samples were calculated using CO2SYS (Pierrot et al., 2006).

RESULTS AND DISCUSSION

Sensor Conditioning Time and Performance

Two processes occur when the Deep-Sea pH sensor is introduced to a new sample of seawater. First, the external electrode equilibrates with the new ionic concentration of the seawater or conditioning. This conditioning can take minutes to days depending on how different the ionic composition of the seawater is from the seawater the pH sensor was calibrated in at Sea-Bird (Pacific seawater collected near Hawaii). Second, the ISFET and counter electrode polarize. This polarization can take minutes to hours to complete. Once the conditioning of the pH sensor is complete, if sensor power is removed or the connection between the ISFET and the counter electrode is broken (e.g., a drying period) the sensor will need to repolarize again. We conducted a series of tests to determine sensor conditioning time initially (**Figure 2A**), and conditioning after variable time periods when the sensor was either turned off and kept wet or removed from tank and kept dry (**Figures 2B–E**). In the initial test, pH determined from the new sensor conditioned and reached within 0.005 pH units from the discrete pH values after 4–5 days of soak time in the natural seawater tank (**Figure 2A** and **Supplementary Material**). This is most likely due to the sensor equilibrating to the new seawater for the first time.

After this initial conditioning time, the pH/CTD sensor was turned off for 2 h while submerged in the tank then turned back on with the pH measurements stabilizing immediately and the offset between glider and discrete pH returning to within 0.003 pH units (**Figure 2B** and **Supplementary Material**). The glider and sensor were then turned off and removed from tank and kept dry for 3 h then placed back in the tank and turned on. The pH measurements stabilized and the offset returned to within 0.002 pH units within 17 h, and this likely occurred much sooner but discrete samples were not collected during the overnight period to confirm (**Figure 2C** and **Supplementary Material**). This conditioning was likely due to either a bubble trapped on the sensor that was cleared shortly after it was turned back on or the sensor repolarizing after being dried. The glider and sensor were then turned off and removed from tank and kept dry for 24 h then placed back in the tank and turned on. The pH sensor conditioned within 17 h, but the pH offset stabilized (±0.003 pH units) between 0.006 and 0.008 pH units for the next few days (**Figure 2D** and **Supplementary Material**). This test was repeated, except the dry period lasted 3 days prior to placing the glider/sensor back in the tank. The pH offsets stabilized (±0.003 pH units) after nearly 3 days, but this final offset between glider and discrete pH measurements was larger (0.012 – 0.015 pH units) (**Figure 2E** and **Supplementary Material**).

It is likely that after the 4–5 days of initial sensor stabilization, the sensor continued to condition or drift but at slower, gradual rate until reaching an average pH offset from discrete samples of 0.013 ± 0.001 after 18 days. This pH offset was similar to that seen *in situ* after initial sensor conditioning during the 3-week May 2018 glider deployment in the Mid-Atlantic Bight (absolute value range: 0.001–0.017; mean ± SD: 0.011 ± 0.005, n = 12). Therefore prior to a glider deployment, we recommend a minimum of 5 days of soak time in natural seawater collected from the field location. Another possibility for the gradual increase in pH offset between the glider and the discrete samples could be biofouling in the tank. The tank was filled with coarsely filtered, unsterilized natural seawater and kept at room temperature (not temperature-controlled). Although it was not visibly apparent, it is possible that a biofilm layer could have developed during the 18-day trial and contributed to or primarily caused the gradual sensor drift.

Nonetheless, an accuracy of 0.013 pH units achieved in the tank test (and 0.011 pH units in the field; see below) exceeded our expectations given the current specifications for this deep ISFET-based pH sensor are ±0.05 pH units in accuracy and ±0.001 pH units in precision.

In situ Glider and Discrete Sample pH and A_T Comparisons

On the first deployment (May 2018), absolute pH differences observed between glider pH and pH measured spectrophotometrically from discrete samples were quite variable, ranging from 0.001 to 0.032 pH units (**Table 1**). Discrepancies in the surface water at deployment were largest (mean ± SD: 0.031 ± 0.001, n = 3) compared to surface water at recovery and subsurface water at both deployment and recovery (absolute value range: 0.001–0.017; mean ± SD: 0.011 ± 0.005, n = 12). We attribute the large pH discrepancies in the surface at the start of the deployment and water sample collection to the sensor not yet being stabilized or conditioned after being out of the tank for 4–5 h during transit from the lab to the field. Offsets observed in surface water at recovery and subsurface water at both deployment and recovery might represent the logistical challenges faced when attempting to collect discrete water samples next to the glider, resulting in either salinity inputs, depth, and/or sampling time differences between glider pH measurement and pH in discrete seawater samples.

The Niskin sampling bottle used for seawater collection did not have a CTD attached which posed two challenges. First, to calculate pH using the spectrophotometric method, temperature and salinity data at target depths from the initial CTD cast conducted prior to Niskin water bottle sampling commenced were used as inputs to calculate pH. Therefore, potential salinity (and pH) changes at target depths between the CTD cast and water sampling (0.5 – 1.5 h) could have occurred due to boat drift and/or currents. Second, cable metered markings were relied upon to reach target depths, and currents or slack on the cable could have resulted in sampling at depths above the target causing mismatch between glider pH and spec pH measurements. This is supported also by high variability observed in discrete pH between replicate Niskin casts/bottle samples at certain depths (May 2, 15 m: discrepancy of 0.014 pH units; **Table 1**). Improvements in sampling techniques are now being employed. For example, upon deployment on July 2, surface seawater samples were collected using a Niskin water bottle deployed adjacent to the glider just after its deployment from the vessel (within a 5 m distance from the glider pH sensor), which greatly reduced the discrepancies between glider pH and discrete pH seen in the first deployment (range: 0.001–0.004 pH units; **Table 2**). Further improvements in water sampling technique could be made, specifically for subsurface seawater pH comparison, by using a CTD mounted on a rosette frame with multiple Niskin bottles to ensure sampling occurs at target depth and simultaneous measurements of salinity and temperature with each depth-specific sample collection.

The greatest challenge with *in situ* sensor validation was obtaining subsurface water samples next to the glider. During the time water sampling was being conducted on board (1–2 h), the pH glider conducted repetitive dives to sample the full water column near the vessel. While water sampling was conducted in proximity to the glider (within ∼100 m), it could have occurred far enough away that different patches were sampled by the two methods creating the offset in pH measurements. Simply, the two different sampling techniques were not measuring pH (glider) or collecting seawater for pH measurements (Niskin/discrete) at the same depths at the same place and at the same time. Future missions should test different sampling techniques (e.g., attaching glider to CTD rosette) to improve subsurface sensor validation that will minimize discrepancies at depth.

During multiple deployment and recovery practices in the U.S NES, glider salinity-based estimations of A_T were consistently lower than A_T measured in discrete samples (**Tables 1–3**). Overall, the differences in water column showed similar ranges of −11.2 to −30.5μmol kg^{-1} for the spring deployment and recovery (**Table 1**) and of −7.3 to −41.8μmol kg^{-1} and −6.0 to −34.8μmol kg^{-1} for summer deployments and recoveries (**Tables 2**, **3**), with averages of −18.5±7.5, −22.9±11.1, and −26.5±10.9 μmol kg^{-1}, respectively. The discrepancies between glider salinity-based estimates and discrete A_T likely reflect differences in water properties and/or water masses measured

TABLE 2 | Comparisons between glider pH and derived total alkalinity (A_T) and discrete pH and A_T measured from seawater samples during the summer glider deployment (July/August 2018).

At glider deployment (July 5) and recovery (August 28), water samples were collected from various depths using a 5 L Niskin bottle, preserved, and returned to the laboratory for determination of pH, A_T, and Dissolved Inorganic Carbon (DIC). During this 1–2 h water sampling procedure, the glider sampled the water column in proximity to the vessel. Values displayed here are replicate discrete pH measurements (corrected for in situ temperature and salinity) and glider pH measurements averaged at each sample depth (±0.5 m) over the sampling period. Additionally, glider A_T (μmol kg^{-1}) was calculated using a linear regression determined from the salinity-A_T relationship at three cross-shelf transects along the U.S Northeast Shelf (Massachusetts, New Jersey, and Delaware) sampled during the ECOA-1 cruise (summer 2015).

During deployment in July 2018, the pH glider experienced moderate biofouling. On July 31, the glider was intercepted off of Long Island, NY, United States. Upon glider retrieval, seawater samples were collected at various depths and preserved for later analysis for comparison of glider and discrete pH and total alkalinity (A_T) measurements. An attempt was made to clean the glider and pH/CTD sensor unit before the glider was re-deployed. The data shown here are comparisons between glider pH and derived total alkalinity (A_T), just before (pre-clean) and after (post-clean) attempted cleaning of biofouling, and discrete pH and A_T measured from seawater samples. Glider pH measurements were averaged at each sample depth (±0.5 m) over the sampling period. Glider A_T (μmol kg^{-1}) was calculated using a linear regression determined from the salinity-A_T relationship at three cross-shelf transects along the U.S Northeast Shelf (Massachusetts, New Jersey, and Delaware) sampled during the ECOA-1 cruise (summer 2015).

during these glider deployments and the summer 2015 ECOA-1 cruise (where/when the salinity-A_T relationship was derived). These include seasonal differences in low-salinity end-member and nearshore organic alkalinity input, and ultimately, challenges for sampling and validation in this dynamic environment. The offsets between glider-derived and discrete A_T yielded lower glider-estimated Ω_{Arag}, offset from discrete Ω_{Arag} by −0.010 to −0.025 for surface waters during the Spring deployment (see **Supplementary Material**). Further work is needed for better evaluation of the relationship between A_T and salinity at nearshore lower salinity waters and different water masses in order to reduce the uncertainty that is propogated in the calculations of Ω_{Arag} using CO2SYS.

Sensor Time Lags

Two patterns emerged from the pH sensor time lag correction analyses. First, there was a change in time lag throughout the deployment in May 2018 (47 s during first week, 30 s for last 2 weeks) (**Figures 5C,D**). This may indicate a pH sensor conditioning period, wherein the sensor was acclimating to new seawater conditions. Second, the time shift had the greatest effect in areas of abrupt water type transition, specifically in the thermocline and halocline and offshore where we encountered a warmer, saltier water mass (**Figure 5B**). The glider moved rapidly (10–15 cm s^{-1}) through these vertically narrow transition zones without acclimating completely, which possibly increased pH sensor response time and caused the increased time lag observed at these depths. This could be due to either a lag in the thermal equilibration of the sensor or salinity response of the reference electrode or relatively slow flushing of the cell by the CTD pump. Further investigations on sensor conditioning, response time, and variability are recommended in order to improve this initial lag correction method. Additionally, modifications in CTD pump flow rate or glider dive approaches in highly stratified periods in coastal systems, including slower dives or step-wise vertical descents/ascents, should be considered.

Carbonate Chemistry Dynamics in the Mid-Atlantic Bight

The pH and Ω_{Arag} ranges observed during this Spring (May 2018) deployment were 7.906–8.205 and 1.48–2.22 respectively. pH was frequently observed highest in subsurface waters and was associated with the depth of chlorophyll and oxygen maximums (**Figure 6**). Higher pH values in the chlorophyll maximum throughout the transect ranged between 7.993 and 8.127. During primary production, photosynthesis increases pH due to the uptake of CO_2. So, while the observed association between pH and chlorophyll was not surprising, the ability to resolve the subsurface pH peak from the high-resolution vertical sampling with the glider provides a valuable perspective from which to not only evaluate concurrent vertical distributions of pelagic organisms, but also to put into context past pH monitoring efforts that mostly sample surface waters (Boehme et al., 1998; Wang et al., 2013, 2017; Wanninkhof et al., 2015; Xu et al., 2017). Higher pH in offshore slope waters was also associated with a warmer, saltier water mass and suggests mixing processes could play a major role in driving pH dynamics on the shelf. During the deployment, the glider measured warmer water in the upper mixed layer on its return transect, depicting the strengthening of seasonal summer stratification in the upper mixed-layer due to incident solar radiation. These warm surface waters on the return transect were associated with increased pH values (**Figure 6**). Higher Ω_{Arag} values were consistently observed in surface waters throughout the deployment, and highest values were associated with the warm, salty, higher alkaline water mass (**Figure 6**).

The lowest pH typically occurred in bottom waters of the middle shelf and slope and nearshore following a period of heavy precipitation (**Figure 6**). Lower pH values in the mid-shelf and slope bottom waters ranged between 7.918 and 8.027. Lower pH in mid-shelf bottom water occurred in the Cold Pool as defined by remnant winter water in the Mid-Atlantic Bight centered between the 40 and 70 m isobaths (Lentz, 2017). The Cold Pool is fed by Labrador Sea slope water and is isolated when vernal warming of the surface water sets up the seasonal thermocline. The annual formation of Cold Pool water means its carbonate chemistry should reflect near real-time increases in atmospheric CO_2 and pCO_2 in its Labrador source water which is weakly buffered and exhibits lower pH and Ω_{Arag} (Wanninkhof et al., 2015). Thus, the dominant drivers of low pH, as well as high DIC and low Ω_{Arag} (Wang et al., 2013), in shelf bottom water were likely a combination of stratification, biological activity (i.e., higher respiration at depth), and the inflow of Labrador Sea slope water into the Cold Pool. Nearshore, lower pH was associated with lower salinity from freshwater input that was most substantial during a high period of precipitation near the end of the deployment, whereby 4.45 inches of rainfall was recorded at Atlantic City Marina, NJ, between May 12–22 (NJ Weather & Climate Network[1]; **Figure 6**). This storm event resulted in the freshening of the entire water column near shore (30 m; **Figure 6**). River runoff has low pH from the equilibration with atmospheric CO_2 concentrations, and its zero salinity and low/zero alkalinity greatly reduces buffering capacity to offset changes in pCO_2 and contributes to low Ω_{Arag} (Salisbury et al., 2008; Johnson et al., 2013). Lowest Ω_{Arag} values consistently occurred in bottom waters on the shelf (**Figure 6**). This was likely driven by lower pH in these bottom waters.

When pH is plotted as a function of temperature and salinity (**Figure 7**), the pH characteristics of specific water masses become more apparent. For example, the fresher nearshore surface waters and surface water over the mid-shelf are distinctively different in pH (**Figure 7**). Thus, carbonate chemistry variability in this system over a range of scales will be driven by: (1) episodic storm mixing, upwelling, and precipitation events; (2) Mixing of water masses and the degree of horizontal intrusion of offshore water masses onto the shelf; (3) Seasonal stratification and vertical mixing/overturning processes; and (4) a combination of biological and physical drivers on the shelf and in shelf source waters. Both the horizontal and vertical gradients of pH observed were, at times, particularly sharp, and this new glider pH sensor suite demonstrated the ability to characterize the variability and drivers of this variability in these critical zones.

Current Limitations and Need for Future Research and Development

Comparative results between the glider deep ISFET-based pH sensor and pH measured spectrophotometrically from discrete seawater samples indicate that the glider pH sensor is capable of accuracy of 0.011 pH units or better for several weeks throughout the water column in the coastal ocean, with a precision of 0.005 pH units or better. These values are similar to those reported for the Deep-Sea DuraFET sensor deployed on moorings in Johnson et al. (2016).

However, in addition to the logistical issues related to sampling seawater next to the glider for *in situ* validation described above, the primary limitation we encountered and foresee is glider and sensor biofouling during deployments. Glider batteries have been evolving over time, from alkaline to lithium one-time use to rechargeable lithiums that have greatly improved the endurance capability of gliders and glider sensors. But as the potential deployment time for gliders has increased, the chance of biofouling is increased. Biofouling can impact glider flight behavior (e.g., increased drag and reduced efficiency; Rudnick, 2016) and greatly reduce sensor performance, as was observed in the SeaFET on week to month timescales (Bresnahan et al., 2014).

During our July deployment, we experienced moderate biofouling after about 3 weeks (**Figure 4**), which degraded the pH measurements over deployment time (**Tables 2**, **3**). This suggests that, at a minimum, the sensor unit was impacted, yielding unreliable pH voltage data and subsequent calculations of pH. This biofouling was likely intensified when the glider was entrained in a warm core ring for a 4–5 days period. After this event, the glider was intercepted south of Montauk, NY, United States. Seawater samples collected near the glider showed

[1]https://www.njweather.org/data/daily/272

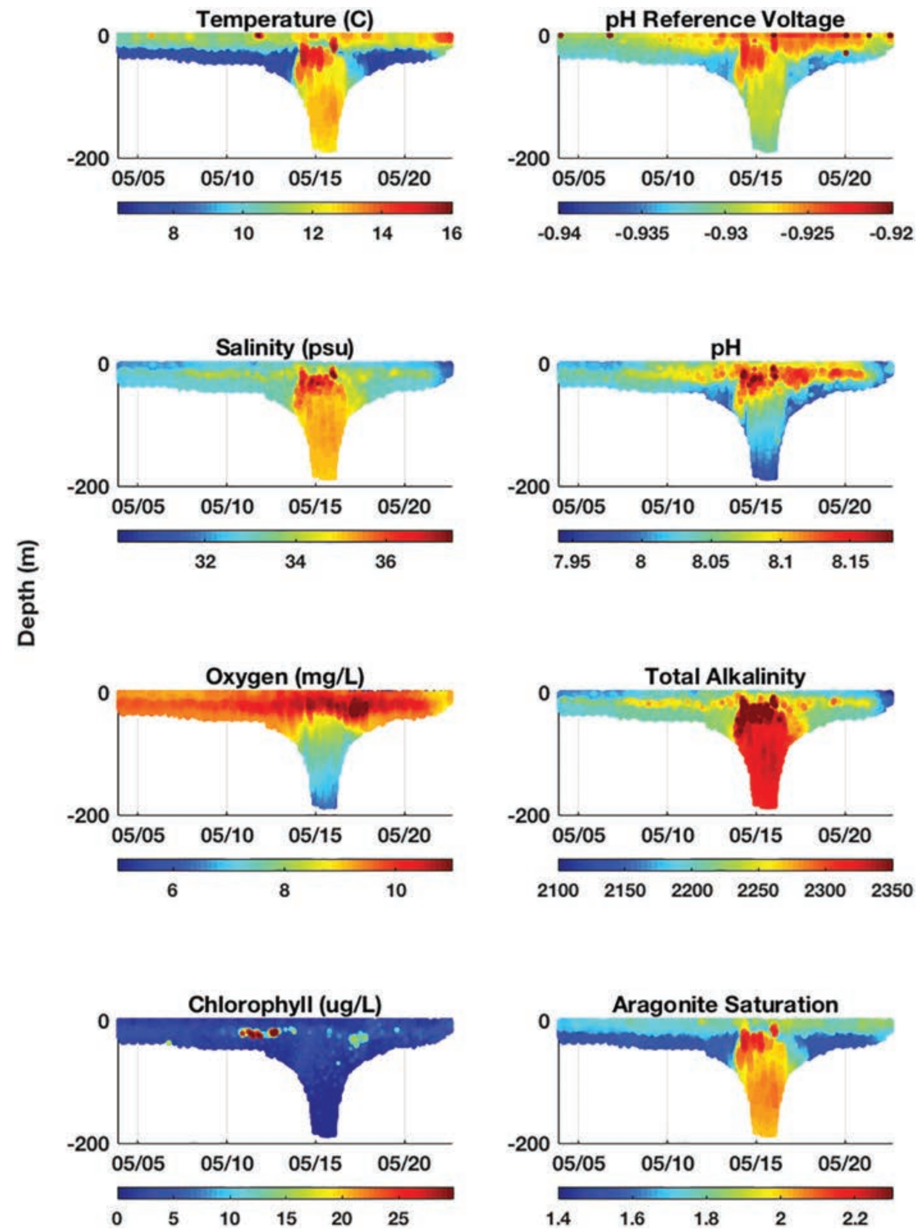

FIGURE 6 | Complete cross-sections of variables measured by the glider and calculated from glider measurements during deployment in May 2018. The glider's on-board scientific instruments measure temperature, conductivity (used to calculate salinity), dissolved oxygen concentration, chlorophyll fluorescence, and pH reference voltage (used to calculate pH). Salinity was used to estimate total alkalinity (TA) throughout deployment (see Methods). TA and pH were used as inputs into CO2SYS to resolve all carbonate system parameters, including aragonite saturation state, shown here.

the pH offsets between the glider and discrete samples were much higher compared to those at deployment (**Tables 2**, **3**). Offsets between glider and discrete pH ranged from −0.144 to 0.081 pH units (**Table 3**). We made an attempt to clean the glider and sensor by flushing the sensor with seawater and using brushes of various sizes on the outer structures of the glider and sensor unit, but biofouling in the internal structure of the pH sensor unit that we could not access was still evident. Nonetheless the glider was redeployed after this cleaning process. The offsets between glider and discrete pH, ranging from −0.03 to 0.134 pH units, remained unsatisfactory (**Table 3**). These offsets worsened rapidly over time, and when the glider was recovered on August 28, offsets in pH measurements ranged from −0.084 to 0.249 pH units (**Table 2**). The magnitude and the variability of the offsets resulting from heavy biofouling yielded pH data not acceptable for OA research. The biofouling impact seems specific to the pH sensor and not the CTD, specifically the conductivity sensor. Comparisons of salinity between the glider CTD profiles and the hand-lowered SeaBird-19 CTD conducted at each glider deployment and recovery passed the *in situ* verification process.

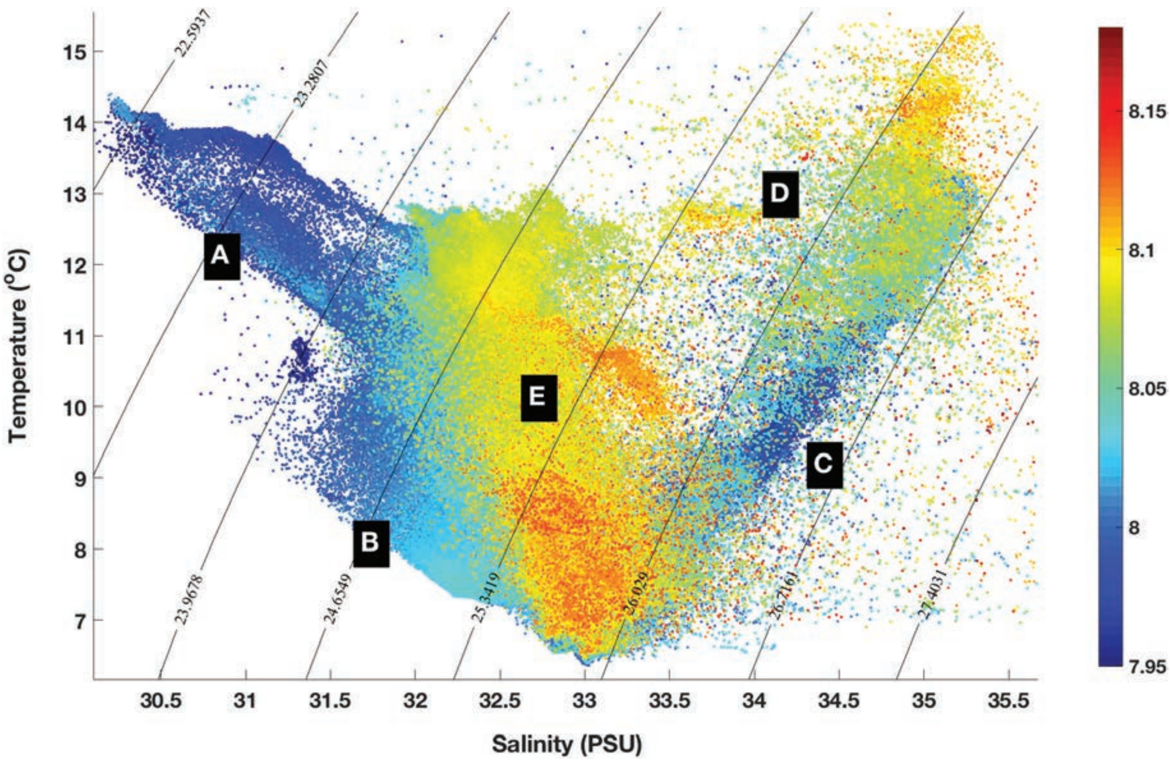

FIGURE 7 | Temperature/Salinity plot of pH. During the May 2018 deployment, lower pH water was found in fresher nearshore surface waters **(A)** and bottom waters of the colder mid-shelf **(B)** and shelf break **(C)**. Higher and more variable pH was found in surface water of the shelf break **(D)** and mid-shelf **(E)**.

Furthermore, the offsets between glider derived salinity-based calculations of A_T and discrete A_T on July 31 (when the glider was intercepted and re-deployed; 24.8 ± 14.3, $n = 20$) and August 28 (when the glider was recovered; 26.2 ± 9.2, $n = 9$) were similar to those from the May deployment (18.5 ± 7.5, $n = 15$). It is likely that biofouling impacted pH sensor response time, as indicated by the increasing sensor time lag corrections that were applied to the glider data from the start of the deployment on July 5 to recovery on August 28 (46–81–104 s).

Current biofouling prevention measures for this sensor are the enclosure of the coupled pH/CTD sensor to block light, an anti-fouling cartridge in the pH sensor's intake, and the active seawater pumping capability of the CTD that flushes water through the sensor package continuously during deployment. However, advances to improve anti-fouling mechanisms would greatly improve sensor performance, durability, endurance, and applicability. Approaches could include installation of an additional anti-fouling cartridge in the sensor intake and turning the glider CTD pump off at regular intervals during deployment to facilitate diffusion, concentration, and exposure of the anti-fouling agent into the water chamber surrounding the pH sensor. Furthermore, to enable sustained glider-based acidification monitoring in a coastal system, especially in warm and shallow conditions, researchers will require the ability to routinely clean and/or swap out sensors to prevent data degradation over time from biofouling.

Additionally, investigation of the mechanism that impacts pH measurements (i.e., affects on sensor response time or reference voltage readings) needs to be conducted. Finally, the current salinity-A_T relationship in the U.S. NES is only based on summer data. This relationship may be subject to change with time, particularly during other seasons, and under different conditionsthat impact freshwater influx and/or the presence of distinctive water masses in this dynamic coastal region. We recommend to determine a salinity-A_T relationship in collected water samples before and after the glider survey in order to use the salinity-based A_T together with the glider pH to reduce the uncertainty of estimating Ω_{Arag}.

SIGNIFICANCE

This new glider pH sensor suite has demonstrated its potential to: (1) Provide high resolution measurements of pH in a coastal region; (2) Determine natural variability that will provide a framework to better study organism response and design more realistic experiments; and (3) Identify and monitor high-risk areas that are more prone to periods of reduced pH and/or high pH variability to enable better management of essential habitats in future, more acidic oceans. The first glider deployment reported here provided data in habitats of commercially important fisheries in the U.S. Northeast Shelf, and allowed for the examination of temporal and spatial pH variability, the identification of areas and periods of lower pH water, better understanding of how mixing events and circulation impact pH across the shelf, and the creation of a baseline to track changes over time during future, scheduled deployments. Furthermore, the integration of simultaneous measurements from multiple sensors on the glider provides the ability to not only distinguish interactions between the physics, chemistry, and biology of the ecosystem, but also to conduct salinity- and temperature-based estimates of A_T in order to derive Ω_{Arag}. As such, if made commercially available, this sensor suite could undoubtedly be integrated in the planned national glider network (Baltes et al., 2014; Schofield et al., 2015; Rudnick, 2016) to provide the foundation of what could become a national coastal OA monitoring network serving a wide range of users including academic and government scientists, monitoring programs including those conducted by OOI, IOOS, NOAA and EPA, water quality managers, and commercial fishing companies. Finally, data resulting from this project and future applications can help build and improve biogeochemical and ecosystem models. A range of data validated and data assimilative modeling systems has matured rapidly over the last decade in the ocean science community. Many of these systems are being configured to assimilate glider data (temperature and salinity) (i.e., ROMs). The technology produced from this project will contribute to efforts to develop coastal forecast models with the capability to predict the variability and trajectory of the low pH water.

AUTHOR CONTRIBUTIONS

GS introduced the research ideas and led the proposal that funded this work. AB and CB developed and finalized the glider deep ISFET-based pH sensor design and provided technical support for the duration of this project. CJ worked with AB and CB on the deep ISFET-based pH sensor integration into the glider to ensure seamless hardware and software compatibility. EW-F and TM led glider data analysis efforts and figure production. BC, W-JC, and KW analyzed all discrete samples for pH, A_T, and DIC. GS wrote the draft. All authors contributed to the writing of the manuscript.

FUNDING

This project was funded by the National Science Foundation's Ocean Technology and Interdisciplinary Coordination Program (NSF OCE1634520). EW-F received support from the Rutgers University Graduate School Excellence Fellowship.

ACKNOWLEDGMENTS

We thank the Rutgers University Center for Ocean Observing Leadership (RU COOL) glider technicians David Aragon, Nicole Waite, and Chip Haldeman for glider preparation, deployment planning, and piloting glider missions. We also thank Rutgers undergraduate students Brandon Grosso and Laura Wiltsee for glider-based laboratory and field support, and RU COOL faculty Oscar Schofield, Josh Kohut, Scott Glenn, and Michael Crowley for facility support. We acknowledge Dave Murphy, Cristina Orrico, Vlad Simontov, and Dave Walter at Sea-Bird Scientific and Christopher DeCollibus, Clara Hulburt, and staff at Teledyne Webb Research for technical assistance. This original work was presented in October 2018 at the OCEANS'18 MTS/IEEE meeting in Charleston, SC, United States and in May 2019 at the 8th EGO meeting and International Glider Workshop in New Brunswick, NJ, United States.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fmars.2019.00664/full#supplementary-material

***Abstract*—Accurate ocean initial conditions are necessary to improve hurricane intensity forecast. We assessed qualitatively the impact of glider data assimilation on the Global Ocean Forecasting System (GOFS 3.1), which provides the initial conditions to the NOAA hurricane forecasting models. For this assessment we used temperature data from two gliders that were within the range of influence of hurricane Michael and Florence. We conclude that the assimilation of glider data in GOFS 3.1 was crucial to improve the pre-storm vertical stratification during Michael. However, the assimilation frequency in the current setup, once a day, was insufficient to capture the rapid cooling of the surface layer. During Florence, GOFS 3.1 did not predict the evolution of the sea surface temperature because the model did not capture the extend of the MAB cold pool.**

***Index Terms*—autonomous underwater glider, GOFS, data assimilation, hurricanes**

I. Introduction

During the last three decades hurricane forecast track errors have been reduced substantially but intensity forecast errors have seen only limited improvement [7]. Operational hurricane forecasting models such as the Hurricane Weather Research and Forecasting model (HWRF) and the Hurricanes in a Multi-scale Ocean-coupled Non- hydrostatic model (HMON) coupled to the Hybrid Coordinate Ocean Model (HYCOM), run by NOAA EMC, require accurate ocean initial conditions in order to better forecast storm intensity [4]. Currently the ocean initial conditions for these models are provided by the Real Time Ocean Forecast System (RTOFS), which in turn is initialized by the Navy's Global Ocean Forecasting System (GOFS 3.1) that implements the 3DVar Navy Coupled Ocean Data Assimilation (NCODA) System. With the purpose of evaluating the initial conditions provided to the NOAA hurricane forecasting models, we conducted a qualitative assessment of the impact of glider data assimilation on the performance of GOFS 3.1. We did our assessment during the 2018 hurricane season for two storms: hurricane Florence and hurricane Michael. we used temperature data from a fleet of sentinel gliders deployed in the North Atlantic.

II. Methods

The glider data was accessed through the Integrated Ocean Observing System (IOOS) glider data assembly center (DAC) (https://data.ioos.us/gliders/erddap), with a total of 62 deployments during the 2018 hurricane season (Jun 1-Nov 30) (Fig. 1). These gliders were deployed collaboratively with gliders supplied by the U.S. Navy, U.S. IOOS, NOAA, NSF, academic institutions, state agencies and private companies. All the glider data reported to the IOOS glider DAC is subsequently sent to the Global Telecommunication System (GTS) where it is accessed by GOFS 3.1 and a number of numerical models for data assimilation purposes.

In this work we show temperature transects from two gliders, Ramses and ng288, that were closest to the track of hurricane Florence and hurricane Michael respectively. We obtained the corresponding along-track temperature glider-transects from the Navy operational ocean model GOFS 3.1 by interpolating the glider position and time onto the model grid and output timestamp. The model output corresponds to the hindcast output from Jan-1 2018 to present (https://tds.hycom.org/thredds/dodsC/GLBv0.08/expt_93.0/ts3z.html).

GOFS 3.1 is a global model based on the Hybrid Coordinate Ocean model (HYCOM). It has 41 vertical levels and a horizontal resolution of 0.08^o from 40^o south to 40^o north of latitude, and 0.04^o for locations poleward of 40^o. The output frequency is 3 hourly. The GOFS 3.1 system implements NCODA [6], a 3DVar data assimilation algorithm that uses satellite altimeter data, satellite and in-situ surface temperature, in-situ vertical temperature and salinity from Argo floats,

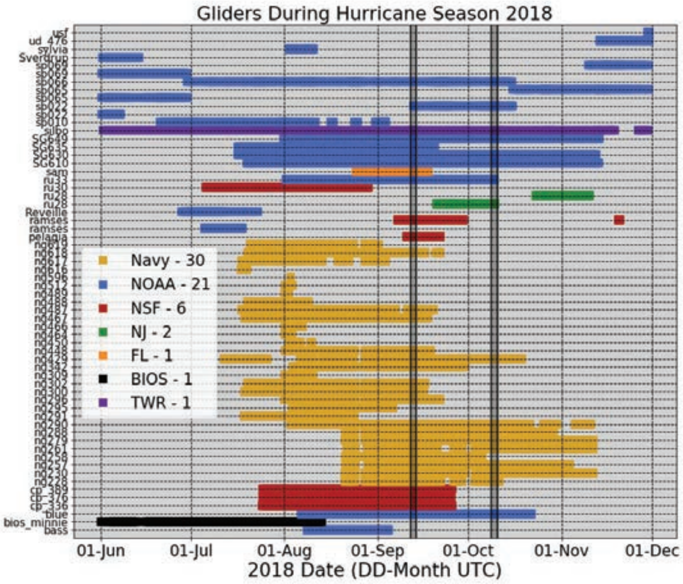

Fig. 1. Deployment period for the gliders reporting to the IOOS glider DAC during the 2018 hurricane season (Jun 1-Nov 30). The different colors indicate the institutions in charge of the deployments: U.S Navy, NOAA, NSF, New Jersey Department of Environmental Protection (NJ), State of Florida in collaboration with Florida Fish and Wildlife Conservation Commission (FL), the Simons Foundation International (BIOS) and Teledyne Web Research Corporation (TWR). In the legend, the number next to the institution is the number of glider deployments by that institution. The two grey vertical bars show the time period for hurricane Florence (Sep 11-Sep 14) and hurricane Michael (Oct 7-Oct 11).

buoys, gliders and XBTs (only temperature). NCODA uses a 24 hours update cycle centered at 12Z. For profile and altimetry data, it currently uses data within the 24 hours window but looks back up to 4 days and 5 days, respectively, due to data latency. The 3DVAR system selects data based on receipt time instead of observation time [2]. In this way all the data received since the previous assimilation cycle is used in the next assimilation cycle. As a consequence, non-synoptic measurements (more than 24 hours apart) are used in an assimilation cycle introducing errors in the analysis. This error is reduced using the First Guess at Appropriate Time (FGAT) technique. FGAT reduces the error by comparing observations against time-dependent background fields. More details about GOFS 3.1/NCODA system can be found in the GOFS 3.1 validation test report [6].

The code used to retrieve the glider data, model output and perform the interpolation between the glider position and time onto the model grid and time step is available at https://github.com/MariaAristizabal/glider_model_comparisons_Python.

III. Results

A. Hurricane Michael

In the Gulf of Mexico during the passage of hurricane Michael there were seven Navy gliders deployed in this region (Fig. 2). The eye of Hurricane Michael passed within 36 km of Navy glider ng288 on Oct 10 at 06:00 UTC. The oceanic response to Michael, a category 5 hurricane at landfall, was characterized by a 30 meter deepening of the surface layer that can be seen in the temperature and salinity profiles (Fig. 3). As the surface layer deepened, there was a cooling of about 0.8 degrees in the top 50 meters of the water column. There were also internal-inertial waves generated at the thermocline depth, defined here as the depth of the 26 degrees isotherm, that can be seen in the ng288 transect after the passage of Michael (Fig. 4 (a), Fig. 6 (b)), which are a typical response of the ocean to hurricane winds [8], [10].

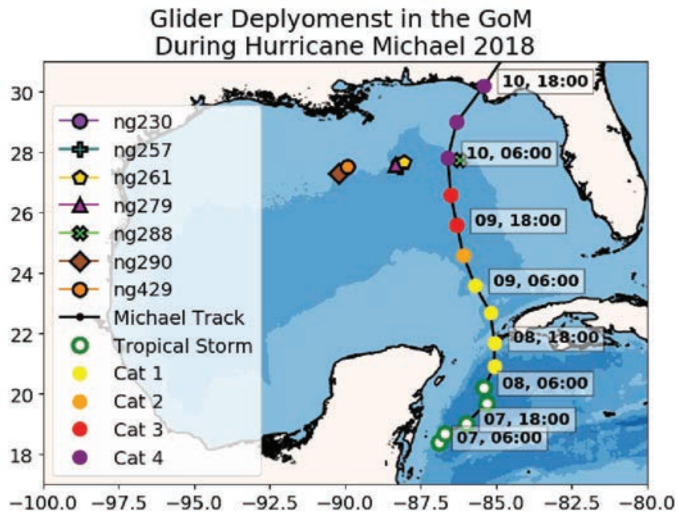

Fig. 2. Mean position of the gliders deployed in the Gulf of Mexico during the passage of hurricane Michael (Oct 7-Oct 10). The black line and colored circles show the trajectory and intensity in the Saffir-Simpson scale of hurricane Michael.

Five days before the eye of Michael passed closest to ng288, the depth of the thermocline estimated by GOFS 3.1 was deepened after every data assimilation cycle in order to match the glider data (Fig. 4 (b)). Two days previous to landfall, the thermocline had reached a stable depth (Fig. 4 (b) and (c)), though it was still a little shallower than the observed depth. As a result, the time series of temperature at 100 m from GOFS 3.1 exhibited positive jumps right after almost every increment insertion window (Fig. 4 (c)) when the NCODA algorithm was attempting to deepen the thermocline.

The spatial distribution of the temperature increments from the NCODA analysis at 100 meters depth on Oct 10 2018 revealed that the largest positive increments happen around the locations of the gliders (Fig. 5) and this is consistent with the positive temperature jumps that the model temperature experienced at 100 m (Fig. 4 (c)).

At the surface two days before landfall, the modeled and observed sea surface temperature (SST) agreed extremely well (Fig. 6 (c)), with both decreasing gradually. As the eye of Michael passed closest to ng288, the observed surface temperature decreased more rapidly. However, the modeled SST increased abruptly after the increment insertion window on Oct 10, driving the SST away from the observed value. We will discuss a possible explanation of why the data

B. Hurricane Florence

In the Middle Atlantic Bight (MAB) there were a total of 9 gliders during the passage of hurricane Florence (Sep 11-Sep 15) (Fig. 7). The closest glider to the eye of hurricane Florence was Ramses, located 188 km north from the eye on Sep 14 00:00Z. At this shallow location, the water column mixed completely before and during the passage of Florence with a decrease in SST of 5 degrees (Fig. 8 (a)). This dramatic drop in temperature is comparable with the temperature change during hurricane Irene [3] and it is caused by the intense vertical mixing, either wind-induced or shear-induced, and the presence of the cold pool, a cold bottom layer of water that characterizes the Middle Atlantic Bight at this time of the year [1], [5]. The along-track temperature in GOFS 3.1 (Fig. 8 (b)) shows that the model captures the main features of the cold pool during the first part of the track (Sep 8-Sep 12), such as the bottom to surface temperature difference and the depth of the 26 degrees isotherm. But the model fails to produce the extend of the cold pool around Cape Hatteras, where Ramses was located during the passage of Florence. Instead the model shows a water column that is warm top to bottom. As a result, the model cannot produce the drop in SST because there is not cold bottom water to mix vertically.

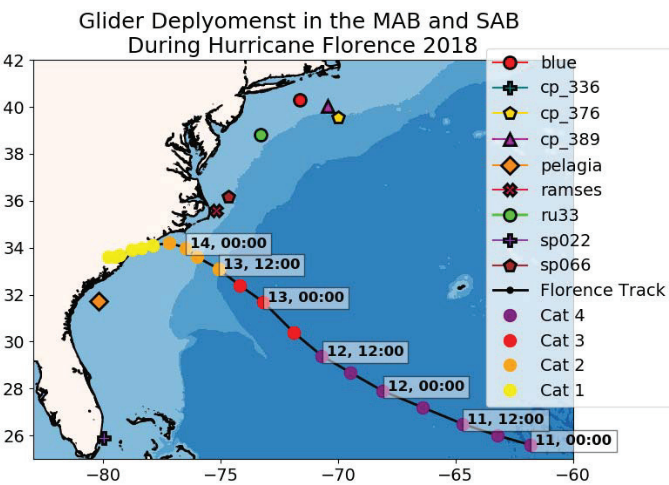

Fig. 7. Mean position of the gliders deployed in the Mid and South Atlantic Bight during the passage of hurricane Florence (Sep 11-Sep 14). The black line and colored circles show the trajectory and intensity in the Saffir-Simpson scale of hurricane Florence. The passage times next to the trajectory are in UTC.

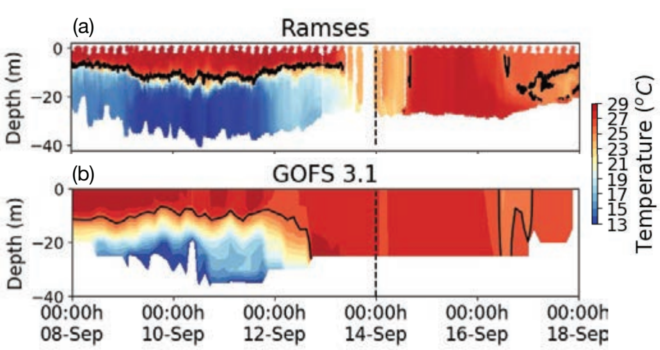

Fig. 8. (a) Temperature transect for Ramses from Sep 8 to Sep 18 2018. (b) The same along-track transect as for Ramses but interpolated onto GOFS 3.1 grid and timestamp. The black contour in both panels shows the 26 degrees isotherm. The vertical dashed line in both panels shows the time when the eye of hurricane Florence was closest to the Ramses location: Sep 14 00:00 UTC.

IV. Discussion and Conclusions

During hurricane Michael, ocean data assimilation in GOFS 3.1 proved to be critical to improve the pre-storm vertical stratification. This is important for hurricane forecasting because the deepening of the thermocline, caused by the storm-induced vertical mixing, and subsequent surface cooling are controlled by the pre-storm vertical stratification. It is crucial to correctly estimate the change in SST under the passage of a storm as this change in temperature controls the direction and magnitude of the heat fluxes [9]. These heat fluxes can significantly contribute to the weakening or strengthening of a storm. This result highlights the importance of deploying a glider fleet ahead of possible storms in order to capture the pre-storm subsurface conditions.

On the other hand, at the surface the data assimilation algorithm degraded the modeled SST by driving the SST away from observations during the period of rapid surface cooling. We think that the reason for this is that GOFS 3.1/NCODA system has a 1-day data assimilation cycle. This means that for the data assimilation cycle centered on Oct 10 12Z, NCODA assimilated data before the start of the rapid cooling and this may have shifted the SST towards warmer values. This suggests that the 1-day data assimilation cycle used by NCODA is not adequate to capture the rapid cooling during a storm.

During hurricane Florence, the closest glider to the eye of the storm shows that there was a cooling of about 5 degrees in the SST before and during the passage of the storm. This cooling happened thanks to the presence of the MAB cold pool and therefore it is an important feature that controls the magnitude of the cooling in this region [3]. GOFS 3.1 did not capture the extend of the cold pool, inhibiting a realistic prediction of the evolution of the SST.

To model the evolution of the SST during a storm is essential for coupled atmosphere-ocean hurricane models, as the heat fluxes are controlled by the SST differences between the upper ocean and the atmosphere. In the open ocean, the cooling is mostly controlled by the wind-induced vertical mixing [9]. In the shelf, there are other processes that can take place like shear-induced vertical mixing at the base of the thermocline driven by a two-layer cross-shelf circulation [3]. In either case, the coupled atmosphere-ocean hurricane models need to capture first the pre-storm vertical stratification as a necessary condition to improve the hurricane forecast intensity.

Central place foragers select ocean surface convergent features despite differing foraging strategies

Received: 10 November 2017

Matthew J. Oliver[1], Josh T. Kohut[2], Kim Bernard[3], William Fraser[4], Peter Winsor[5], Hank Statscewich[5], Erick Fredj[6], Megan Cimino[7], Donna Patterson-Fraser[4] & Filipa Carvalho[8]

Discovering the predictors of foraging locations can be challenging, and is often the critical missing piece for interpreting the ecological significance of observed movement patterns of predators. This is especially true in dynamic coastal marine systems, where planktonic food resources are diffuse and must be either physically or biologically concentrated to support upper trophic levels. In the Western Antarctic Peninsula, recent climate change has created new foraging sympatry between Adélie (*Pygoscelis adeliae*) and gentoo (*P. papua*) penguins in a known biological hotspot near Palmer Deep canyon. We used this recent sympatry as an opportunity to investigate how dynamic local oceanographic features affect aspects of the foraging ecology of these two species. Simulated particle trajectories from measured surface currents were used to investigate the co-occurrence of convergent ocean features and penguin foraging locations. Adélie penguin diving activity was restricted to the upper mixed layer, while gentoo penguins often foraged much deeper than the mixed layer, suggesting that Adélie penguins may be more responsive to dynamic surface convergent features compared to gentoo penguins. We found that, despite large differences in diving and foraging behavior, both shallow-diving Adélie and deeper-diving gentoo penguins strongly selected for surface convergent features. Furthermore, there was no difference in selectivity for shallow- versus deep-diving gentoo penguins. Our results suggest that these two mesopredators are selecting surface convergent features, however, how these surface signals are related to subsurface prey fields is unknown.

Optimal foraging theory suggests central place foragers consider external cues like food quality, distance to food patch, and revisit times to food patches to maximize fitness[1]. The end result of the feedback between prey patch characteristics and the desire and ability of the predator to find food is manifested as random walks[2], Lévy walks[3], or other diffusive[4] or multi-modal movements. Interpreting the ecological significance of these movement modes necessitates an understanding of the dynamic nature of the available environmental cues, the relative response of predators and prey to these cues, and how organisms remember these cues[5]. For example, many organisms appear to exhibit Lévy walks, which are documented to optimize foraging success of random searchers[6]. However, the selective interactions that lead to the emergence of these patterns are often unknown, hence in the absence of an understanding of selective cues between the environment and the focal individual, alternative movement modes may equally explain observed movement patterns[7,8]. Therefore, it is not enough to only establish a movement mode to understand the ecological significance of foraging behaviors or how these behaviors might change in dynamic environmental conditions. Discovering the environmental predictors of foraging locations is equally important, yet can be challenging and is often the critical missing piece for interpreting the ecological significance of observed movement patterns of predators. It is difficult to map environmental cues at the appropriate scale to

determine if they are being selected[9,10], especially in a fluid marine environment. In the coastal Western Antarctic Peninsula (WAP), the food web is short and characterized by intense phytoplankton blooms that are grazed by Antarctic krill (*Euphausia superba*, referred to hereafter as "krill"), a primary prey source for penguins and other predators. Although krill aggregations occur throughout the WAP[11], their distribution is extremely patchy even on scales less than 1 km[12,13]. Krill have intermediate Reynolds numbers (~10^2–10^3), compared to drifting phytoplankton (~10^{-2}) and swimming penguins (~10^6), which means they can make directed movements, even though they are also heavily influenced by local circulation.

Lagrangian convergent features are representations of time-dependent concentrating ocean dynamics at scales relevant to marine predator foraging ecology. Broadly, they are regions that concentrate neutrally buoyant particles and are often associated with filaments and mesoscale features, such as eddies, jets and fronts. Convergent features, identified by time varying concentrations of buoyant particle densities, may be proxies for the mechanisms by which sparse food resources move through marine trophic levels by collapsing the essential components of the food web in time and space. Realistic particle simulations show that convergent features have much higher concentrations of zooplankton[14]. Seabirds have also been associated with convergent features such as mesoscale eddies[15], and their flight paths are coherent with dynamic convergent features[16]. Macaroni penguins have been shown to associate with convergent features at relatively large scales (10–100 km), presumably because they concentrate prey resources[17]. These studies have focused on relatively large-scale associations using infrequent satellite composites of ocean features. However, convergent features are dynamic in space and time, and therefore should optimally be examined at space and time scales relevant to predator foraging behaviors.

At our study site, Adélie penguin (*Pygoscelis adeliae*) populations have decreased rapidly over the last three decades, while numbers of gentoo penguins (*P. papua*) have increased[18]. These population changes have resulted in relatively recent sympatry between these two congeneric central place foragers in our study site, where they also exhibit partially overlapping foraging ranges over the Palmer Deep canyon (Fig. 1). In this study, we determine if these two species select convergent features in a similar way to guide their foraging behavior. To do this, we used an integrated ocean observatory (Fig. 1) to estimate the relationship between surface convergent features and the foraging behavior of these two mesopredators.

Table 1. The p-value and number of observations for KS tests comparing the field RPD to Adélie and gentoo ARGOS locations classified into transiting, search diving and forage diving behavior. The classifications were based on 1, 2.5, 5, and 15 minute windows before and after the ARGOS hit to classify the location. Bold text indicates that ARGOS locations had higher RPD than the field RPD.

Results

Penguin Locations Relative to Ocean Features. During the austral summer of 2014–2015, we mapped penguin foraging patterns relative to sea surface currents derived each hour from a High Frequency Radar (HFR) network over Palmer Deep canyon (Fig. 2a)[19]. Simulated passive particles released in the hourly surface current maps were used to identify the location and intensity of convergent features that may locally concentrate prey biomass during penguin foraging days. Maps of Relative Particle Densities (RPD) derived from particles released each hour across the HFR footprint were used to estimate the location of convergent features each hour between January 1st and March 1st 2015, where higher RPD values were indicative of convergence (Fig. 2b).

For 11 Adélie and 7 gentoo penguins, there was a total of 124 and 98 ARGOS class 1–3 locations representing 27 and 17 foraging trips, respectively. These locations were spatially matched to hourly RPD (Tables 1 and 2). ARGOS locations were classified as transiting, searching or foraging based on their dive profiles within 1, 2.5, 5, and 15 minutes of the ARGOS location (Tables 1 and 2). Adélie penguin dives associated with ARGOS locations had significantly higher RPD values compared to RPD values across the entire HFR field and significantly higher RPD values compared to the RPD values sampled by simulated Adélie penguins ($p \ll 0.001$ and $p \ll 0.001$, two-sample Kolmogorov-Smirnov tests respectively, Fig. 3a). Gentoo penguin locations had higher RPD values compared to RPD values across the entire HFR field but these were weakly significant ($p = 0.03$, two-sample Kolmogorov-Smirnov tests respectively, Fig. 3b). However, compared to RPD values sampled by simulated gentoo penguins, tagged gentoo penguins showed a significant selection for higher values as well ($p \ll 0.001$, two-sample Kolmogorov-Smirnov tests, Fig. 3b).

Both simulated and tagged penguins covered different areas of the HFR field during our experiment, and therefore experienced different RPD. However, simulated penguins within the convex hull of their tagged counterparts still showed significantly lower RPD values compared to tagged Adélie and gentoo penguins ($p = 0.02$ and $p = 0.0005$, respectively). To test the sensitivity of these results to the effects of individual trips or individual penguins, we resampled these ARGOS locations, systematically leaving out one foraging trip or one penguin (represented by the grey envelope in Fig. 3a,b). In all resampling cases, the Adélie and gentoo ARGOS RPD

Table 2. The p-value and number of observations for KS tests comparing the RPD of simulated Adélie or gentoo penguins to Adélie or gentoo ARGOS locations classified into transiting, search diving and forage diving behavior. The classifications were based on 1, 2.5, 5, and 15 minute windows before and after the ARGOS hit to classify the location. Bold text indicates that ARGOS locations had higher RPD than the simulated penguins RPD.

values were significantly higher than both the field and simulated penguin RPD values ($p \ll 0.001$, two-sample Kolmogorov-Smirnov tests). As a result, it is likely that both Adélie and gentoo penguins were systematically selecting for higher RPD.

We partitioned the ARGOS locations by behavior classification within the above mentioned time intervals (Tables 1 and 2). For Adélie penguins, ARGOS locations classified as foraging and search diving behavior occurred in significantly higher RPD compared to both the background RPD and the simulated penguin RPD. The exception was for the search diving behavior classified with a 15 minute time window, likely due to a low sample size ($n = 4$). Adélie penguin ARGOS locations classified as transiting had higher RPD compared to the background RPD, except when using a 15 minute time window due to low sample size ($n = 2$). Furthermore, only RPD for transiting Adélie penguins classified with the 2.5 minute window were significantly higher than the simulated penguins, although it should be noted that for the shorter time window of 1 minute the p-value was 0.075. For the tagged gentoo penguins, only ARGOS locations classified as forage diving had significantly higher RPD compared to the simulated penguin RPD for all time classifications. Search diving behavior had very few samples. The largest sample size for ARGOS locations classified as transiting with a 1 minute time window had significantly higher RPD compared to both background and simulated penguin RPD, while the longer time windows with fewer samples did not have significantly higher RPDs compared to both the background and simulated RPD. Overall, only ARGOS locations classified as forage diving had significantly higher RPD compared to simulated penguin RPD across both species and all time windows (Table 2).

Adélie and gentoo penguins displayed markedly different diving behaviors relative to oceanographic features. Adélie penguins foraged in waters above the mixed layer at depths between 5 and 50 m, where the surface layer is sensitive to atmospheric forcing, while gentoo penguins foraged both above and below the mixed layer, at depths between 5 and 100 m (Fig. 3c,d). The mixed layer depth (MLD), estimated from the maximum buoyancy frequency[20], was ~30 m during the time period that Adélie penguins were tagged and deepened to ~50 m during the period gentoos were tagged, which accords with natural seasonal changes[21]. We partitioned the gentoo data by dive depth relative to MLD. Gentoo penguins diving shallower than the MLD selected for higher RPD values than the simulated gentoo penguins ($p = 0.028$). Gentoo penguins diving deeper than the MLD also selected for higher RPD values compared to the simulated gentoo penguins ($p \ll 0.001$). The distributions of RPD targeted by the shallow and deep diving penguins were not significantly different ($p = 0.1$), indicating that gentoo selectivity of surface RPD was not dependent on penguin foraging depth.

Relative Particle Density Values in Diurnal and Semi-Diurnal Tidal Regimes. Prior work has shown that local tides are coherent with Adélie penguin ARGOS locations over Palmer Deep[22]. The dominant tidal constituent near Palmer Station is the diurnal K_1 followed closely by another diurnal constituent, O_1. The two prominent semi-diurnal constituents, K_2 and M_2, are smaller in magnitude[23]. The interaction of these constituents leads to a unique mixed tide that is slightly diurnal-dominated based on tide gauge data collected at Palmer Station[23]. The result is a tidal forcing and response that transitions from a diurnal to semi-diurnal regime approximately every two weeks. A long-term (2002–2011) record of Adélie penguin foraging distances showed that Adélies foraged at greater distances from shore during semi-diurnal tides, compared to diurnal tides (Fig. 4)[22]. In 2015, Adélie ARGOS locations expanded to the south and east during semi-diurnal tides, while gentoo ARGOS locations translated to the north and west during semi-diurnal tides. During the austral summer of 2014–2015, we mapped the location of strong convergent features based on the hourly RPD maps partitioned by days with semi-diurnal and diurnal tides. The convergent features were defined as grid cells with particle counts, normalized by subtracting the spatial median, greater than 100. The location frequency of these strongest fronts associated with the semi-diurnal and diurnal tidal regimes are shown in Fig. 4. During the semi-diurnal tidal regime, the highest occurrence of convergent features was located offshore over the central canyon (Fig. 4a), consistent with the offshore historic Adélie penguin foraging locations observed during semi-diurnal tides. During the diurnal tidal regime, the location of the highest percentage of convergent features moved south and inshore (Fig. 4b), closer to the penguin colonies. We suggest that the predictability of the locations of convergent features associated

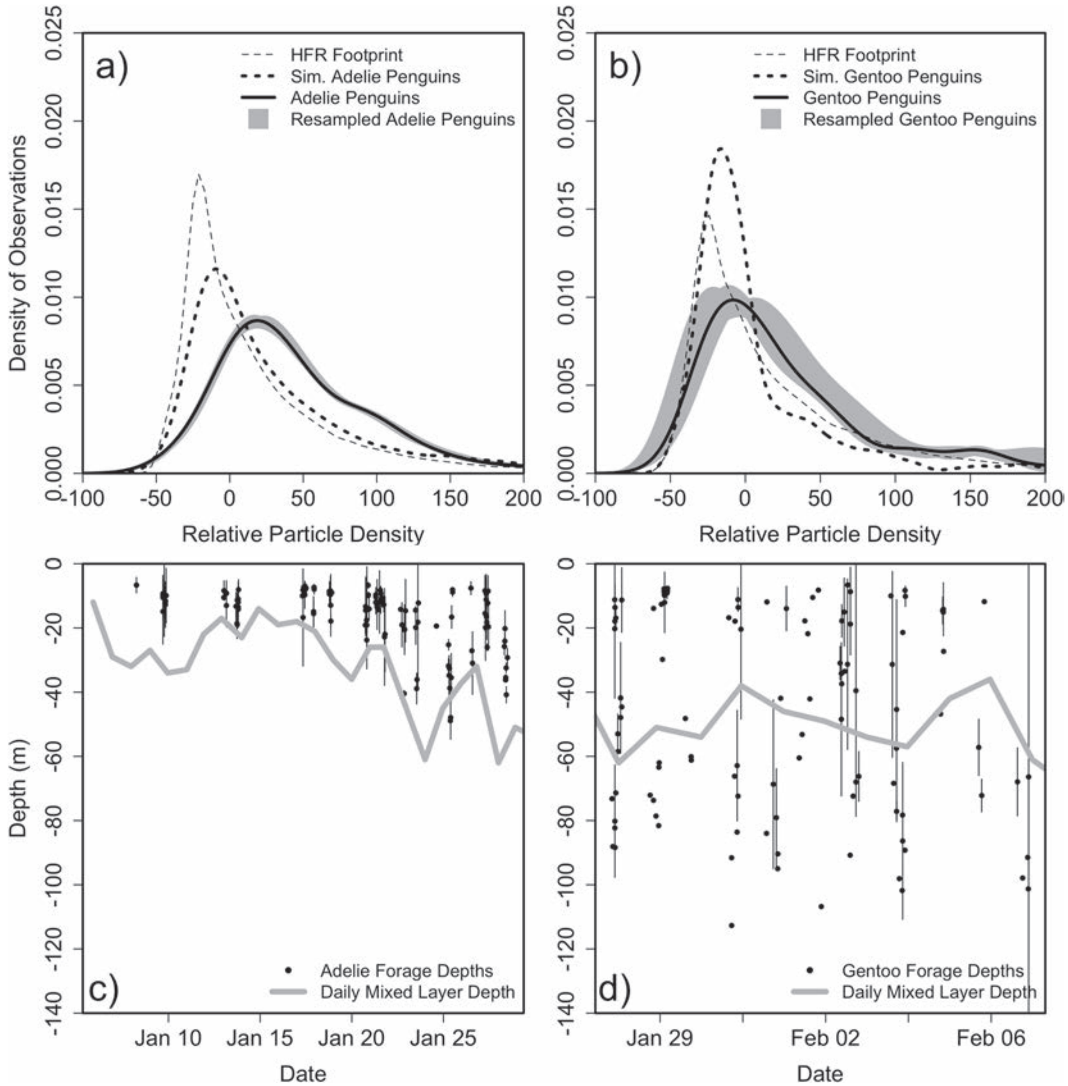

Figure 3. Penguin selectivity relative to convergent ocean features. Distribution of observed field PD values available to the penguins (grey dashed) and distribution of PD values at the tagged (solid black) and simulated (black dashed) penguin dive location for the (**a**) Adélie and (**b**) Gentoo Penguins. The range of solutions with of the resampled penguins by individual and by foraging trip is shown as a gray shade. with the changing tidal regimes combined with their selection for these convergent features provides a mechanistic explanation for the variability in historic foraging locations observed in Adélie penguins[22].

Discussion

The outer and mid WAP continental shelf is characterized by irregular, episodic intrusions of Upper Circumpolar Deep Water (UCDW)[24,25] that drive intense phytoplankton blooms that may be advected into coastal regions[26,27]. These blooms are fed on by krill, which show a high degree of interannual variability in their abundance[28,29], both along the shelf and into coastal regions[30–32]. Palmer Deep canyon supports enhanced phytoplankton production[33] and is considered a biological hotspot that is home to Adélie, gentoo and chinstrap penguins[34]. This region is also a common feeding ground for humpback whales (*Megaptera novaeangliae*)[35], indicating that it is a place where upper trophic levels are persistently linked to primary producers through krill and other zooplankton. What is not known are the specific physical mechanisms that concentrate the various levels of the food web at the scales of the individual predators.

Within the Palmer Deep hotspot, a historical analysis (10 years) of Adélie penguin foraging locations demonstrated a correlation to local tidal regimes, indicating that individual penguins may track tidally-driven features, such as convergent zones, associated with the diurnal and semi-diurnal tides[19,22]. Here we show that as the tidal regime shifts from diurnal to semi-diurnal, the spatial patterns in the occurrence of strong convergent features is matched by similar shifts in penguin foraging locations. While penguin foraging locations and the occurrence

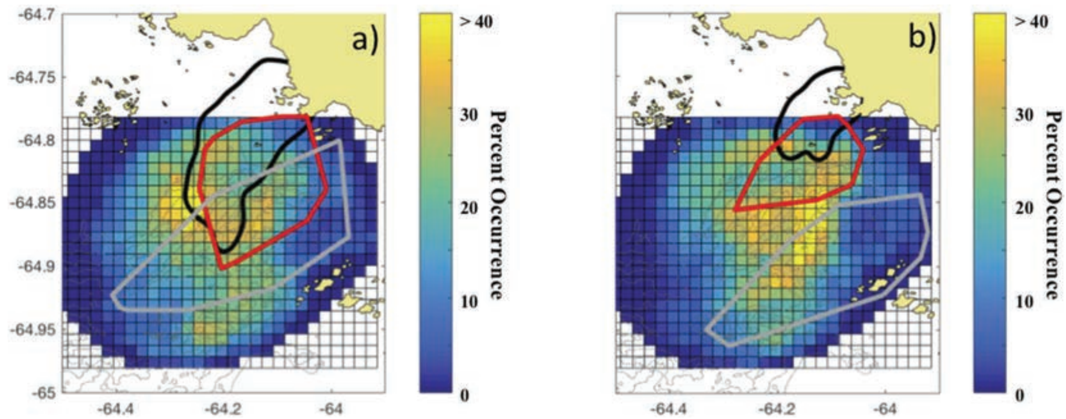

Figure 4. Maps of the percent of occurrence of the convergent features based on RPD (number of particles minus median > 100) observed during (**a**) semi-diurnal and (**b**) diurnal days. The spatial density kernels (black contours) based on 10 years of tagged Adélie data are shown in panel a) for the semi-diurnal days and in panel b) for diurnal days[25]. The convex hulls for the 2015 Adélie (red) and gentoo (grey) ARGOS locations are also shown. In 2015, Adélie penguins also foraged closer to their home colony during diurnal, compared to semi-diurnal tides. The maps were generated by the corresponding author J.K. using Matlab version R2016b (www.mathworks.com).

of convergent features covaried with tidal regime (Fig. 4), we show that both Adélie and gentoo penguins were specifically selecting for stronger surface convergent zones than were available based on simulations, suggesting the importance of these features at the scale of the individual. Despite the different typical dive depths exhibited by these two species, both the shallow-diving Adélie and deeper-diving gentoo penguins selected for surface convergent features (Fig. 3).

Penguins in the Palmer Deep canyon region travel relatively short distances (~8–25 km) during foraging trips compared to penguins breeding in many other locations, where foraging distances may reach up to 100 km[36]. These short foraging distances are also combined with the persistence of foraging locations across both tidal regimes, suggesting that these penguins may not need to use environmental cues to initiate foraging behavior; that is, they are simply returning to the same general location to find prey because the prey field spans the entire area. However, we argue that this is not always the case. Although the prey-scape was not spatially resolved in this study, previous vessel and AUV acoustic surveys in the region report typical krill patch length scales on the order of 40 m[12,37]. These patches are dispersed hundreds of meters apart across the +20 km foraging range of the local Adélie and gentoo colonies[12]. This spacing by itself might suggest that both Adélie and gentoo penguins could return to the same foraging ground and be successful, independent of foraging cues. However, measurements of the residence time of this region indicate that the surface layer is replaced on average every two days, and can be as short as 18 hours[38]. This leads to a very patchy and rapidly evolving prey environment within the penguin foraging range that is simultaneously targeted by other species including whales and seals. Therefore, the rapid replacement of the surface layer may necessitate individual foraging responses triggered by oceanographic conditions at the scale of the individual, along with memory of recent successful foraging trips, or social cues from other foragers[5].

At Palmer Station, Adélie penguins are often relatively shallow divers (<50 m)[39] compared to gentoo penguins that often dive deeper (<100 m)[37,40]. Gentoo penguins are the larger of the two species and consequently have a greater scope for maximum diving depth, even though Adélie penguins are capable of dives to similar depths[41]. During our study, Adélie penguins not only selected for stronger surface convergent features compared to their availability, but their foraging was also limited to the surface mixed layer. In contrast, gentoo penguins foraged both above and below the surface mixed layer, with some dives as deep as 150 m, yet also selected for stronger surface convergent features. We suggest that despite the variable foraging dive depths relative to the mixed layer, both species use surface layer convergent features as foraging cues.

ARGOS locations associated with foraging behavior for both species had consistently higher RPD compared to simulated penguins and background RPD suggesting that convergent features may cue foraging behavior. What is less clear is the impact of higher RPD for transiting Adélie and gentoo penguins. Gentoo penguins showed little selectivity for increased RPD during transiting behavior, with only one exception, suggesting that perhaps gentoo penguins are using past foraging experiences to get to a general foraging region before selecting for higher RPD values at finer spatial scales. Transiting Adélie penguins, however, showed some selectivity for higher RPD compared to background concentrations. As the time window we used to behaviorally classify ARGOS locations widened (Table 1), all but two ARGOS locations were considered to be associated with foraging behavior, suggesting foraging behavior could be interspersed throughout a foraging trip. It has been shown previously that ARGOS locations without diving behavior were strongly coherent with ARGOS locations with diving behavior in this location for Adélie penguins[22].

The link between the occurrence of strong convergent features and the foraging behavior of satellite-tagged penguins raises important questions about the coupling mechanisms operating throughout the entire food web. These convergent features may coincidently concentrate or attract krill in the surface layer, and trigger penguin foraging behavior, irrespective of whether penguins are shallow- or deep-diving. This would be consistent with a penguin that repeatedly dives in the same location once a prey patch is found[5]. Alternatively, there may be different physical mechanisms that concentrate prey above and below the mixed layer. For example, barotropic tides influence the entire water column, while the seasonal surface mixed layer circulation is likely driven by local winds[38] but retains a tidal signal when integrated over the foraging season. Below the mixed layer, circulation is likely driven by the bathymetric steering of density currents along isobaths (i.e. along f/H contours), suggesting the influence of the Palmer Deep canyon. Critically, these depth-dependent features could be co-located with deeper gentoo prey aggregations, thus explaining why deep-diving gentoos appear to be selecting for higher surface convergence, even though they are feeding well below the surface mixed layer. Another speculative possibility that could explain why deep diving penguins selected for higher surface RPD, is that they may select convergent features independently of visual prey detection. Dimethylsulphoniopropionate is released from grazed phytoplankton, which is volatilized in the ocean surface as dimethyl sulphide (DMS)[42], and is not necessarily correlated to surface phytoplankton concentrations[43]. Krill-consuming chinstrap penguins (*P. antarctica*), for example, have been shown to be attracted to DMS[44], and African penguins (*Spheniscus demersus*) have been shown to use DMS as a foraging cue[45]. If surface RPD values are a proxy for higher DMS, this may explain why deep diving gentoo penguins select for higher RPD values.

Given our results, we believe that physical factors like surface convergent features are an important mechanism that influences penguin foraging locations, and are therefore a critical feature influencing the maintenance of the Palmer Deep biological hotspot for penguins. Convergent fronts likely concentrate krill, the primary prey of penguins[46] in this region. This example of tight coupling from the hydrography through the lower trophic levels to foraging penguins shows the important role that these physical features may have on the coastal Antarctic food web. If these features are commonly targeted by predators, they may represent a key physical mechanism that is critical for the persistence of the Palmer Deep biological hotspot over the last 1000 years[34], despite known climate and environmental variability. However, because this study did not simultaneously resolve the distribution of krill and all of their major predators, there is still much work to be done to understand how important prey convergence is relative to other factors affecting prey distributions. Even though both penguin species selected, on average, for higher convergence zones, both also utilized a wide range of particle densities. This suggests to us that there are other important factors, in addition to surface convergence, affecting foraging behavior. One possibility is the top-down impact of other krill predators. For example, Adélie penguins at Cape Crozier in the Ross Sea increased their foraging duration and dove deeper as krill were removed by predation near the colony[47], suggesting a significant top-down control on penguin foraging location. In our study, we also observed a deepening of forage depths by Adélie penguins (Fig. 3c). Because this study did not resolve the distribution of krill, or account for other krill predators like whales, it is difficult for us to tell if prey depletion was an important factor in this study. One important difference between the colonies at Cape Crozier and those at Palmer Deep is that of colony size; the colonies in the Ross Sea that showed the prey depletion effect are two orders of magnitude larger than those near Palmer Deep. Because of this, we speculate that top-down effects like prey depletion play a relatively smaller role in determining foraging location near Palmer Deep. However, the relative importance of bottom up physical concentration factors and top down biological factors on penguin foraging remains an open and important question for understanding how these ecosystems may change in the future.

Materials and Methods

High Frequency Radar (HFR). HFR systems, typically deployed along the coast use Bragg peaks within a transmitted signal (3~30 MHz) scattered off the ocean surface to calculate radial components of the surface velocity at a given location[48]. Individual sites, composed of electronics, cables and a transmit and receive antenna, generate maps of surface component vectors directed toward the antenna with range resolution of 500 m horizontally and 5 degrees in azimuth. To provide sufficient coverage over the penguin foraging grounds associated with Palmer Deep, a three-site HFR network was deployed in November 2014 (Fig. 2). The first site was deployed at and powered by Palmer Station. The other two sites, deployed at the Joubin and Wauwermans Islands, relied on remote power systems that were constructed on site, lightered to shore via zodiac with ship support. Remote Power Modules (RPMs) generated the required power for the HFRs through a combination of small-scale micro wind turbines and a photovoltaic array with a 96-hour battery backup[19]. The RPMs consisted of a single watertight enclosure, used to house power distribution equipment, the HFR, and the communication gear. Built-in redundancies within the RPMs, including wind charging/resistive loads, solar energy, and independent battery banks ensured that, should any one component fail, the unit would be able to adjust autonomously. Each site also collected 15-minute meteorological measurements of air temperature, wind, relative humidity, and solar radiation. Communication between the two remote sites and Palmer Station was with line of sight radio modems (Freewave), which enabled remote site diagnostics and maintenance and provided a real-time data link.

The three-site network collected hourly measurements of ocean surface current component vectors throughout the penguin foraging season (November 2014 through March 2015). Every hour, the radial components from each site were combined into two-dimensional vector maps using the optimal interpolation algorithm of[49]. Throughout the time of active penguin foraging, a roughly 1,500 km2 area of ocean over Palmer Deep was covered greater than 80% of the time with hourly maps of surface ocean circulation. The evolution of these current fields was used to identify convergent features, including fronts and eddies, relative to known penguin foraging.

Surface Convergent Features. Various metrics have been used to map ocean convergent features. Maps of Lagrangian Coherent Structures (LCS), specifically Finite-Time Lyapunov Exponent (FTLE) and Finite-Space Lyapunov Exponent (FSLE) have seen greater application to marine ecological studies[14,16,50,51]. While these metrics often delineate boundaries in a fluid that distinguish regions with differing dynamics[52] they are based on an assumption that the input velocity fields are horizontally non-divergent (i.e. zero vertical velocity). The highly resolved current maps provided by the HFR network deployed over Palmer Deep display complex currents that do not meet this important criterium for both FTLE and FSLE. Consequently, we define a more appropriate metric to map the convergent features within our study site consistent with the dynamics captured by the HFR surface current maps.

To objectively map the time and location of convergent ocean features in the mapped surface current time series, we used a metric derived from simulated particle releases in the HFR surface current fields. Our relative particle density (RPD) metric is calculated based on the movement of simulated particles released in the HFR footprint and tracked over time. Each hour, we released simulated particles over a 200 × 200 m grid over the HFR footprint. The Lagrangian particles were advected in the HFR velocity field with a 4th-order Runge-Kutta integration scheme for a period of 48 hours. In our application, we compute hourly maps of RPD from t_1 = December 31, 2014, to t_N = February 19, 2015 (spanning the date range that penguins were tagged and actively foraging).

The hourly RPD was determined by the number of particles within 1 × 1 km boxes within the overlapping HFR coverage and penguin foraging grounds (Fig. 2b). To minimize the effect of the grid on the particle densities, only particles in the field for at least 6 hours were included in the count. To correct for time varying residence time of particles throughout the study period[38], each count was normalized by subtracting the median count across all 1 km boxes within the field for each time step (Fig. 2b), termed RPD for the purposes of this analysis.

Slocum Glider. Gliders are buoyancy driven vehicles that dive and climb at a nominal 26° angle and travel in a vertical "sawtooth" pattern between predetermined surface events 49. Glider-based sampling provided a continuous presence, through all weather conditions, over the spatial domain identified by the HFR network. Simultaneous measurements of physical and biological variables from the gliders sampled the spatial and temporal variability over Palmer Deep. A glider was programmed to complete a mission as a virtual mooring between January 5, 2015 to February 26, 2015 (Fig. 1), diving between the surface and 100 m. The glider was equipped with a sensor suite to characterize the ecosystem's physical structure (Seabird C, T, D). This glider provided the time series of mixed layer depth throughout the penguin foraging time period used in this analysis[20].

Penguin Tagging and Dive Analysis. From January 5 to 28, 2015, we deployed ARGOS satellite transmitters on 12 Adélie penguins (8 female, 4 male) that nested on Torgersen Island (64°46′S, 64°5′W), and from January 27 to February 7, 2015, we deployed satellite transmitters on 7 gentoo penguins (2 female, 5 male) at Biscoe Point (64°49′S, 63°46′W). All protocols were carried out in accordance with the approved guidelines of the Columbia University Institutional Animal Care and Use Committee (Assurance #AAAH8959). Tagged penguins were paired and had brood-stage nests containing two chicks. Penguins were equipped with SPOT 5 satellite transmitters (Wildlife Computers Redmond, WA, USA) and Lotek LAT1400 time-depth recorder (Lotek Wireless, Inc, St. John's Canada; resolution of 0.05 m, accuracy of 2 m) sampling at 2 Hz. Dive depths less than 5 m were not recorded to save space on the memory cards. Transmitters were attached to the anterior feathers on the lower dorsal region using waterproof tape and small plastic zip ties. Transmitters were removed and rotated to new penguins every 3–5 days dependent on weather conditions. Penguin locations were filtered to remove inaccurate location data due to erroneous terrestrial positions, unreasonable locations based on swimming speed and coastal geometry, following published the data processing methods[37]. We time-matched dive records to location data and the maximum dive depth was determined for each dive. Penguin dives were classified into transit, search and foraging dives, where foraging dives consisted of wiggles, plateaus or bottom time where prey was likely pursued (see[37] for more information). The convex hulls of penguin locations were computed using chull in the grDevices package[53].

Penguin Habitat Selectivity Statistical Tests. We compared the distribution of penguin ARGOS locations to distributions of available RPD values using two-sided Kolmogorov-Smirnov tests (ks.test in the stats package)[53] to test for habitat selectivity. Penguin selectivity is inferred from the distributional differences between RPD values at penguin ARGOS locations. Several considerations are needed for comparing penguin ARGOS locations to RPD simulations. For this analysis, we used ARGOS classes 1–3 (estimated accuracy is 350–1000 m, 150–350 m and <150 m, respectively), which have errors similar to, or smaller than the RPD grid cells. Penguins periodically haul-out on sea ice or islands during their foraging trips, so we restricted our analysis to ARGOS locations where the wet sensors were triggered and were within the field of computed RPD values. We used two estimates of available habitat for Adélie and gentoo penguins. The first estimate of available RPD habitat is the entire RPD HFR field over Palmer Deep during the times the penguins were foraging, because both Adélie and gentoo penguins are capable of traversing the entire RPD field in a single foraging trip. The second estimate of available RPD habitat was based on simulated Brownian motion of central place foragers (simm.bb in the adehabitatLT R package)[54], nesting at the Adélie and the gentoo penguin colonies (Fig. 1). We simulated two penguins per day from each colony, which was similar to the tagging effort during the field season. A 10-year analysis of foraging trip duration showed that these penguins take forage trips up to 48 hours, but most are 6–24 hr[22]. Simulated foraging trip duration was limited to 24 hr in one hour time steps, and the simulated penguin speeds were normally distributed around a mean of 4 km hr^{-1}, and a maximum of 8 km hr^{-1} to mimic Adélie and gentoo penguin swimming speeds[55]. Brownian motion is an uncorrelated movement that represents random foragers not selecting for environmental features, remembering previous feeding locations, or cuing off of other environmental proxies. We used these simulated penguin locations as a null metric of available RPD values by a non-selecting central place forager originating from the Adélie and gentoo penguin nesting sites.

The possibility of individual effects in tagging studies is a persistent problem reflected in their foraging trips or individual behavior. To deal with the possibility of foraging trip level effects driving the results of the of the

Kolmogorov-Smirnov tests, we systematically withheld individual foraging trips and individual penguins from our analysis to test the sensitivity of our results to individuals foraging trips being withheld from the analysis.

Data Availability

The HFR datasets are archived and accessible through the United States National HF radar archive housed at the National Oceanic and Atmospheric Administration (NOAA) National Data Buoy Center (NDBC): http://hfradar.ndbc.noaa.gov/. Additionally, the post-processed raw and de-tided total vector maps can be accessed via the Rutgers HFR Environmental Research Division Data Access Program (ERRDAPP) Service: http://hfr.marine.rutgers.edu/. The other datasets including the glider and penguin tagged data are available from the corresponding author on reasonable request, as some of these data are still in use for student dissertations.

ABSTRACT: A large-eddy simulation (LES) initialized and forced using observations is used to conduct a process study of ocean surface boundary layer (OSBL) turbulence in a 2-km box of ocean nominally under Hurricane Irene (2011) in 35 m of water on the New Jersey shelf. The LES captures the observed deepening, cooling, and persistent stratification of the OSBL as the storm approaches and passes. As the storm approaches, surface-intensified Ekman-layer rolls, with horizontal wavelengths of about 200 m and horizontal-to-vertical aspect and velocity magnitude ratios of about 20, dominate the kinetic energy and increase the turbulent Prandtl number from about 1 to 1.5 due partially to their restratifying vertical buoyancy flux. However, as the storm passes, these rolls are washed away in a few hours due to the rapid rotation of the wind. In the bulk OSBL, the gradient Richardson number of the mean profiles remains just above (just below) 1/4 as the storm approaches (passes). At the base of the OSBL, large-aspect-ratio Kelvin–Helmholtz billows, with Prandtl number below 1, intermittently dominate the kinetic energy. Overall, large-aspect-ratio covariance modifies the net vertical fluxes of buoyancy and momentum by about 10%, but these fluxes and the analogous diffusivity and viscosity still approximately collapse to time-independent dimensionless profiles, despite rapid changes in the forcing and the large structures. That is, the evolutions of the mean temperature and momentum profiles, which are driven by the net vertical flux convergences, mainly reflect the evolution of the wind and the initial ocean temperature profile.

KEYWORDS: Coastal flows; Turbulence; Boundary layer; Oceanic mixed layer; Large eddy simulations

1. Introduction

Observations (e.g., Savelyev et al. 2018b) and simulations (e.g., Hamlington et al. 2014) show that ocean surface boundary layer (OSBL) turbulence sometimes includes a continuum of horizontal length scales characterized by a negative power spectral slope without a peak in variance near the length scale of the OSBL depth. In particular, prominent large-aspect-ratio[1] structures with horizontal scales larger than the OSBL depth coexist with more isotropic structures with scales similar to and smaller than the OSBL depth. Generically, these large-aspect-ratio structures can be generated in the OSBL by extracting energy from the mean profile (e.g., via an instability) and via nonlinear transfers of variance from other scales of variability, or they can propagate into the OSBL from below.

Prior work has loosely classified observed large-aspect-ratio structures into a few categories: 1) wind/wave/buoyancy-driven Langmuir circulations that are characterized by horizontally anisotropic rolls and streaks approximately aligned with the wind vector and perpendicular to surface wave crests (Langmuir 1938; Leibovich 1983; Smith 1992; Thorpe 2004; Kukulka et al. 2009), mostly with cross-roll length scales less than 4 times the OSBL depth but with some notable larger exceptions (Marmorino et al. 2005; Gargett et al. 2004; Sundermeyer et al. 2014; Gargett and Savidge 2020); 2) internal waves (Elachi and Apel 1976; Wijesekera and Dillon 1991; Shaun-Johnston and Rudnick 2009); 3) stratified shear instabilities such as the Kelvin–Helmholtz (KH) mode (Seim and Gregg 1994; Chang et al. 2016); and 4) submesoscale vortex and frontal dynamics (Munk et al. 2000; Savelyev et al. 2018a; D'Asaro et al. 2018; Marmorino and Chen 2019).

Other boundary layers also contain prominent large-aspect-ratio structures, which exhibit some similarities to their OSBL cousins. For example, numerous observations reveal roll vortices and associated streaks characteristic of shear instabilities in the atmospheric boundary layer (ABL) (Lemone 1973, 1976; Etling and Brown 1993; Young et al. 2002). In addition, laboratory measurements and direct numerical simulations reveal long streaks extending up to 10 times the BL height approximately aligned with the shear in high-Reynolds number wall-bounded flows with and without rotation and/or stratification (Tatro and Mollo-Christensen 1967; Marusic et al. 2010; Smits et al. 2011; Hutchins et al. 2012; Sous et al. 2013; Deusebio et al. 2014).

However, the role of large-aspect-ratio structures in OSBL turbulence and their implications for larger-scale ocean dynamics remains to be fully understood. Here, we build understanding

[1] Unless otherwise specified, we define large-aspect ratio to mean that the characteristic horizontal length scale is larger than the characteristic vertical length scale (no specific physical process is implied). Confusingly, many features of interest are also elongated and anisotropic in the horizontal plane. Hence, unless otherwise specified, the characteristic horizontal length scale of a structure refers to the shortest possible characteristic horizontal scale that can be derived.

by reporting on a large-eddy simulation (LES) that models the rapid turbulent entrainment and sea surface temperature (SST) cooling observed on the New Jersey shelf during the passage of Hurricane Irene in 2011 (Glenn et al. 2016; Seroka et al. 2016) and contains vigorous large-aspect-ratio structures, which participate with smaller-scale turbulence in driving the entrainment and surface cooling.

Many previous studies have used LES to investigate transient and unsteady OSBL dynamics. LES provides a local perspective on OSBL turbulence that is generated by the surface forcing, dynamical instabilities and nonlinear transfers across the resolved scales, without the convoluting effects of lateral advection or propagation from remote locations or local transfers of energy from scales that are unresolved on the grid. However, only a few studies have used LES to study OSBL turbulence including horizontal wavelengths greater than 10 times the OSBL depth. Most of these studies have used large-aspect-ratio domains to study the interactions between submesoscale vortex and frontal dynamics and smaller-scale turbulence (e.g., Skyllingstad and Samelson 2012; Hamlington et al. 2014; Sundermeyer et al. 2014; Taylor 2016; Smith et al. 2016; Whitt and Taylor 2017; Skyllingstad et al. 2017; Callies and Ferrari 2018; Sullivan and McWilliams 2018, 2019). Comparatively little work has been devoted to investigating the role of such large-aspect-ratio structures in OSBLs forced simply by wind, before considering buoyancy and/or surface gravity wave effects. However, previous LES studies have noted interactions between surface boundary layer turbulence and short internal waves (Polton et al. 2008; Czeschel and Eden 2019). Sullivan et al. (2012) noted that it was necessary to use a 1500-m-wide domain (12.5 times the maximum OSBL depth) in order to resolve some spontaneously generated internal waves under hurricane forcing. Others (Sundermeyer et al. 2014; Skyllingstad et al. 2017) found large-aspect-ratio Ekman-layer rolls with horizontal scales 5–10 times the OSBL depth in both observations and LES, regardless of whether surface wave effects were included in the LES. Although ABL LES is limited by the similar computational challenges, previous studies have repeatedly simulated large structures approximately aligned with the geostrophic flow in the Ekman ABL (e.g., Moeng and Sullivan 1994; Khanna and Brasseur 1998; Fang and Porté-Agel 2015). However, it is still not well known how large-aspect-ratio structures contribute to the net fluxes and mean evolution of the OSBL under time-variable wind. But, it seems likely that large structures are important in some circumstances.

The purpose of this paper is to describe the simulated large-aspect-ratio structures and their role in OSBL turbulence under a hurricane in a large-aspect-ratio oceanic domain in which the OSBL depth ranges from 1/200 to 1/55 the horizontal domain length. The simulation is realistic in that it is initialized with observed temperature and salinity vertical profiles just before the storm and forced by a time-dependent 3-hourly surface wind stress, heat flux, and penetrative radiative heating derived from atmospheric reanalysis. On the other hand, the simulation is idealized in that all other processes are omitted, including the effects of ocean surface gravity waves and the larger-scale ocean circulation. The expectation is not that these other processes or their interactions with wind- and buoyancy-forced OSBL turbulence are not important. Rather, the expectation is that it is necessary to study these different processes both in isolation and in combination to obtain a full understanding of OSBL dynamics. This paper is a step toward that broader goal. After a description of the model, the results include two parts: the first is a descriptive analysis of the life cycle and characteristics of the simulated large-aspect-ratio structures. The second demonstrates how the evolution of the large-scale structures relates to and impacts the evolution of the mean profiles of momentum and buoyancy via the turbulent vertical fluxes that drive the evolution of the mean profiles.

2. Model configuration

a. Model description and initial conditions

The numerical model is similar to that used in Whitt and Taylor (2017) [and described in more detail by Taylor (2008)]. Briefly, the evolution of the resolved flow is obtained by time-stepping the rotating Boussinesq equations on a traditional f plane with Coriolis frequency $f = 9.3 \times 10^{-5}\,\mathrm{s}^{-1}$ using a mixed method, in which the Crank–Nicholson scheme advances the vertical viscous/diffusive terms, a third-order Runge–Kutta scheme advances all other terms, and the projection method is used to enforce incompressibility and update the pressure. Spatial derivatives are discretized using a pseudospectral approach in the horizontal and second-order central differences in the vertical. The fluid density ρ and buoyancy $b = -g\rho/\rho_0$ depend on both temperature and salinity via a linear equation of state $\rho = \rho_0[1 + \alpha(T - T_0) + \beta(S - S_0)]$, where $\rho_0 = 1022.8\,\mathrm{kg\,m^{-3}}$, $T_0 = 17.0°\mathrm{C}$, $S_0 = 31.5$ psu, $\alpha = -0.000\,281\,°\mathrm{C}^{-1}$, and $\beta = 0.000\,766\,\mathrm{psu}^{-1}$, and $g = 9.81\,\mathrm{m\,s^{-2}}$. Subgrid-scale (SGS) momentum fluxes are obtained using a modified Smagorinsky approach (Kaltenbach et al. 1994). The subgrid-scale fluxes of salt and temperature are represented by a down-gradient diffusion, where the diffusivities of heat and salt are equal but vary spatially and temporally with the subgrid-scale viscosity and Prandtl number, that is $\kappa_{\mathrm{SGS}} = \nu_{\mathrm{SGS}}\mathrm{Pr}_{\mathrm{SGS}}^{-1}$. As in Whitt and Taylor (2017), $\mathrm{Pr}_{\mathrm{SGS}}^{-1} = 1/(1 + \mathrm{Ri}_{\mathrm{GS}}/0.94)^{1.5}$ (Anderson 2009) and the gridscale gradient Richardson number $\mathrm{Ri}_{\mathrm{GS}} = \delta z\delta b/(\delta u^2 + \delta v^2)$, where δ denotes the difference between two vertically adjacent grid cells and u and v denote the horizontal components of the velocity vector.

The numerical solution is obtained in a horizontally periodic domain that is 1958 m × 1958 m × 35 m and spanned by a mesh with 2304 × 2304 × 85 grid points that are evenly spaced 0.85 m × 0.85 m × 0.42 m apart. A study of the sensitivity of the LES solutions to the domain size is not pursued here. However, we note that horizontal domains of 245, 122, and 41 m with the same horizontal and vertical grid spacings were also attempted. In the larger two of three domains, the simulations revealed dominant domain-scale structures and intermittency in the statistics, both of which were deemed undesirable. These issues were somewhat mitigated in the smallest domain, but the statistics in that case are not very robust with so few points.

The time step is varied dynamically so that the Courant number remains sufficiently small and the time stepping

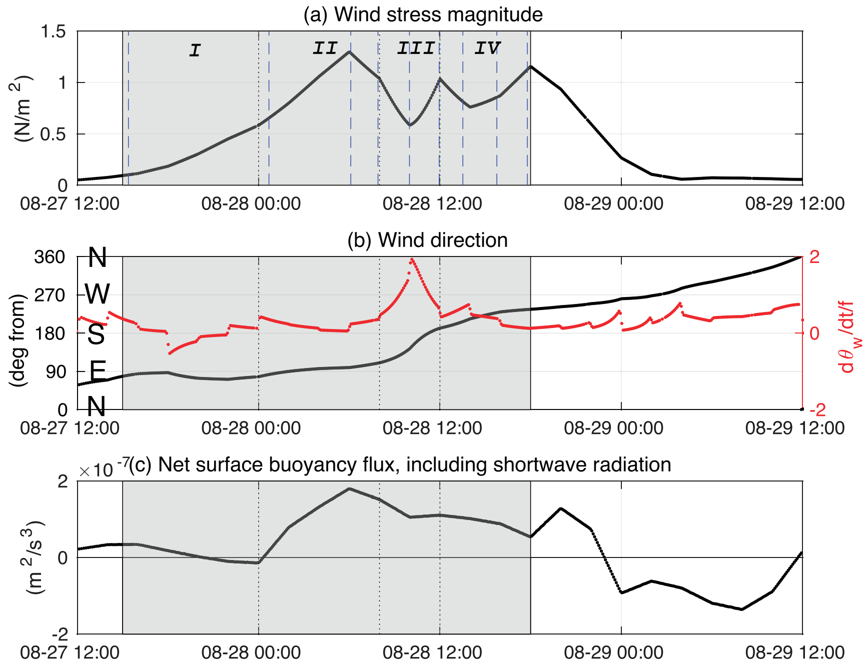

FIG. 1. Ocean surface fluxes during the storm. The surface stress has (a) magnitude $|\boldsymbol{\tau}|$ and (b) direction θ_w (left axis) and rate of rotation normalized by the Coriolis frequency $d\theta_w/dt/f$ (right axis). (c) The net surface buoyancy flux, which is (atypically) injecting buoyancy into the ocean during most of the storm, includes the penetrating shortwave, net longwave, latent, and sensible heat fluxes. Surface freshwater/salinity fluxes are set to zero for simplicity. This paper focuses on the gray-shaded time period and separates that period into four phases, as described in the text.

scheme remains stable. Due to the strong currents during the storm, the time step drops below 0.15 s late in the storm. Hence, the simulation requires about 370 000 time steps to reach the end of phase IV in Fig. 1a. The depth of the domain is chosen to be approximately the same as the ocean bottom depth roughly 100 km east of Cape May, New Jersey (about half way from the coast to the shelf break), where glider observations of temperature and salinity profiles were available before and during the storm; the glider maintained station-keeping operations near the 40-m isobath as shown in Fig. 2 with surfacing for upload of data every 3 h (Glenn et al. 2016).

The velocity field is initialized with a small-amplitude random kick in each grid cell with root-mean-square of order 10^{-4} m s^{-1}, and the temperature and salinity are initialized with horizontally uniform profiles that are defined by analytic functions designed to approximately match observed temperature and salinity profiles obtained by a glider on the New Jersey shelf just before the storm (Fig. 3) [for details about the observations, see Glenn et al. (2016)]. The simulation begins at 0000 UTC 27 August 2011 and runs through 1800 UTC 29 August, but the atmospheric forcing is modest until 1500 UTC 27 August, when our analysis begins (Fig. 1).

b. Atmospheric forcing and boundary conditions

The surface and bottom boundary conditions for vertical velocity are $w = 0$; temperature, salinity, and horizontal velocity are horizontally uniform but time-dependent vertical gradients. At the top, the vertical gradients of horizontal velocity, e.g., $\nu_{SGS}\partial\mathbf{u}/\partial z = \boldsymbol{\tau}/\rho_0$ where $\nu_{SGS} = 10^{-6}$ m^2 s^{-1}, and temperature are defined by 3-hourly surface wind stress and heat fluxes (excluding penetrating shortwave) derived from a regional ocean model published by Glenn et al. (2016) (Fig. 1). That regional ocean model in Glenn et al. (2016) is initialized from a state obtained via data assimilation and forced by the 3-hourly/12-km resolution reanalysis from the North American Mesoscale forecast model, and the surface fluxes are calculated using the COARE algorithm (Fairall et al. 2003). As in the regional ocean model of Glenn et al. (2016), shortwave radiation penetrates and acts as an interior heat source in the LES that follows a modified Jerlov type II two-component exponential profile (Paulson and Simpson 1977) with the first e-folding depth scale $\zeta_1 = 5$ m instead of 1.5 m to avoid a collapse of turbulence near the surface under stabilizing buoyancy forcing and weak wind before the storm. This approach is ad hoc and may need to be reconsidered in future work, but it is plausibly justified based on observations that the top few meters are sometimes more turbulent than expected from the wind stress and buoyancy flux alone due to surface wave effects (e.g., Anis and Moum 1995).

To aid in the latter description, we separate the forcing into four phases of interest as shown in Fig. 1a. In phase I, there is a period of rising but modest ($|\boldsymbol{\tau}| < 0.5$ N m^{-2}) and consistently easterly wind as the storm approaches from the south along the U.S. east coast. Then, in phase II there is a period of stronger

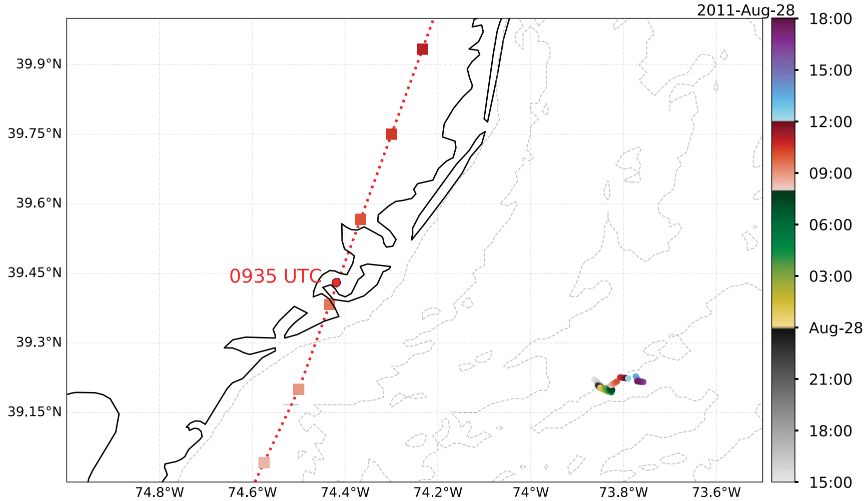

FIG. 2. The track of a profiling buoyancy glider (small dots) and bathymetry contours (dotted lines every 10 m). Color indicates the time (UTC), which is separated into four phases: I (black), II (green), III (red), and IV (blue) (see Fig. 1). The approximate location of the hurricane's eye is indicated by squares, which are spaced every 30 min and are colored to indicate the time, similar to the glider track. The red dot on the hurricane track indicates the time and location of landfall (Glenn et al. 2016).

winds from the east ($|\boldsymbol{\tau}| > 0.5\,\mathrm{N\,m^{-2}}$), which is punctuated by the maximum wind stress ($1.2\,\mathrm{N\,m^{-2}}$) at 0600 UTC 28 August. Phase III includes the eye passage, when winds are strong but weaker than the maximum ($1 > |\boldsymbol{\tau}| > 0.5\,\mathrm{N\,m^{-2}}$) and the stress vector rotates rapidly. Since the LES domain is situated to the right of the eye track, the wind stress vector rotates clockwise from a westward stress (easterly winds) to a northeastward stress (southwesterly winds) as the eye passes (Fig. 1b). Finally, phase IV represents the period of strong and persistently southwesterly wind after the eye passes. The subsequent periods of decaying winds and low poststorm winds are not considered in this paper.

Atypically, the net heat flux is into the ocean during most of the storm and during almost all of 28 August (Fig. 1c). During phases II and III, as the wind ramps up and eventually the eye passes at about 0900 UTC 28 August, the turbulent heat and buoyancy fluxes and the corresponding vertical temperature gradient at the surface boundary of the LES are positive (injecting heat into the ocean) during nighttime (Figs. 1b,c). During phase IV and the remainder of 28 August after the eye passage, there are weak turbulent heat losses from the ocean and a negative surface temperature gradient at the top boundary of the LES, but solar radiation makes the net heat flux positive until nearly nightfall at roughly 0000 UTC 29 August. This unusual situation, in which the turbulent surface latent and sensible heat fluxes are into the ocean, is thought to have been caused by the rapid entrainment-driven ahead-of-eye cooling of the SST, which contributed to the observed rapid decay of the hurricane during this period (Glenn et al. 2016; Seroka et al. 2016).

Before proceeding, consider the relative importance of the surface buoyancy flux $F_b(0)$ (Fig. 1c) and momentum flux $\mathbf{F}_m(0) = \boldsymbol{\tau}/\rho_0$ for the OSBL turbulence using Monin–Obukhov similarity theory (e.g., Monin and Obukhov 1954; Businger et al. 1971; Lombardo and Gregg 1989). First, the Monin–Obukhov length $L_{\mathrm{MO}} = |\mathbf{F}_m(0)|^{3/2}/[k|F_b(0)|] > 300\,\mathrm{m}$, where $k = 0.4$ is the von Kármán constant. And, the boundary layer is only 10–30 m deep. So, the conditions are generally near neutral, that is $|z/L_{\mathrm{MO}}| < 0.1$ and the wind-driven turbulence is expected to be only modestly impacted by the stable surface buoyancy flux at all depths and throughout the duration of the analysis (i.e., the shaded gray area in Fig. 1).

During the analysis period reported here (the gray shaded area in Fig. 1), the bottom layer remains nearly motionless and stratified on average, and the magnitude of the bottom stress never exceeds $10^{-4}\,\mathrm{N\,m^{-2}}$, so the details of the bottom gradient conditions and the associated wall model are thought to be unimportant and omitted for brevity although the bottom may still be significant, e.g., due to the trapping of internal wave energy that might otherwise radiate downward in the open ocean.

3. Visualization and description

We begin by reporting the results of flow visualizations and describe the dominant large turbulent structures in the OSBL, which we separate from more quiescent water below by the depth of maximum stratification $z = -D_{N^2}$, where the stratification is defined by $\langle N^2\rangle_{x,y} = \langle \partial b/\partial z\rangle_{x,y}$ (here, $\langle\rangle_{x,y}$ denotes an average over the horizontal dimensions x and y). This section is separated into two parts to facilitate a description of the two types of large structure that are, conveniently, dominant at two distinct depth levels: the first is a discussion of the near-surface layer, and the latter is focused on the base of the OSBL (i.e., just above D_{N^2}).

a. Near surface

Plan views of the simulated currents at 5-m depth early on 28 August (the beginning of phase II) reveal striking anisotropic

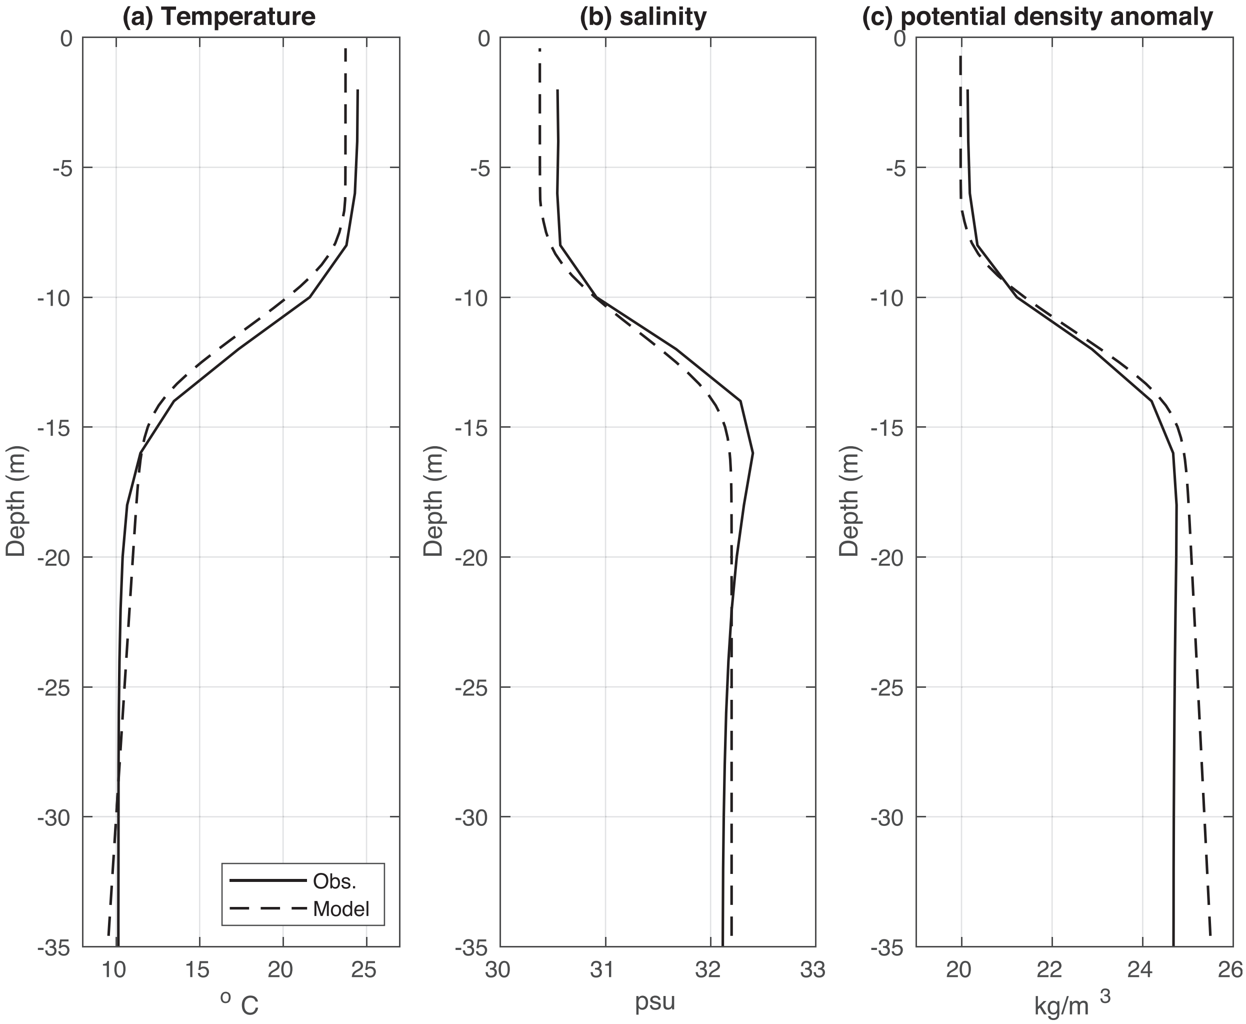

FIG. 3. A comparison between the modeled and observed (a) temperature, (b) salinity, and (c) potential density profiles just before the storm at 1200 UTC 27 Aug 2011, when the glider was at 39.24°N, 73.88°W.

streaks that are elongated in the wind direction (Fig. 4). We begin with a chronological description of the life cycle of these structures. Then we describe the spatial structure in more detail using vertical sections of several key variables in a streak–roll coordinate system.

It may be noted that the features are reminiscent of Ekman layer rolls [for stratified linear stability analysis, see Kaylor and Faller (1972), Brown (1972), and Asai and Nakasuji (1973); for atmospheric observations, see Lemone (1973, 1976); for recent oceanic perspective, see Sundermeyer et al. (2014), Duncombe (2017), and Skyllingstad et al. (2017)], but comparisons between the associated theory, prior observations, and the structures reported here are deferred to the discussion section.

1) CHRONOLOGY

To begin with, it is notable that it takes about 15–24 h for the streaks shown in Fig. 4 to first emerge as dominant features of the turbulence during phase I (which begins 15 h into the simulation at 1500 UTC 27 August), either because it takes this long for the wind to reach sufficient strength and/or because the motions take this long to achieve finite amplitude via another dynamic mechanism such as a linear instability. In particular, the power spectrum of kinetic energy as a function of time at 5-m depth and at large-scale wavelengths $\lambda > 3D_{N^2}$ exhibits approximately exponential growth in time $e^{t/\tau}$ with $\tau \sim 10^4$ s. At the same time, the wind stress magnitude and the associated magnitude of the mean wind-driven currents in the OSBL also increase approximately exponentially at about the same rate as the storm approaches. However, the largest of the large scales ($\sim$1 km) are energized somewhat more slowly than the smaller of the large scales ($\sim$0.1 km) (not shown; but the netCDF files with the spectra are published in Watkins and Whitt 2020). As a result, the fraction of the horizontal kinetic energy associated with wavelengths longer than 3 times $D_{N^2} \approx 10$ m is less than 25% of the total variance before 2000 UTC 27 August (Figs. 5a–c). In addition, the maxima in the radially integrated horizontal wavenumber spectra of both horizontal and vertical kinetic energy are both at about 0.1 cycles per meter

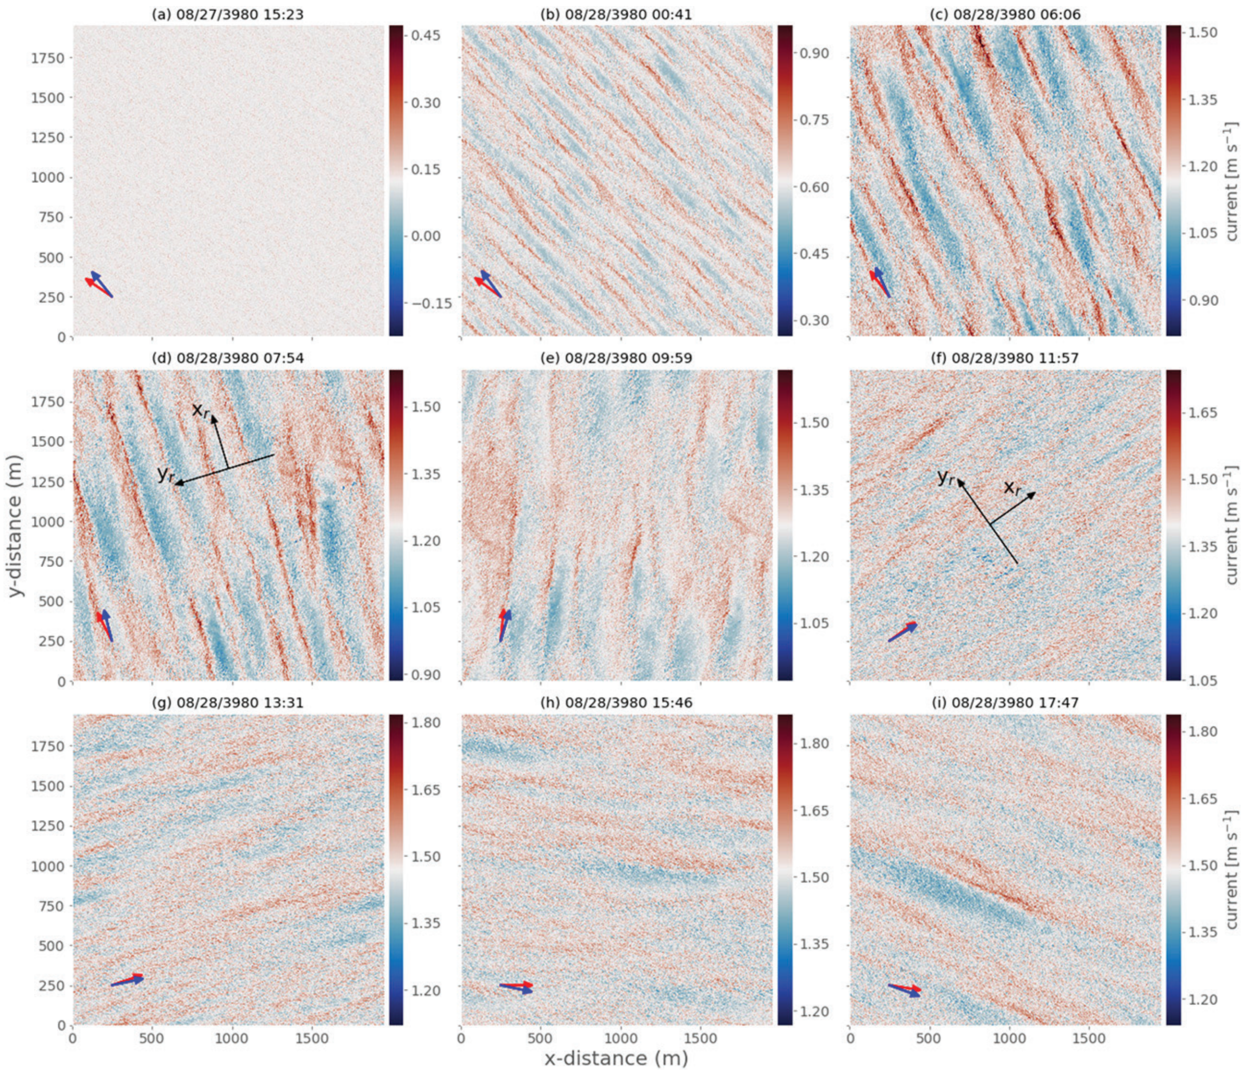

FIG. 4. Snapshots showing the speed of the horizontal current 5 m below the surface at nine times during phases (a) I, (b)–(d) II, (e),(f) III, and (g)–(i) IV of the storm; the time points are indicated by blue dashed lines in Fig. 1a. The diverging color bar is centered on the horizontal average to highlight the current anomalies. The domain is rotated counterclockwise 45° from the geographic coordinates referenced in Fig. 1b. Hence, winds initially from the east flow from the bottom right to the top left over the domain. As the eye of the storm passes during phase III [(d)–(f)], the source direction of the wind quickly rotates clockwise around the bottom of the domain to the left side, i.e., the southwest. The directions of the surface stress $\boldsymbol{\tau}$ and horizontally averaged shear vector at 5 m $\langle \partial \mathbf{u}_h/\partial z \rangle_{x,y}$ are indicated by the red and blue arrows, respectively, in the bottom-left corners. The roll coordinate charts used in Figs. 7 and 8 are overlaid in black.

at 5-m depth before 1500 UTC 27 August (see Watkins and Whitt 2020). Hence, the dominant large turbulent eddies are nearly isotropic with a characteristic scale similar to the OSBL depth during most of 27 August.

As the wind strengthens during the first half of 28 August (phase II), variance in both the horizontal currents and buoyancy increases at horizontal wavelengths $\lambda > 3D_{N^2}$ associated with large aspect ratios. In particular, horizontal kinetic energy at wavelengths $\lambda > 3D_{N^2}$ increases to more than half of the total horizontal kinetic energy at 5-m depth (Figs. 5a–c). And, the anomalous current speed in the streaks reaches a maximum characteristic magnitude of about 10 cm s^{-1}, which is roughly 10% of the mean speed, which grows from about 0.5 to 1.3 m s^{-1} during phase II. At the same time, the buoyancy variance at wavelengths $\lambda > 3D_{N^2}$ comes to represent more than 75% of the total variance shallower than 5-m depth (Figs. 5g–i). Hence, qualitatively similar streaks are visible in the plan views of temperature at 5 m, like the currents (cf. Figs. 4d and 6a), and the characteristic temperature anomalies in the streaks are a few tenths of a degree Celsius. The vertical kinetic energy also increases at wavelengths $\lambda > 3D_{N^2}$ during phase II (Figs. 5d–f). However, this large-scale vertical kinetic energy remains about two to three orders of magnitude weaker than the corresponding large-scale horizontal kinetic energy, as expected based on the aspect ratio of the flow structures. In addition, this large-scale vertical kinetic energy remains a small

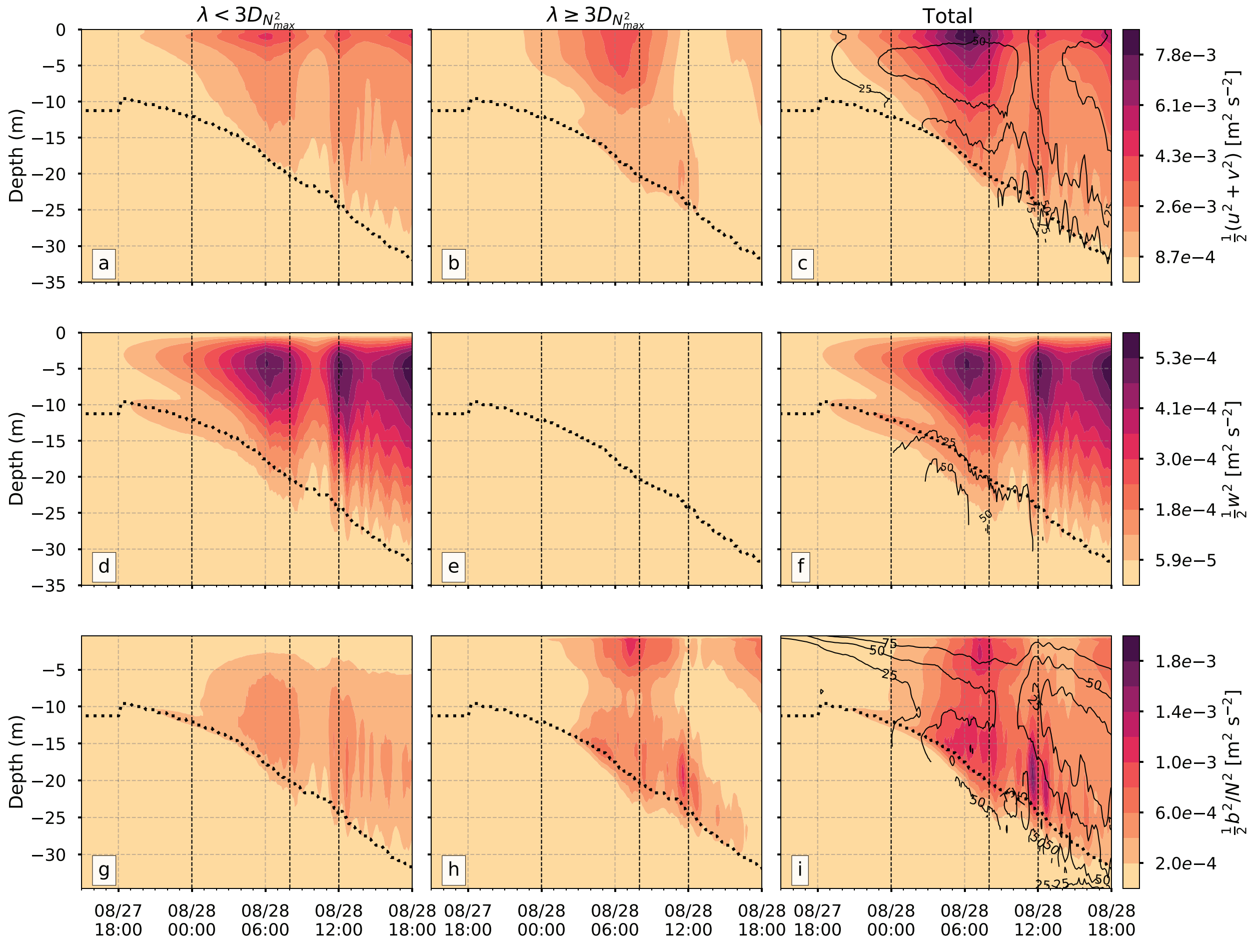

FIG. 5. (a)–(c) Horizontal and(d)–(f) vertical kinetic energy of the perturbations from the horizontally averaged flow, and (g)–(i) the buoyancy variance normalized by twice the mean vertical buoyancy gradient $\langle N^2 \rangle_{x,y}$. All three are decomposed using Fourier methods into wavelengths λ greater (center column) and smaller (left column) than 3 times D_{N^2}, the depth of maximum $\langle N^2 \rangle_{x,y}$, which is marked by a black dotted line. The black contours (every 25%) in the right column indicate the percentage of the variance accounted for by large scales (shown in the center column).

fraction of the total vertical kinetic energy, which remains dominated by wavelengths $\lambda < 3D_{N^2}$ typical of more isotropic OSBL turbulence.

Although the large-aspect-ratio streaks are prominent throughout phase II, when the wind is strong and persistently easterly, the streaks are not static. First, the streaks propagate at speeds comparable to the mean flow $\sim$1 m s^{-1}, such that their characteristic time scale measured at a fixed position is of order 100 s. For example, at the beginning of phase III, the streaks propagate to the northwest in about the same direction as mean surface current, which points at an angle about 45° to the right of the wind (the mean flow will be discussed in later sections). However, in a reference frame following the mean flow in the upper 10 m, the streaks are nearly stationary and evolve with a much longer characteristic time scale more appropriately measured in hours than seconds, consistent with the time scale over which they initially emerge (see videos in the online supplemental material, https://doi.org/10.1175/JPO-D-20-0134.s1). Second, the dominant cross-streak wavelength λ_r increases with time during phase II, from approximately 100 to 300 m (Fig. 4). Perhaps not coincidentally, the depth D_{N^2} deepens from about 12 to 20 m at the same time (Fig. 5), such that the ratio λ_r/D_{N^2} remains in a narrower range of about 8–15. However, the orientation of the along-streak axis remains fairly consistent during phase II: it is rotated slightly clockwise $\sim$10° from the wind vector (Fig. 4), which rotates slowly clockwise during phase II. As the wind rotates more quickly during phase III, the streaks also rotate more quickly clockwise with the wind. However, the amplitude of the current and temperature anomalies associated with the large-aspect-ratio streaks decays in both absolute terms and as a percentage of the total variance. The most obvious factor associated with the washing out of the streaks/rolls is the rate of rotation of the surface wind stress, which exceeds the local Coriolis frequency during eye passage in phase III. Thereafter, the streaks are not dominant features of the flow (Fig. 4), although the large-scale variance does increase toward the end of phase IV as the wind rotation slows and the direction stabilizes becoming consistently

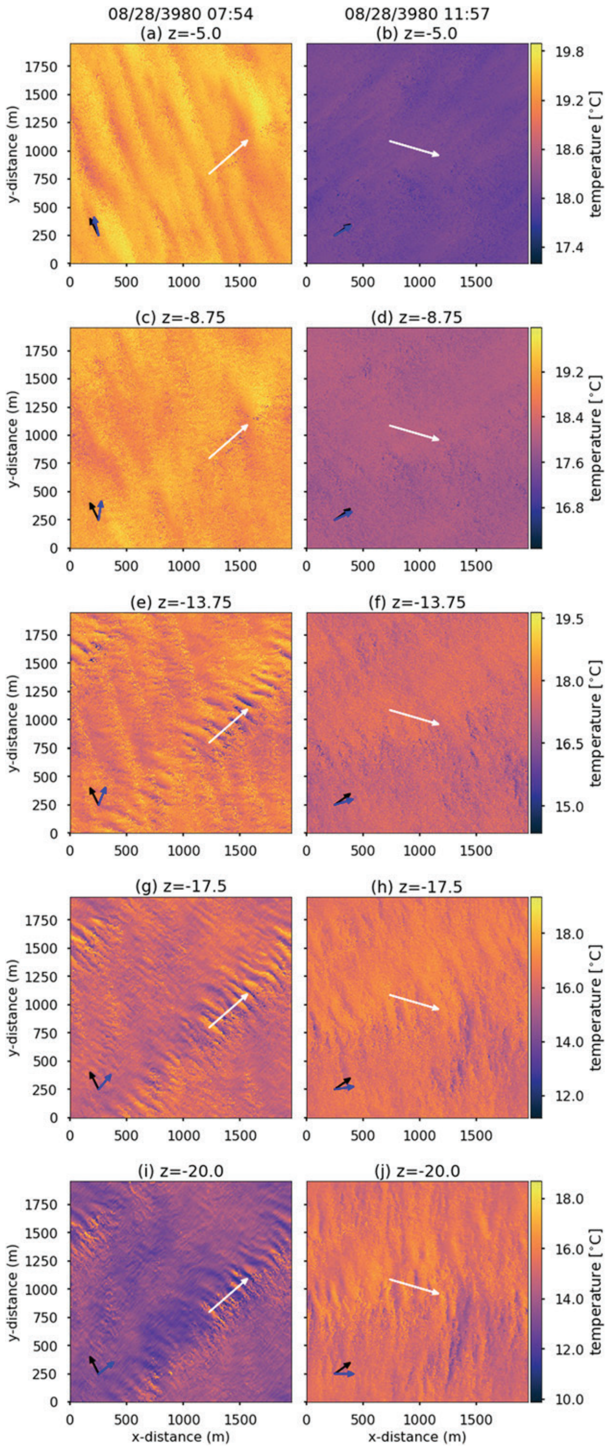

FIG. 6. Snapshots of temperature at both the (left) beginning and (right) end of phase III and at several depths (from top to bottom). The arrows in the bottom-left corner indicate the direction of the surface stress $\boldsymbol{\tau}$ (black) and the horizontally averaged shear vector $\langle \partial \mathbf{u}_h / \partial z \rangle_{x,y}$ at that depth. The white lines indicate the location of the vertical sections in Fig. 9.

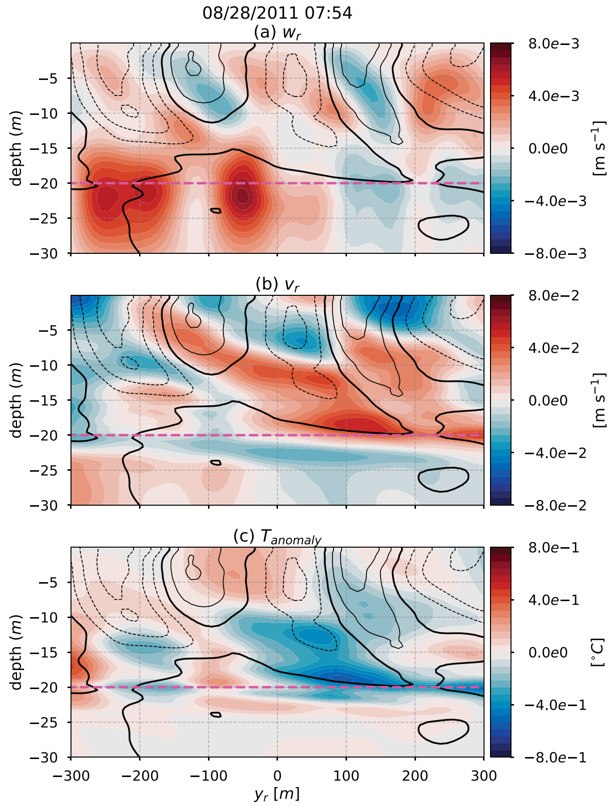

FIG. 7. (a) Vertical sections of vertical velocity, (b) cross-roll horizontal velocity, and (c) temperature, all of which are anomalies relative to the horizontal domain average. Overlaid is the along-roll streak velocity u_r (black contours every 4 cm s^{-1} have positive values marked by thin solid lines, negative values marked by thin dashed lines, and zero marked by the thick solid line) and D_{N^2} (magenta). The sections are along the cross-roll coordinate y_r shown in Fig. 4d, after smoothing with a 25-m Gaussian filter.

southwesterly to westerly (Figs. 4g–i and 5b,h), and the spinup time scale of the streaks in phase IV seems similar to their initial spinup time scale before the eye passes.

2) VERTICAL SECTIONS OF ROLLS/STREAKS IN ROLL COORDINATES

Vertical sections oriented perpendicular to the streak axis at the end of phase II highlight several key characteristics of the streaks/rolls and their impact on smaller-scale OSBL turbulence. We find that the cross-streak v_r and vertical w_r velocities form tilted rolls (Fig. 7) that are associated with the streaks u_r shown at 5-m depth in Fig. 4. The amplitude of the streaks/rolls decays rapidly with depth below 10 m, but their orientation in the horizontal plane does not rotate with depth despite substantial rotation of the mean shear vector (see Figs. 6 and 7). The simulated roll vertical velocity anomalies w_r have a characteristic scale of a few millimeters per second, and the corresponding cross-streak roll velocities v_r are a few centimeters per second, that is $v_r \sim 10 w_r$ consistent with the aspect ratio of about 10. The simulated horizontal cross-streak roll velocity v_r is about 3 times weaker than the along-roll streak velocity u_r.

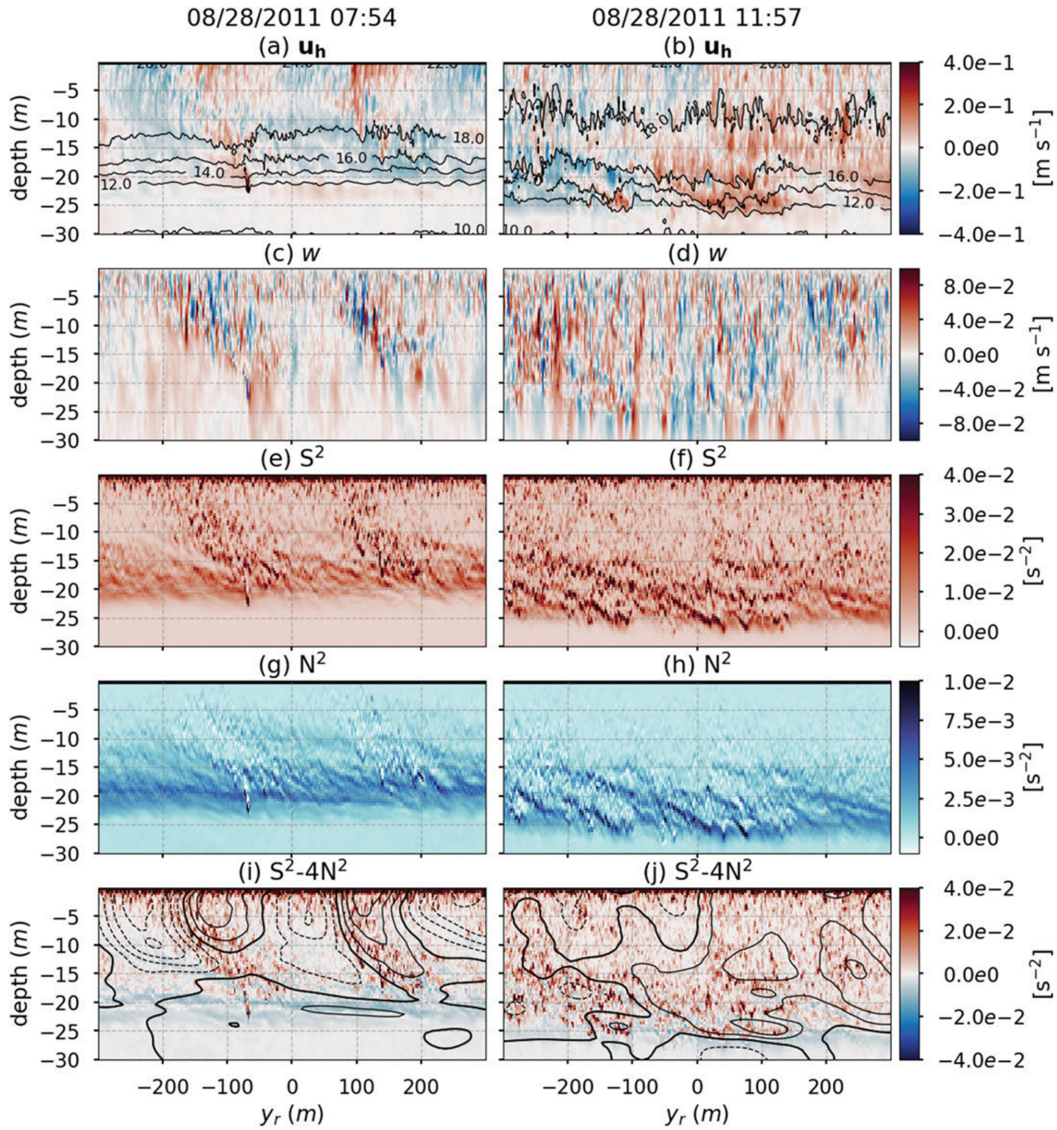

FIG. 8. As in Fig. 7, but without smoothing: (a),(b) anomaly in the horizontal speed $|\mathbf{u}_h|$, (c),(d) vertical velocity w, (e),(f) squared vertical shear of horizontal velocity S^2, (g),(h) stratification N^2, and (i),(j) reduced shear $S^2 - 4N^2$, just before (left) and just after (right) the eye. For reference, temperature contours are overlaid in (a) and (b) and smoothed u_r (also shown in Fig. 7) is overlaid in (i) and (j). The coordinate systems for before-eye and after-eye are plotted in Figs. 4d and 4f, respectively.

Thus, v_r stands out less prominently from other variability and appears less organized than u_r.

In addition, we find systematic correlations between the roll/streak variables, and thus an indication of net vertical transport by the streaks/rolls. In particular, the simulated streak velocity u_r is negatively correlated with w_r, although they are not perfectly aligned. The phase shift ϕ_r that minimizes the lagged correlation (to about -0.8) between $u_r(y_r)$ and $w_r(y_r + \phi_r)$ occurs at from $\phi_r \approx -20$ to -40 m or about $-0.1\lambda_r$. Conversely, temperature anomalies T_r are positively correlated with w_r, but the correlation coefficient is maximum (about $+0.6$) for a phase shift applied to w_r from $\phi_r \approx +10$ to $+40$ m or about $+0.1\lambda_r$. Thus, the results suggest that the roll-streak system may be associated with a downgradient momentum flux and positive shear production and upgradient buoyancy flux and positive buoyancy production. In a later section, we will separate by length scale and compare the turbulent vertical transport of momentum and buoyancy by these and all other structures and thereby explicitly quantify the impact of these structures on the evolution of the mean current and buoyancy profiles during the storm.

3) MODULATION OF SMALLER TURBULENCE

The vertical section plots in Fig. 8 show that the streaks modulate smaller-scale turbulence as well as the shear and stratification that influence the energetics of smaller scales. In particular, the region of strongest $\partial u_r/\partial z$, which is to the left (lower

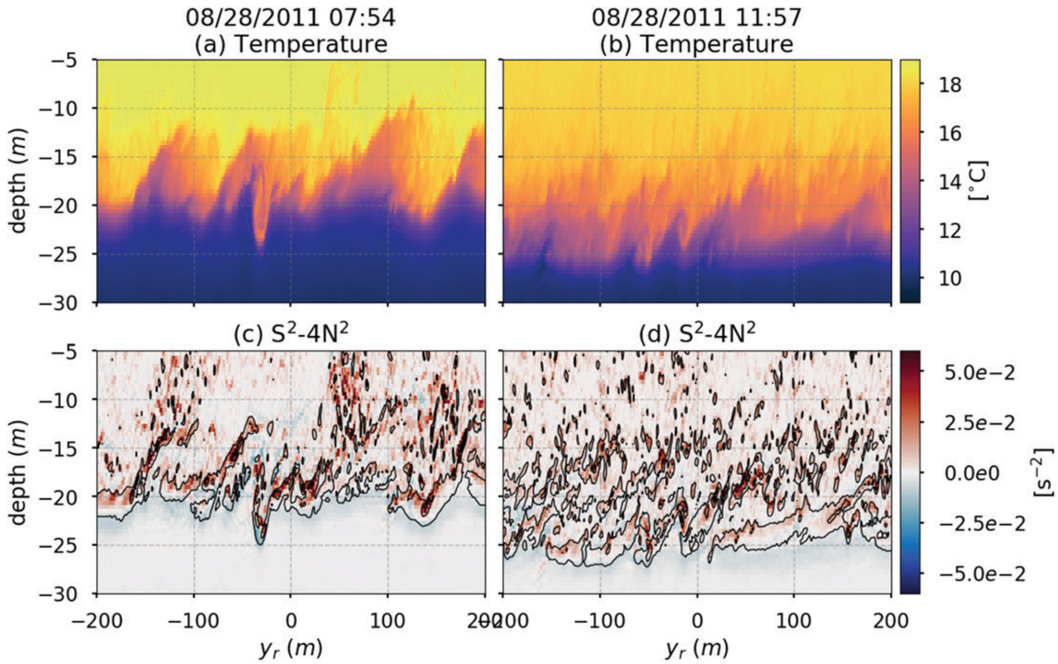

FIG. 9. (a),(b) Temperature and (c),(d) reduced shear with contours of vorticity (in x_r) overlaid in black along the white coordinate lines in Fig. 6.

y_r in roll coordinates) of and below positive streak anomalies ($u_r > 0$), is associated with a tongue of enhanced vertical velocity w variance, squared shear $S^2 = (\partial u/\partial z)^2 + (\partial v/\partial z)^2$ variance and stratification N^2 variance that extends downward and under the positive u_r anomaly, from the surface to the thermocline. In addition, the enhanced turbulence coincides with roll-scale downdrafts $w_r < 0$, which occur 20–40 m to the left of the streaks (toward lower y_r) and are correlated with cold temperature anomalies. This enhanced turbulence coincides with and is plausibly explained by strongly positive reduced shear, $S^2 - 4N^2 > 0$, in these regions (Fig. 8i), which is indicative of both a gradient Richardson number $\mathrm{Ri}_g = N^2/S^2 < 1/4$, hence the necessary conditions for instability are met (Miles 1961; Howard 1961; Hazel 1972), and substantial energy is available to the turbulence via shear production (Turner 1979; Rohr et al. 1988; Holt et al. 1992). Conversely, below the low-speed negative streak velocity anomalies ($u_r < 0$) turbulence is particularly weak and generally the reduced shear is negative and $\mathrm{Ri}_g \geq 1/4$. For comparison, a similar set of sections is shown after the eye passage in Fig. 8 in order to highlight the remarkable degree of periodicity imposed upon the turbulence by the streaks/rolls before the eye, under strong surface forcing.

b. Thermocline

Do the streaks and rolls discussed in the previous section, or large-aspect-ratio structures more generally, influence the entrainment of cold water from the thermocline and thereby the SST in the LES?

To begin addressing this question, we describe the characteristics of the dominant large structures in the turbulence near the thermocline, where the cold water enters the surface boundary layer. There, large scales $\lambda > 3D_{N^2}$ represent a majority of the horizontal kinetic energy and buoyancy variance between phases II and III (Fig. 5). In addition, plan views of temperature at different depths in Fig. 6 show that the characteristics of the large structures are qualitatively different at the thermocline compared to the surface-layer streaks/rolls. At the thermocline, the large-scale variance is dominated by smaller ~100-m-scale wave-like structures with crests and troughs perpendicular to the local shear vector $\partial\langle\mathbf{u}\rangle_{x,y}/\partial z$, which is rotated about 90° to the right of the wind stress. These wave-like features are reminiscent of organized KH billows (Fig. 9), so we refer to them as such before explicitly comparing to theory and prior observations in the discussion section below.

The significant spatial modulation of the KH billows is a feature of particular interest in such a large-aspect-ratio model domain. At the beginning of phase III, these features are organized into bands that are approximately parallel to the local shear vector, a few hundred meters wide, and spaced 1 km apart (Fig. 6g). Each band is associated with an undulation in the thermocline and horizontal velocity (e.g., it is warmer on the bottom-right and cooler on the top-left side of each band in Fig. 6g). These larger thermocline undulations are plausibly due to internal waves, but since these 1-km structures are not always this organized, we do not pursue a simple explanation for this kilometer-scale modulation. Nevertheless, the simulated axial coherence of the rolls (along lines of constant phase) is often at least several wavelengths, which is qualitatively consistent with existing albeit limited knowledge of axial coherence of KH-like billows observed in the atmosphere and laboratory (Thorpe 2002).

Although we do not explicitly plot the time evolution of the billows, we note that similar structures are prominent with

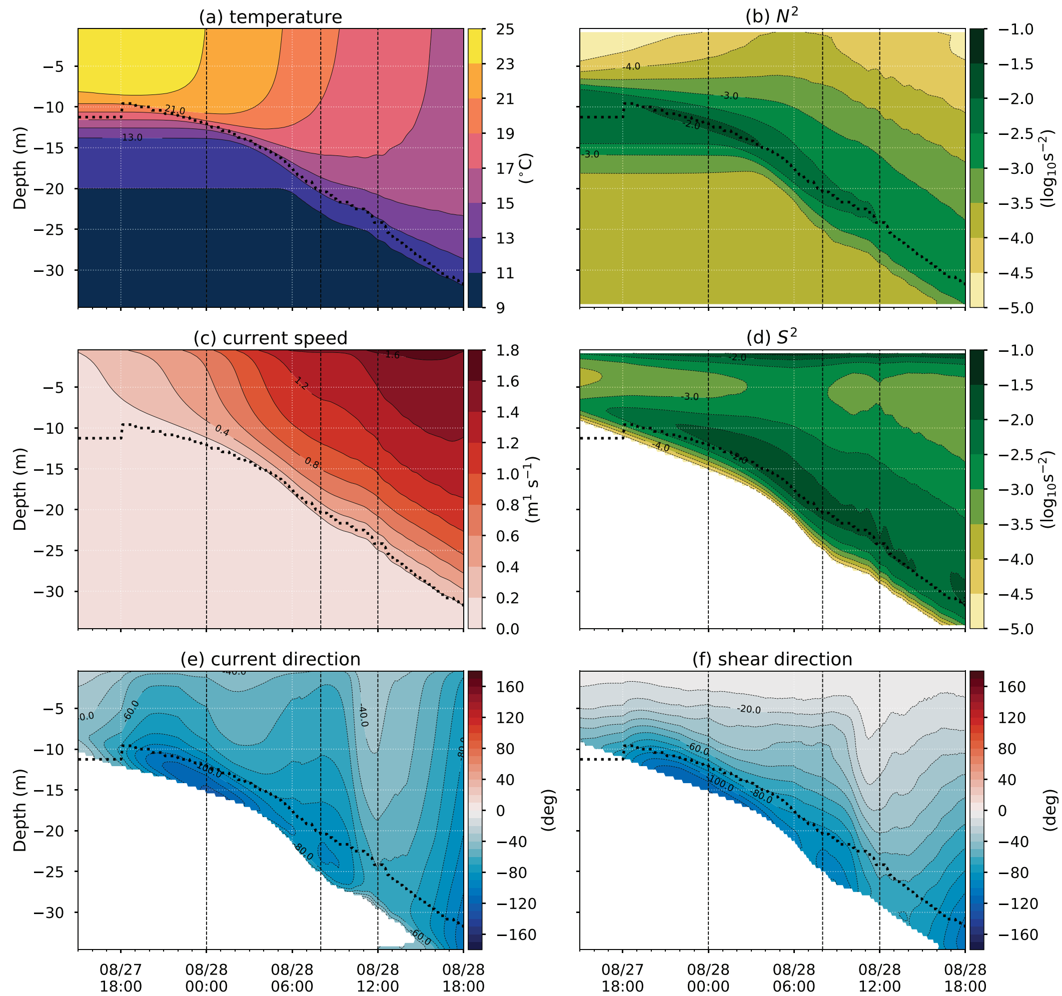

FIG. 10. (a) Mean vertical profiles of temperature, (b) vertical buoyancy gradient N^2, (c) horizontal current speed $|\mathbf{u}_h|$, (d) squared vertical shear of horizontal velocity S^2, (e) horizontal current direction, and (f) shear direction. Both of the angles in (e) and (f) indicate the direction the vector points and are given in degrees counterclockwise relative to the direction that the wind points. The angles are mostly negative and smaller than 90°, which indicates the current and shear vectors are to the right of the wind vector, as expected. Angles are only shown for speeds and shears greater than $10^{-3}\,\mathrm{m\,s^{-1}}$ and $\mathrm{s^{-1}}$, respectively. The dashed black line indicates the depth of maximum stratification D_{N^2}.

different degrees of organization at most times in phases II–IV (cf. Figs 9a and 9c with Figs. 9b and 9d; see also Fig. 6). In addition, the temporal evolution of the radially integrated horizontal wavenumber spectra of buoyancy variance and vertical kinetic energy at the time-dependent depth $z = -D_{N^2}$ both contain distinct local maxima at a wavelength λ that increases slowly from about 10–20 m at 1500 UTC 27 August to about 100 m at 0754 UTC 28 August (the beginning of phase III), during which time the depth D_{N^2} increases from about 10 to 20 m. Hence, unlike the surface streaks/rolls, which are more ephemeral and sensitive to the time-variability of the mean flow/forcing, the presence of organized wave-like or billow structures at the top of the thermocline is relatively robust to variations in the large scale conditions, although their precise spatial orientation and organization, characteristic scale, and magnitude varies.

4. Evolution of the mean profiles

The temporal evolution of the large-aspect-ratio structures is both dependent on and impacts the evolution of the mean profiles of momentum, temperature, salinity, and hence buoyancy. This section describes the temporal evolution of the horizontally averaged profiles of temperature, buoyancy, and momentum and then quantifies the net effects of the turbulence, including at large scales, on the mean profiles of momentum and buoyancy via vertical fluxes.

a. Mean profiles and comparisons to observations

In addition to generating the turbulence, the hurricane forcing also drives the evolution of the mean profiles, including the acceleration, deepening, and cooling of the OSBL (Figs. 10a,c).

For example, the forcing accelerates a sheared and surface-intensified mean current with speeds in excess of $1\,\mathrm{m\,s^{-1}}$ and shears in excess of $10^{-1}\,\mathrm{s^{-1}}$ (Figs. 10c,d). Even though the wind and currents are unsteady, the mean surface current vector points about $45° \pm 20°$ to the right of the wind vector until late in phase IV (Fig. 10e), and the current vector rotates clockwise with increasing depth throughout phases I–IV, as in an idealized steady Ekman layer (Ekman 1905). In phase III, the wind rotates rapidly clockwise at an angular frequency of about $2f$ while fluctuating in speed as the eye passes (Fig. 1). As a result, the simulated angle between the ocean surface current vector and the wind vector is briefly reduced (Fig. 10e), as the wind rotates clockwise faster than the ocean surface current. In phase IV, the current angle decreases throughout the OSBL at a rate of about 15°–20° $\mathrm{h^{-1}}$ as the wind direction stabilizes, as in an idealized inertial oscillation (Ekman 1905; Pollard and Millard 1970).

The simulated OSBL depth begins deepening at the beginning of phase II and continues to deepen from about 10 to 30 m through the end of phase IV (Figs. 10a,b). In addition, the overall extent of the deepening as well as the time of most rapid deepening, which occurs just ahead of the eye passage at the beginning of phase III, are reasonably similar to the observations (Fig. 11). In addition, the deepening is reasonably consistent with the theoretical model of wind-driven mixed layer deepening without a bottom by Pollard et al. (1972), whose Eq. (6.1) suggests a poststorm mixed layer depth of 34 m based on just the initial stratification profile and the maximum wind stress.

As the OSBL deepens, the simulated SST cools by more than 4°C ahead of the eye during phase II and by more than 6°C by the end of phase IV, similar to observations (see Fig. 2 of Glenn et al. 2016). In addition, the most rapid SST cooling occurs before the eye passage and earlier than the most rapid OSBL deepening, as observed (Glenn et al. 2016).

Interestingly, the mean OSBL profiles remain stratified ($\langle N^2\rangle_{x,y} \sim 10^{-5}$–$10^{-4}\,\mathrm{s^{-2}}$) as well as sheared ($\langle S\rangle^2_{x,y} \sim 10^{-4}$–$10^{-3}\,\mathrm{s^{-2}}$) throughout the storm (Figs. 10b,d and 11). In addition, the mean shear and stratification within the OSBL evolve similarly so that the mean profiles contain a region of approximately marginal stability within the OSBL (e.g., Thorpe and Liu 2009; Smyth et al. 2019), where $\mathrm{Ri}_g = \langle N^2\rangle_{x,y}/\langle S\rangle^2_{x,y} \approx 1/4$ from about 5-m depth to about D_N^2 (Fig. 12). Above 5 m, Ri_g remains positive, but it is much less than 1/4 due to the strong surface layer shear near the air–sea interface. During the eye passage, the mean shear and stratification in the OSBL weaken, and Ri_g decreases suddenly from just above 1/4 to just below 1/4 (Fig. 12a). Thereafter, the Ri_g profile remains relatively consistent through the end of phase IV. A statistical measure of the spatial variability in Ri_g (Fig. 12) connects back to Fig. 8; the modulation of the reduced shear by the rolls occurs in conjunction with a reduced percentage (50%–75%) of the area from 5 m to the pycnocline that is locally unstable ($\mathrm{Ri}_g < 1/4$). In contrast, without the rolls and after the eye, more than 75% of the area is locally unstable through most of the OSBL.

The reasonably good comparison between the simulated and observed OSBL depth and SST response suggests that the

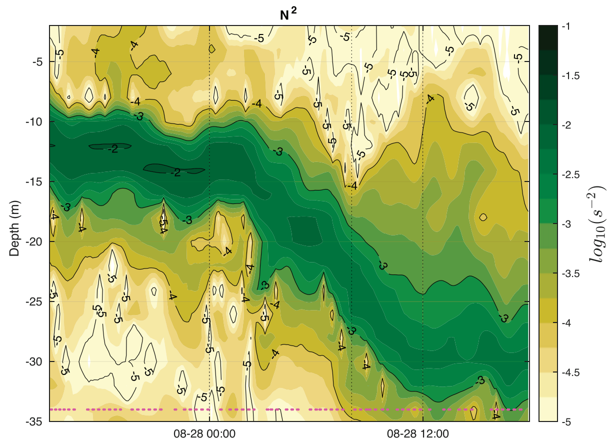

FIG. 11. Observed vertical buoyancy gradient N^2 in the region and time simulated by LES. Magenta dots at 34 m indicate the times of glider profiles sampled at 5-s resolution. The data have been linearly interpolated to a uniform 6 min × 2 m grid and smoothed with a forward-and-backward moving average with a 1-h (10-point) boxcar window and zero phase shift in an attempt to approximately mimic the spatial averaging that is applied in the analysis of the large-eddy simulation.

simulated turbulent transport processes that drive these changes in the LES may be relevant to and important in the real ocean. However, although the evolution of the simulated surface current direction is similar to observations (in Fig. 2 of Glenn et al. 2016), and observed and simulated differences between top and bottom velocities are within about a factor of two, the magnitude of the simulated surface current is sometimes stronger than observed by more than a factor of 2. We attribute the stronger surface currents and weaker bottom currents in the LES to the absence of a pressure-gradient-driven flow opposed to the wind-driven surface current, which Glenn et al. (2016) found was significant via numerical simulations. In addition, it is notable that the observed mean stratification of the OSBL at the beginning of phase III is somewhat weaker than simulated ($\langle N^2\rangle_{x,y} \sim 10^{-5}$ versus $10^{-4}\,\mathrm{s^{-2}}$; cf. Fig. 11 and Fig. 10b). In this case, it is plausible that the relatively strong simulated stratification is attributable to missing surface gravity wave effects, but missing large-scale processes may also contribute to this stratification bias as well. We will return to a discussion of these missing processes below.

b. Momentum flux

In this idealized simulation, the horizontally averaged velocity vector $\langle \mathbf{u}_h\rangle_{x,y}$ only evolves due to the Coriolis force and the convergence of turbulent vertical fluxes of momentum, that is

$$\frac{\partial\langle \mathbf{u}_h\rangle_{x,y}}{\partial t} + \mathbf{f}\times\langle \mathbf{u}_h\rangle_{x,y} = \frac{\partial \mathbf{F}_m}{\partial z},$$

where $\mathbf{f} = (0, 0, f)$ is the traditional Coriolis frequency in vector form. This section complements the previous description of the evolution of $\langle \mathbf{u}_h\rangle_{x,y}$ with a description of the turbulent momentum flux, $\mathbf{F}_m = \langle \nu_{\mathrm{SGS}}\partial\mathbf{u}_h/\partial z - w\mathbf{u}_h\rangle_{x,y}$, which is dominated

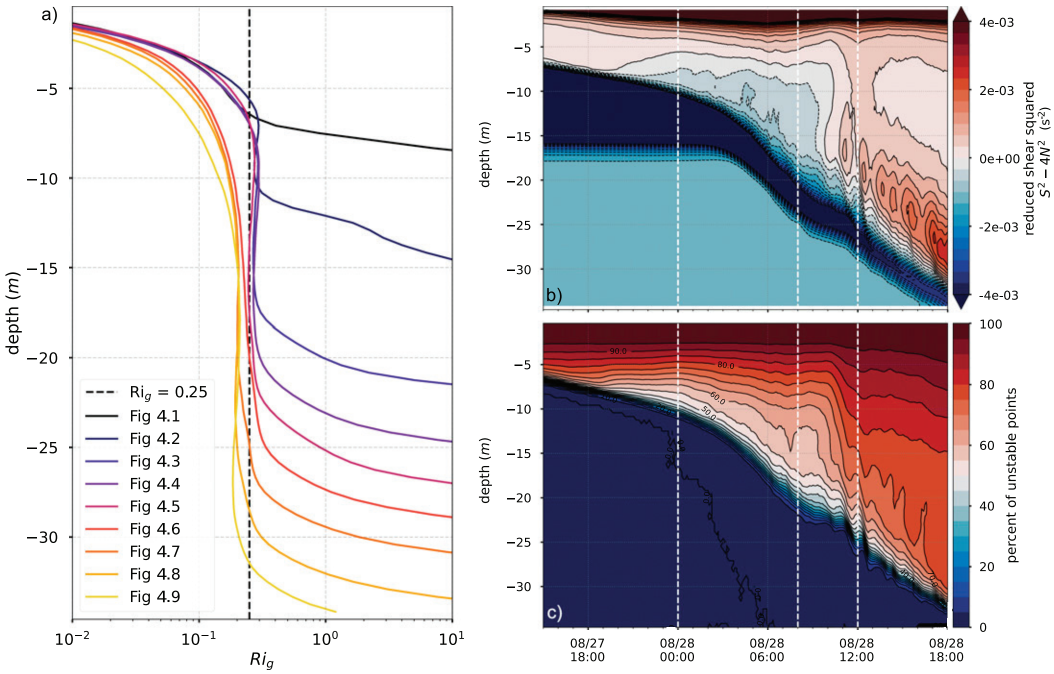

FIG. 12. Profiles of (a) the gradient Richardson number $\mathrm{Ri}_g = N^2/S^2$ and (b) the reduced shear $S^2 - 4N^2$ (s^{-2}) associated with the mean velocity and buoyancy profiles. (c) The percent of all points where the reduced shear is positive at each depth. The profiles all cluster into two regimes that separate by time: before and after eye passage, which occurs at about 0900 UTC 28 Aug (see Figs. 1 and 2).

by the resolved flux $-\langle w\mathbf{u}_h\rangle_{x,y}$ throughout most of the OSBL.[2] We characterize this flux in terms of its magnitude and direction, and we decompose it into two scales: smaller and larger than $3D_{N^2}$ (with subgrid-scale fluxes lumped with small scales). In addition, we quantify the effective turbulent viscosity profile, which we define by

$$\nu_t = \frac{\mathbf{F}_m \cdot \partial\langle \mathbf{u}_h\rangle_{x,y}/\partial z}{|\partial\langle \mathbf{u}_h\rangle_{x,y}/\partial z|^2}. \tag{1}$$

This definition of the scalar turbulent viscosity ν_t does not account for the nonlocal component of $\mathbf{F}_m$, i.e., the component of $\mathbf{F}_m$ that is perpendicular to $\partial\langle \mathbf{u}_h\rangle_{x,y}/\partial z$ (e.g., Large et al. 2019), which modifies ν_t by 3% or less in this scenario. Nevertheless, we still quantify the nonlocal component of $\mathbf{F}_m$ via the angle Ω between $\mathbf{F}_m$ and $\partial\langle \mathbf{u}_h\rangle_{x,y}/\partial z$ (e.g., Large et al. 2019), since the magnitude of the nonlocal flux is as large as 25% of $|\mathbf{F}_m|$ and thus may significantly influence the evolution of $\langle \mathbf{u}\rangle_{x,y}$ but is not accounted for in some OSBL mixing parameterizations (e.g., Large et al. 1994).

In this strongly forced regime, the magnitude of the shear is always positive, and the evolution of the momentum flux is controlled by the surface stress (see Fig. 1), which sets the surface value of $\mathbf{F}_m$. We also find that $|\mathbf{F}_m|$ decays approximately linearly with depth from the surface to about $z = -D_{N^2}$ while entrainment is occurring during phases II–IV (Figs. 13 and 14). Deviations from a linear $\mathbf{F}_m(z)$ profile do occur, but they have a magnitude of only about $0.2u_*^2$ where the friction velocity $u_* = \sqrt{|\boldsymbol{\tau}|/\rho_0}$. In addition, the turbulent viscosity collapses to a virtually time-independent vertical profile when ν_t is made dimensionless by dividing by $ku_*D_{N^2}$ and the depth z is divided by D_{N^2} (e.g., Large et al. 1994).

The decomposition of $\mathbf{F}_m$ into large and small scales (Fig. 14) shows that the flux is dominated by small wavelengths $\lambda < 3D_{N^2}$ at all depths and times. However, larger scales are nonnegligible, particularly during phase II and the beginning of phase III in the top 10 m, where the streaks and rolls are prominent and large scales account for about 10%–20% of the total flux. Just above the thermocline ($z = -D_{N^2}$), the large scale contribution to the flux is more intermittent and relatively weaker; it only just reaches 10% of the total flux at the beginning of phase III.

After the eye passage during phases III–IV, the acceleration of the OSBL continues, but the large-scale contribution to the flux is substantially smaller in percentage terms than before the eye. In addition, $|\mathbf{F}_m|$ briefly exhibits a relatively large ($\sim 0.2u_*^2$) positive deviation from the linear profile in the middle of the

[2] The subgrid-scale terms are only significant within a few meters of the surface and in the thermocline, hence the mean response and large-scale structures are expected to be fairly insensitive to refining the grid resolution (e.g., Whitt et al. 2019). Although it is prohibitively costly to significantly increase the resolution and test this in the large domain considered here, we confirmed this expectation by refining the grid resolution by a factor of 2 in all dimensions in a smaller domain.

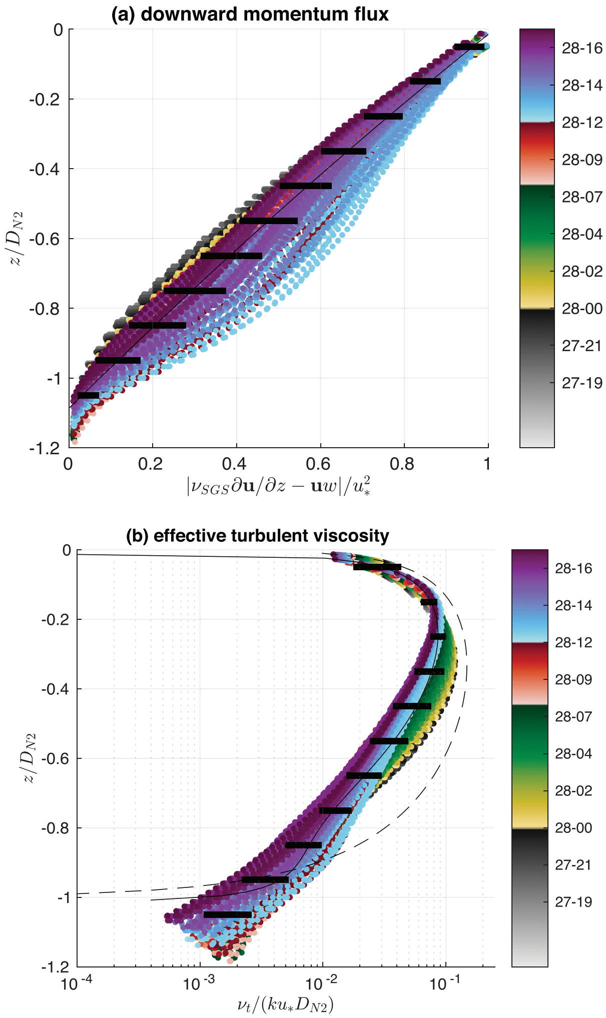

FIG. 13. (a) The momentum flux scaled by the friction velocity u_* decays nearly linearly with decreasing z/D_{N^2} at all times when entrainment is occurring (color bar, day-hour). The correlation coefficient between z/D_{N^2} and $|\mathbf{F}_m|$, where $\mathbf{F}_m = \langle \nu_{\mathrm{SGS}}\partial\mathbf{u}/\partial z - \mathbf{u}w\rangle_{x,y}$, is 0.98. The best fit quadratic (for $z/D_{N^2} > -1.2$) has coefficients -0.11, 1.18, and 1.09 (beginning with the highest-order term). (b) The effective turbulent viscosity, $\nu_t = \mathbf{F}_m \cdot \langle\partial\mathbf{u}_h/\partial z\rangle_{x,y}/|\langle\partial\mathbf{u}_h/\partial z\rangle_{x,y}|^2$, collapses when scaled by $ku_*D_{N^2}$, where $k = 0.4$ is the von Kármán constant. The best-fit quadratic (for $z/D_{N^2} > -1$) has coefficients -1.28, 3.41, -3.09, 0.97, and -0.01 and explains 88% of the variance for $z/D_{N^2} > -1$. Standard deviations in 11 bins are indicated by thick black bars. The dashed line in (b) is the empirical function $-z/D_{N^2}(1 + z/D_{N^2})^2$; a similar function is used in the K-profile parameterization scheme of Large et al. (1994).

OSBL (at about 1200 UTC 28 August, perhaps because the wind is particularly strong and well aligned with the shear, as shown in Fig. 10f) but thereafter returns to a nearly linear profile that persists through the end of phase IV.

The angle Ω between the momentum flux and the mean shear vector is also plotted as a function of time and scale in Fig. 14. In both the total and small-scale part of $\mathbf{F}_m$, Ω is small but nonnegligible, reaching maxima of about 15° and 10°, respectively, between about 5–10 m at the end of phase II (for reference, this implies that the nonlocal component of $\mathbf{F}_m$ is 17%–26% of the magnitude $|\mathbf{F}_m|$). With respect to the total and small-scale fluxes, Ω is very slightly negative at the surface, but positive throughout most of the OSBL during phase II. That is, the corresponding $\mathbf{F}_m$ vector is rotated counterclockwise relative to the local shear $\partial\langle\mathbf{u}_h\rangle_{x,y}/\partial z$ and toward the wind stress vector $\boldsymbol{\tau}$ in most of the OSBL.

It may be noted that the total and small-scale nonlocal fluxes are correlated in time with large-scale nonlocal fluxes, which are associated with much greater Ω, particularly in the middle of the OSBL. Hence, we consider the hypothesis that the nonlocal momentum flux, i.e., the occurrence of $\Omega \neq 0°$ in Figs. 14d–f, is due to the presence and modulating effects of the large-scale rolls/streaks. The evidence in support of this hypothesis is as follows. First, the magnitude ($w_r u_r \sim 10^{-4}\,\mathrm{m^2\,s^{-2}}$), depth range (top 10 m), and angle Ω of the large-scale fluxes (Figs. 14c,f) are consistent with the roll structures described in section 3 (Fig. 7). In particular, Ω (Fig. 14f) is slightly negative near the surface, where the streaks are rotated to the right of the wind stress and local shear, but Ω increases with depth as the mean shear vector rotates clockwise but the rolls and streaks remain at a fixed angle (see Figs. 6 and 7). Second, the temporal evolution of the nonlocal fluxes at small scales (Fig. 14e) is similar to the temporal evolution of the streaks as well as the associated large-scale fluxes (cf. to Figs. 5b,h and 14c). In particular, both the magnitude of the large-scale streaks/rolls and the small-scale nonlocal fluxes are largest during phase II and abruptly transition to much smaller values as the eye passes. Further, the small-scale turbulence is modulated by and more intense below the streaks ($u_r > 0$) (Figs. 8c,e,i), where the large-scale shear vector is rotated counterclockwise relative to the mean shear vector. To the extent this relationship is significant and strong, a positive Ω at small scales (Fig. 14e) is expected at the base of the streaks while they are present. Together, all of this evidence suggests that the nonlocal momentum flux, at large and small scales, is directly or indirectly due to the presence of the large-aspect-ratio streaks and rolls. In addition, explicit models of these large-aspect-ratio structures may be necessary to model nonlocal fluxes in OSBL mixing parameterizations.

Thus, we conclude that the large-aspect-ratio structures fundamentally alter the direction and magnitude of the momentum flux and thus the evolution of the mean momentum profile in this scenario, but the magnitudes of these modifications are relatively small (~10%) compared to the fraction of turbulent kinetic energy in these large scales (>50%).

c. *Entrainment and buoyancy flux*

The rapid SST cooling and the associated impacts on the hurricane are driven by entrainment and the downward turbulent buoyancy flux as the OSBL penetrates into the cold thermocline. In particular, since the OSBL is approximately mixed and the mean buoyancy profile is highly correlated with the mean temperature profile (Fig. 3), the evolution of the SST is governed by the evolution of the buoyancy averaged over $z > -D_{N^2}$ (Stevenson and Niiler 1983), which evolves according to

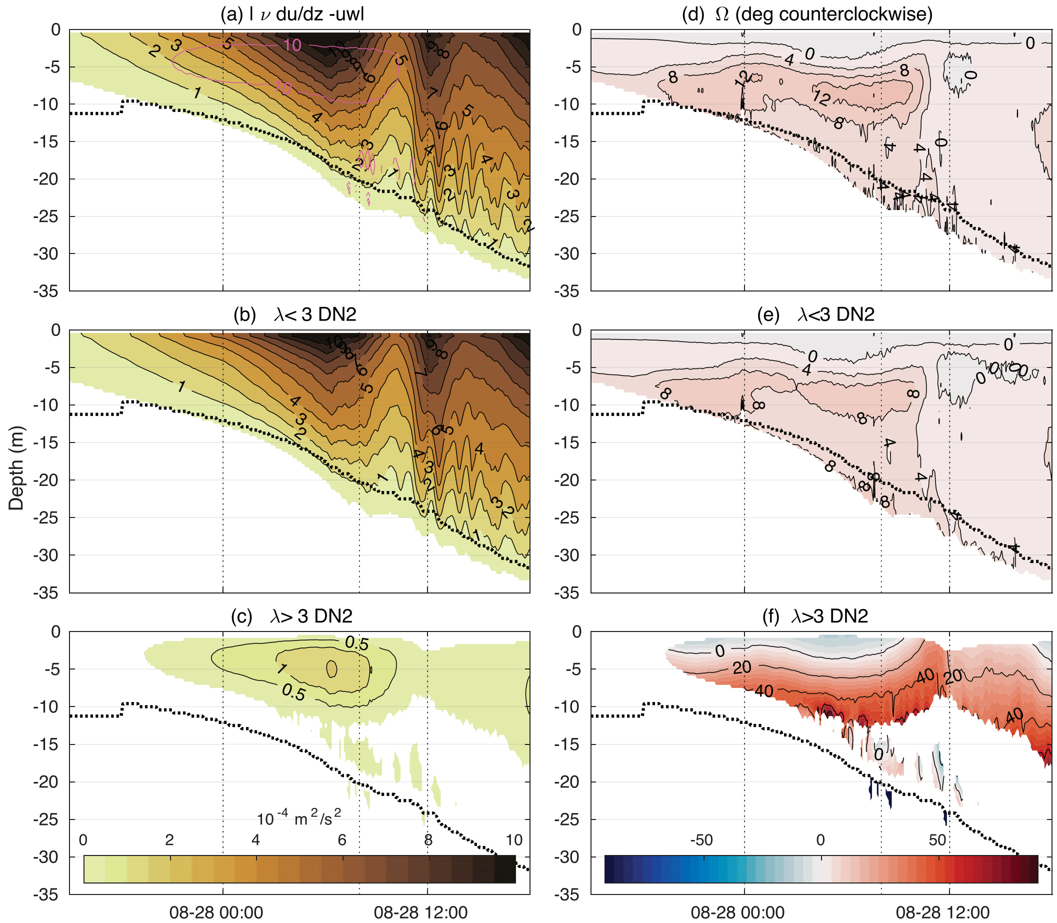

FIG. 14. The (left) magnitude and (right) direction of the downward vertical momentum flux vector $\mathbf{F}_m = \langle \nu_{\rm SGS}\partial \mathbf{u}_h/\partial z - w\mathbf{u}_h\rangle_{x,y}$. The direction is given relative to the local mean shear vector $\langle \partial \mathbf{u}_h(z,t)/\partial z\rangle_{x,y}$, which is shown in Fig. 10f. (a) The total flux is also decomposed, via Fourier transforms, into (b) small scales, that is, horizontal wavelengths $\lambda < 3D_{N^2}$ including subgrid scales, and (c) large scales, that is, horizontal wavelengths $\lambda > 3D_{N^2}$. For reference, the black dotted line indicates D_{N^2}. The magenta contours in (a), marked every 10%, indicate the percentage of the total flux that is attributable to large scales.

$$\frac{\partial}{\partial t}\left(\langle b\rangle_{x,y,D_{N^2}}\right) = \frac{F_b(z=0) - F_b(z=-D_{N^2})}{D_{N^2}} - \frac{\Delta b}{D_{N^2}}\frac{\partial D_{N^2}}{\partial t}, \quad (2)$$

where $\Delta b = \langle b\rangle_{x,y,z>-D_{N^2}} - \langle b\rangle_{x,y}(z=-D_{N^2})$ and

$$F_b = \langle \kappa_{\rm SGS}\partial b/\partial z - wb\rangle_{x,y}.$$

In addition, the evolution of the mean buoyancy profile is governed by

$$\frac{\partial\langle b\rangle_{x,y}}{\partial t} = \frac{\partial F_b}{\partial z}.$$

Therefore, this section quantifies F_b and the related entrainment flux $F_e = -\Delta b \partial D_{N^2}/\partial t$ in order to evaluate the impact of the storm-driven OSBL turbulence, and the large-aspect-ratio structures in particular, on the evolution of the mean buoyancy and stratification profiles, entrainment, and SST cooling.

First, it is notable that the buoyancy flux profile F_b collapses when divided by F_e (Fig. 15c). The maximum of F_b is found at $z \approx -3D_{N^2}/4$ throughout the storm, and the magnitude of this maximum is approximately equal to $3F_e/4$ on average (Figs. 15a,c). About 80% of the temporal variance in the maximum of F_b (Fig. 15a) can be explained by variations in the rate of entrainment F_e. In addition, a similarly large fraction of the temporal variance in F_e (and F_b) can be explained by the rate of working on the surface current by the wind stress $\boldsymbol{\tau}\cdot\mathbf{u}$ ($z = 0$) divided by D_{N^2} (Fig. 16).[3] During the end of phase III and the beginning of phase IV, when the angle between the wind and the current is relatively small (Fig. 10e), the dot product in $\boldsymbol{\tau}\cdot\mathbf{u}$ ($z = 0$) is particularly crucial; it is only at this time that the conventional friction

[3] As Bill Large suggested to us, the shear production averaged above D_{N^2} explains F_e about as well as the wind work. Motivated by that suggestion, we also find that the surface stress dotted into the average shear above D_{N^2}, i.e., $\tau\cdot\langle\partial\mathbf{u}_h/\partial z\rangle_{x,y,z>-D_{N^2}}$ explains the entrainment about equally well too.

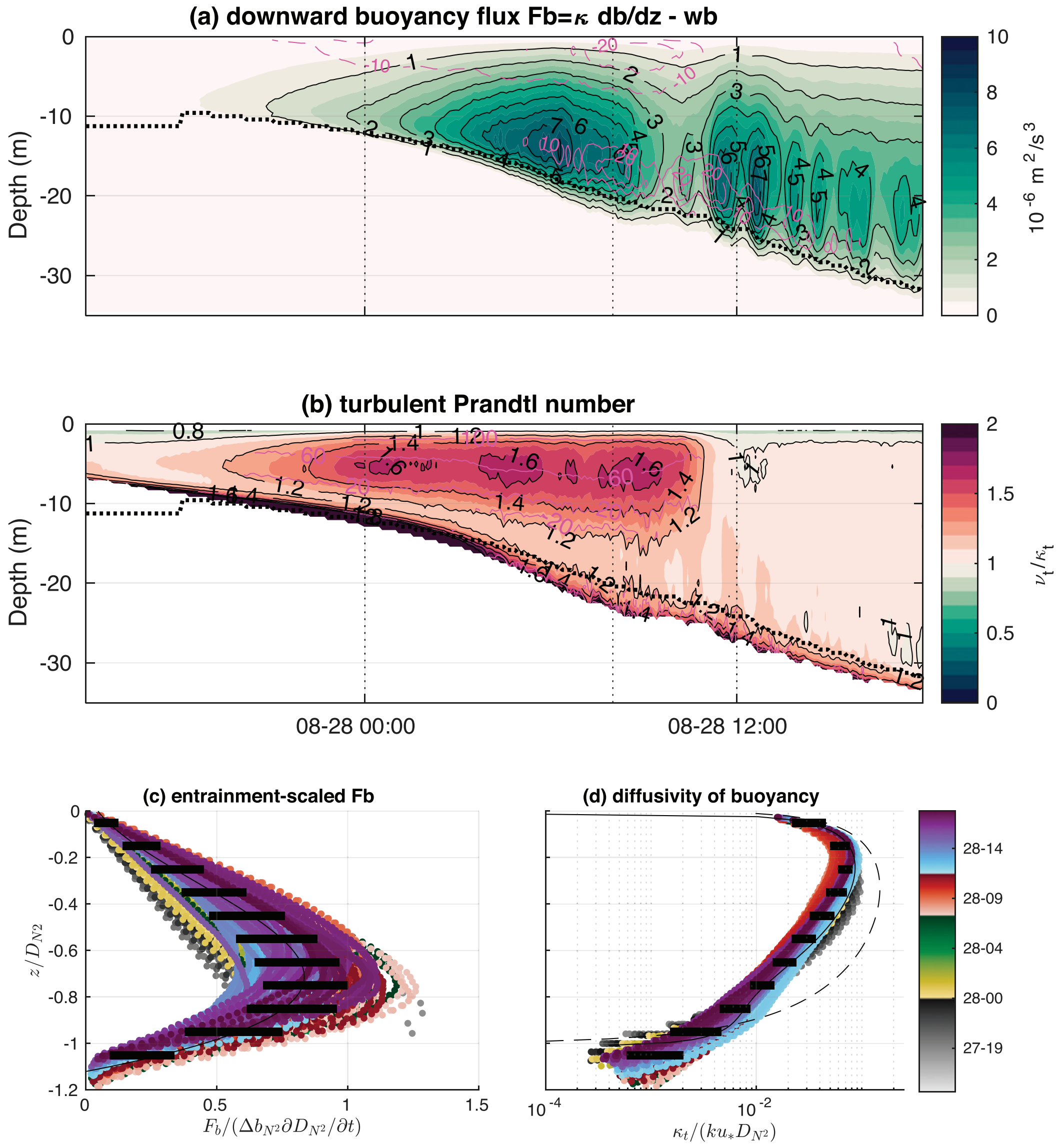

FIG. 15. (a) The vertical buoyancy flux $F_b = \langle \kappa_{SGS}\partial b/\partial z - bw\rangle_{x,y}$, which is collapsed in (c) by dividing by the entrainment buoyancy flux $F_e = \Delta b \partial D_{N^2}/\partial t$, where Δb is the difference between the depth-averaged buoyancy above D_{N^2} and the buoyancy at D_{N^2}. The color bar in (c) and (d) indicates the time (day-hour). The best-fit cubic in (c) (solid black line), which explains 86% of the variance of F_b, has coefficients −3.07, 2.82, 0.65, and 0.05 (from highest to lowest order). The turbulent diffusivity profile $\kappa_t = F_b/N^2$ in (d) is very similar to the turbulent viscosity profile ν_t (plotted in Fig. 13b), but the turbulent Prandtl number $\mathrm{Pr}_t = \nu_t/\kappa_t$ systematically differs from 1, as shown in (b). For reference, magenta contours in (a) and (b) quantify the percentage of F_b and $\mathrm{Pr}_t - 1 > 0.2$, respectively, that are attributable to fluctuations with wavelengths greater than $3D_{N^2}$. In both (c) and (d), horizontal black bars indicate standard deviations in 11 depth bins. For reference, the depth D_{N^2} (dotted black) is overlaid in (a) and (b), and the solid black and dashed black curves in (d) are the same dimensionless viscosity model profiles as in Fig. 13b.

velocity scaling u_*^3/D_{N^2}, which works reasonably well in phases I–III and late in phase IV, is too weak (Fig. 16). Hence, the rapid ahead-of-eye SST cooling in the LES is due to two factors: 1) the relatively large injection of kinetic energy from the wind to the OSBL ahead of the eye passage in phase II (due to the large friction velocity; see Fig. 16), and 2) the relatively small D_{N^2} at that time. The latter effect is quadratically important, since $\partial\langle b\rangle_{x,y,D_{N^2}}/\partial t \sim F_e/D_{N^2} \sim \boldsymbol{\tau}\cdot\mathbf{u}(z=0)/D_{N^2}^2$ [see Eq. (2)].

Second, it is notable that F_b has a relatively large magnitude in the OSBL throughout the storm. Specifically, the flux Richardson number (Osborn 1980)

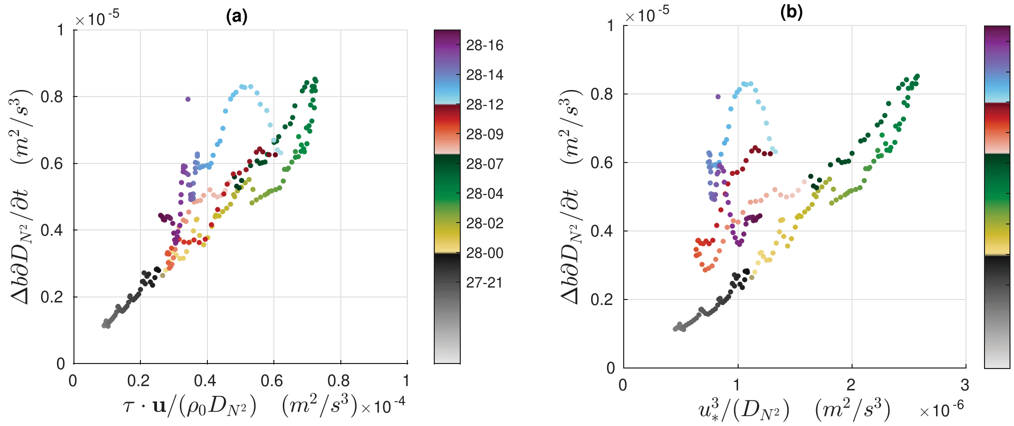

FIG. 16. The relationship between the entrainment flux F_e and the rate of working on the surface current by (a) the wind stress ($r^2 = 0.75$, linear regression slope = 0.1) and (b) the friction velocity u_*^3 ($r^2 = 0.37$, linear regression slope = 2.0) during entrainment. The color bar indicates the time (day-hour).

$$\mathrm{Ri}_f = \frac{F_b}{\mathbf{F}_m \cdot \partial \langle \mathbf{u} \rangle_{x,y} / \partial z} \sim 0.1$$

throughout most of the OSBL. In particular, $\mathrm{Ri}_f \sim \mathrm{Ri}_g$ (Fig. 17), and hence the buoyancy flux is 10% or more of the shear production where $\mathrm{Ri}_g \gtrsim 0.1$. That is, the strong wind makes buoyancy relevant to the turbulence energetics via entrainment, even though the Monin–Obukhov length is at least an order of magnitude greater than D_{N^2}, and the surface buoyancy flux $F_b(z = 0) \ll \max_z(F_b)$ is relatively small (cf. Figs. 1c and 15a).

Third, F_b is composed mostly of small scales $\lambda < 3D_{N^2}$, but large scales $\lambda > 3D_{N^2}$ make a nonnegligible contribution to the total F_b (similar to $\mathbf{F}_m$) (cf. Figs. 15a and 14). Specifically, the large scales are responsible for a countergradient flux $F_b < 0$, which is equal in magnitude to 10%–30% of the total $|F_b|$ in the upper 5–10 m during phases II–III. And, large scales are responsible for a downgradient flux equal to 10%–20% of the total F_b just above the thermocline during phases II–IV (Fig. 15a). Plots of F_b as a function of horizontal wavelength and depth at the beginning and end of phase III in Figs. 18a and 18b highlight the spatial and spectral localization of the large-scale buoyancy fluxes as well as the abrupt decay of the near-surface streaks/rolls and the associated large-scale fluxes during phase III. These spectra also provide explicit quantitative support for the hypothesis implicitly espoused in section 3: that there are a small number of distinct structures that dominate the large-scale dynamics, rather than a turbulent continuum at large scales. That is, although a scale separation is an imperfect way of separating the large-aspect-ratio rolls and billows from the turbulent continuum, the scale separation effectively achieves that end in this case. Most of the large-scale contribution to F_b can essentially be attributed to either the near-surface rolls/streaks in the top 10 m or the KH-like billows just above D_{N^2}, as described in section 3. Nevertheless, a cautious interpretation is still warranted: some of the flux associated with the KH-like billows is apparently categorized as small scale (to the right of the red line in Fig. 18), and some of the large-scale flux is evidently not associated with the dominant large structures described in section 3.

Finally, it is notable that although the buoyancy flux varies systematically with the momentum flux such that the turbulent Prandtl number $\mathrm{Pr}_t = \nu_t/\kappa_t$ is always near 1 [ν_t and κ_t are defined as in Eq. (1)], there are also persistent deviations $\mathrm{Pr}_t > 1$ (Figs. 15b and 17). In addition, these positive deviations in Pr_t coincide with and are partially attributable to: 1) the presence of the Ekman-layer rolls, which increase the overall Pr_t by reducing κ_t and increasing ν_t (see Figs. 18a,c,e; cf. Figs. 17a,b), 2) the increased mean-profile Ri_g, which is associated with higher $\mathrm{Pr}_t = \mathrm{Ri}_g/\mathrm{Ri}_f$ and lower Ri_f relative to Ri_g for $\mathrm{Ri}_g \approx 0.25$ (see Figs. 12 and 17), and 3) the nonlocal momentum flux during phase II, which does not directly modify Pr_t more than a few percent but is thought to be another consequence of the Ekman-layer rolls (Fig. 14). Conversely, the KH-like structures do not directly increase Pr_t. Just above the thermocline, the scale-dependent Prandtl number is generally positive but less than 1/2 over the depth range and wavelengths characteristic of the KH-like billows, which are more effective at transporting buoyancy than momentum and thus directly contribute to lowering Pr_t and increasing Ri_f (ignoring the indirect effects of these structures on Pr_t via smaller wavelengths; see Fig. 18).

In summary, although entrainment and SST cooling is controlled to a first approximation by the mean dynamics [i.e., it is a response to the wind work on the mean flow, as in Pollard et al. (1972)], the large-aspect-ratio structures contribute ~10% to the vertical buoyancy flux and thus may modify the SST response by ~10% (i.e., a few tenths or possibly even a whole degree Celsius).

5. Discussion

Before concluding, we briefly compare our simulation study with a few prior observational studies focused on the instabilities of both the Ekman boundary layer and stratified shear layers, which are thought to be relevant to the near-surface streaks/rolls and the KH-like billows near the thermocline, respectively. In the second section below, we explicitly discuss the possible significance and implications of two omitted processes, surface gravity waves and larger-scale ocean dynamics.

a. Comparisons with prior studies

1) Ekman layer rolls

Perhaps the most plausible dynamical causes of the simulated near-surface streaks and rolls are the linear instabilities of the Ekman layer (Kaylor and Faller 1972; Brown 1972; Asai and Nakasuji 1973; Lemone 1973; Duncombe 2017; Skyllingstad et al. 2017). These instabilities produce helical rolls/streaks approximately aligned with the geostrophic wind in the atmosphere and surface stress in the ocean (often tilted at some small angle $\sim 10°$ relative to the wind or stress) that are qualitatively similar to the near-surface streaks and rolls described in section 3 [e.g., compare Fig. 7 with Fig. 4a of Lemone (1973)]. In particular, the roll circulation (v_r, w_r) as shown in Fig. 7 is typically surface intensified and inclined in the cross-roll-vertical plane. In addition, the cross-roll wavelength $\lambda_r \sim 10D_{\mathrm{Ek}}$, where $D_{\mathrm{Ek}} = \sqrt{2\nu_t/f} \approx 15$ to 30 m and $\nu_t \sim 0.1ku_*D_{N^2}$ as in Fig. 13b (e.g., Lemone 1973; Asai and Nakasuji 1973; Sous et al. 2013).

There are also some notable similarities between the simulated streaks/rolls and observations of such features in the ABL, as reported by Lemone (1973, 1976). In both this LES and the ABL observations, the roll-streak system is associated with a downgradient momentum flux and positive shear production and upgradient buoyancy flux and positive buoyancy production. Further, the simulated roll-scale modulation of small-scale turbulence, which is enhanced in roll downdrafts $w_r < 0$ that correspond with cold temperature anomalies, is qualitatively analogous to the ABL observations, in which turbulence is enhanced in roll updrafts that correspond with warm temperature anomalies.

There are also some notable differences between our simulated rolls/streaks and those observed by Lemone (1973, 1976). For example, the cross-roll velocity v_r was stronger and more organized than the streak velocity u_r in their ABL observations, whereas the streak velocity u_r is stronger and more organized than the cross-roll velocity v_r in these ocean LES. Second, Lemone (1973) only observed the regime where $D_{\mathrm{Ek}} \ll D_{N^2}$ and thus found that $\lambda_r \sim D_{N^2}$, whereas in the LES $\lambda_r \sim 10D_{N^2}$ and w_r is thus much weaker than v_r, unlike their ABL observations. Further, Lemone (1976) finds that the observed modulation of smaller-scale turbulence in the ABL is explained by roll-scale vertical transport of small-scale turbulence via w_r in the absence of strong coherent streaks u_r. Although vertical transport of turbulence plausibly contributes to the observed roll-scale modulation of turbulence in the LES, the strong simulated streaks and the close relationship between positive reduced shear (below $u_r > 0$) and enhanced turbulence in the LES suggests that the strong streaks also contribute energy to the smaller-scale turbulence via shear production and thereby the overall roll-scale modulation of small-scale turbulence in the LES.

The favorable comparisons between the LES and ABL observations is encouraging, but the lack of direct observations of such rolls in the OSBL under Hurricane Irene means the realism of the simulated turbulence cannot be verified observationally. Direct comparisons to oceanic observations of the turbulence derived from the glider are not pursued here as the observations required to estimate vertical velocity variance (e.g., Merckelbach et al. 2019) were unavailable since the glider was lost before recovery. Temperature, conductivity, and pressure data were recorded at 5-s intervals and sent via the Iridium connections approximately every 3 h or every 5–7

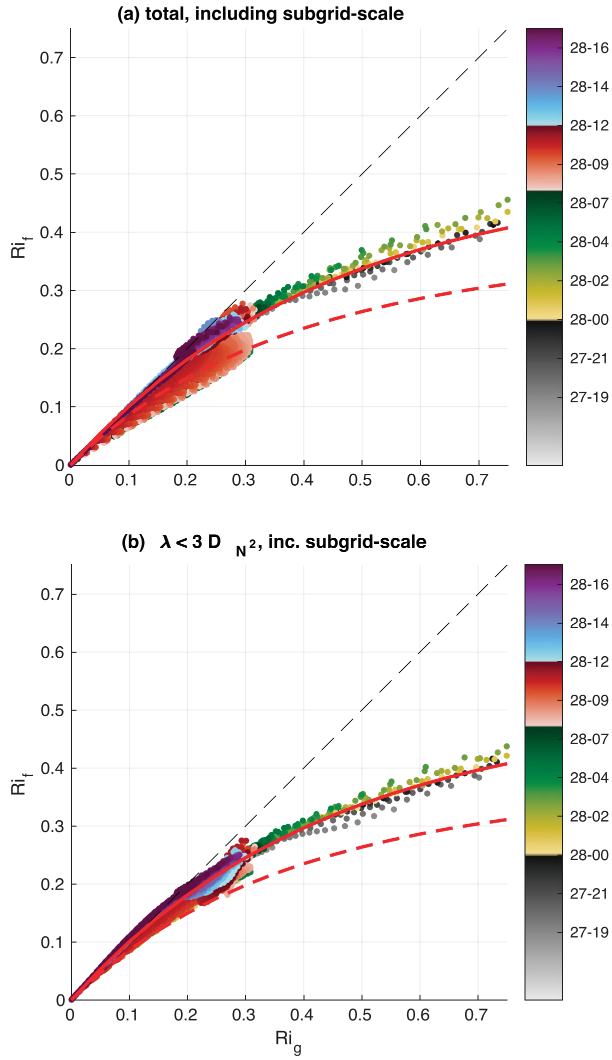

FIG. 17. The relationship between the gradient Richardson number Ri_g and flux Richardson number Ri_f above the depth of maximum stratification D_{N^2} where Ri_f is either as simulated (dots) or determined from Ri_g via $\mathrm{Ri}_f = 0.5(1 - e^{-2.25\mathrm{Ri}_g})$ (the solid red curve), which explains 93% and 98% of the variance in (a) and (b), respectively (e.g., Venayagamoorthy and Koseff 2016). In (a), the simulated Ri_f is calculated using the total buoyancy and momentum fluxes (including the subgrid scales), whereas in (b) the simulated Ri_f is calculated using only the wavelengths $\lambda < 3D_{N^2}$ (and the subgrid scales). The dashed red curve is a parameterization based on the ABL measurements (Anderson 2009), which parameterizes the subgrid-scale Ri_f in the LES (see section 2). The color bar indicates the time (day-hour).

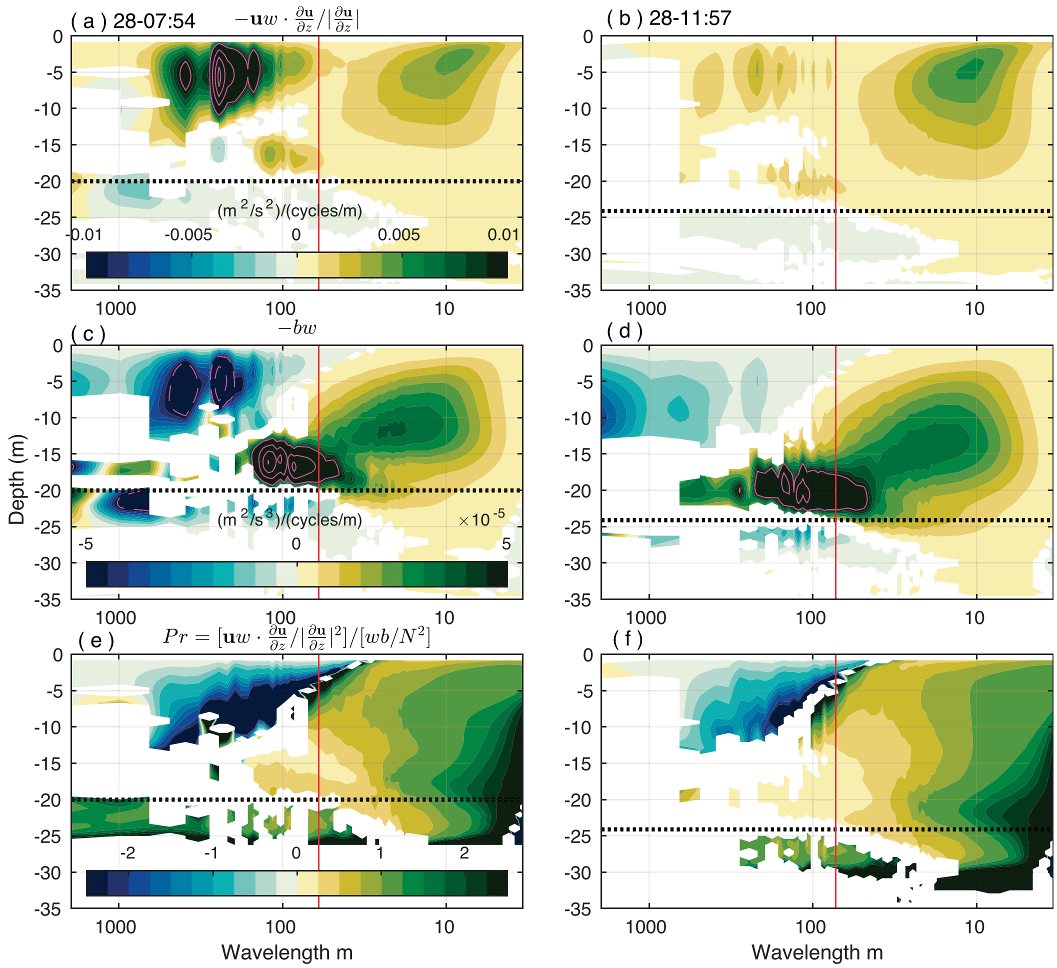

FIG. 18. Momentum and buoyancy flux cospectra at each depth averaged over 2-h windows centered at the (left) beginning and (right) end of phase III (see Fig. 1). Magenta contours, which are given every 0.01 m^2 s^{-2} (cycles per meter) in (a) and 0.000 05 m^2 s^{-3} (cycles per meter) in (c) and (d), respectively, highlight regions and wavelengths of particularly strong covariance before and after eye passage. Areas where the covariance is not significantly different from zero are blanked. The dotted black horizontal lines indicate the depth D_{N^2}, and the vertical red lines indicate the wavelength $3D_{N^2}$. The ratio of the relevant covariances, i.e., the flux Richardson number Ri_f, is decomposed by horizontal wavelength λ and written as a turbulent Prandtl number $\mathrm{Pr} = \mathrm{Ri}_g/\mathrm{Ri}_f$ in (e) and (f), where $\mathrm{Ri}_g = \langle N^2 \rangle_{x,y}/\langle S \rangle_{x,y}^2$ is the gradient Richardson number of the horizontally averaged velocity and density profiles.

downcast–upcast cycles. In summary, we lack the spatiotemporal resolution to isolate the roll structures or other features of interest in the turbulence that would allow for a useful direct comparison between the simulated and observed turbulence under Hurricane Irene.

Nevertheless, there are numerous observational indications of helical rolls such as those simulated in the LES in the ocean [going back to, e.g., Langmuir (1938); see section 1]. And some of these observed OSBL rolls/streaks have been simulated in LES and are qualitatively insensitive to the effects of surface gravity waves, which are omitted here (see Sundermeyer et al. 2014). Thus, the simulated large-aspect-ratio structures are plausibly realistic, even without surface gravity waves or larger-scale processes. However, we only explicitly compare the LES to the particularly relevant, intriguing, and recent observations of Gargett and Savidge (2020). They report observations of the coastal ocean boundary layer in 31 m of water under a hurricane on the South Atlantic Bight. As in the simulation reported above, they observed the oceanic response to a hurricane that moved approximately northward and passed to the west of the observing tower over about a day. The maximum stress in their case is perhaps 50% weaker than in ours, but the temporal evolution is quite similar. The winds come from a fairly consistent direction as the storm approaches, they rotate rapidly and weaken as the eye passes, and then the winds stabilize their direction and intensify after the eye before weakening again.

Most interestingly, Gargett and Savidge (2020) also find coherent large rolls, which they attribute to Langmuir supercells that are strong as the storm approaches, wash away during the eye passage, and then reemerge after the eye. The observed disappearance of the large rolls during the eye passage is qualitatively similar to the LES results above, although the observed forcing is dominated by waves whereas the LES forcing is dominated by winds, and their water column is essentially unstratified whereas ours is strongly stratified. A key conclusion of theirs, which our results seem to qualitatively endorse, is that steady-state nondimensional parameters may be insufficient to qualitatively or quantitatively characterize some features of OSBL turbulence under rapidly variable forcing. They also speculate that the disappearance of the large structures during the eye passage may reflect a sharp sensitivity to a ratio of two time scales: a time scale over which the large structures grow, and a time scale over which the mean flow or forcing evolves. This hypothesis is plausibly relevant in our LES as well, although the growth time scale of Ekman layer instabilities is thought to be much longer than Langmuir cells, and future work is necessary to test this hypothesis. We return to a discussion of the potential implications of missing surface waves in the LES below.

2) Kelvin–Helmholtz billows

The simulated large-scale structures just above the thermocline are also qualitatively similar to various oceanic observations of billows associated with shear instabilities in that they reveal temperature overturns wrapped by broken braids of strong vorticity that in some (rare) cases form cat's-eye patterns consistent with finite-amplitude Kelvin–Helmholtz billows in regions with a mean-profile $\mathrm{Ri}_g \approx 1/4$ (Seim and Gregg 1994; Chang et al. 2016). The crests and troughs of the simulated billows are oriented perpendicular to the mean shear vector at the depth of the thermocline, and their wavelength (about 125 m at the beginning of phase III) is consistent with the fastest growing linear KH instability on a canonical $\tanh(z/L)$ stratified shear layer with $L \approx 10$ m (Hazel 1972). However, the dominant-scale mode is also plausibly a result of merging or some other dynamical interaction and thereby associated with KH modes of a similar but different size [e.g., with half the wavelength and $L \approx 5$ m; see, e.g., Seim and Gregg (1994), Smyth and Moum (2000), and Smyth (2003)]. But, an exact match to theory is neither expected nor pursued since the observed mean shear and stratification are not exactly consistent with the canonical tanh profiles and the KH billows coexist with finite amplitude variance due to a range of other processes and scales (e.g., ambient turbulence lofted down from higher in the boundary layer; see Kaminski and Smyth 2019). Finally, it is worth reiterating that these billow-like structures are more the exception than the norm, although they are still directly responsible for ~10% of the covariances.

b. Missing processes

1) Surface gravity waves

Even though the SST cooling and rapid entrainment response to Hurricane Irene is qualitatively represented in the LES, one missing process that might significantly impact the OSBL turbulence described above is surface gravity waves. A future study with the Craik–Leibovich (CL) equations (e.g., McWilliams et al. 1997; Tejada-Martinez and Grosch 2007; Sullivan et al. 2012; Van Roekel et al. 2012; Large et al. 2019) might elucidate some effects of the time-dependent and misaligned waves and winds. Our omission of the wave effects captured by the CL equations might be cast as an assumption that the turbulent Langmuir number, i.e., $\mathrm{La}_t = \sqrt{u_*/u_s}$, where u_s is the surface Stokes velocity (Li et al. 2005), is sufficiently large. Although calculating the Stokes velocity for the wave field under Hurricane Irene is beyond the scope of this paper, La_t is likely within the range of 0.1–1 most of the time (e.g., as in the scenarios studied by Sullivan et al. 2012; Gargett and Savidge 2020), and thus CL effects are probably nonnegligible and likely dominant at some times. However, since the dominant waves (in the WaveWatch III simulation of Hurricane Irene; https://polar.ncep.noaa.gov/waves/hindcasts/prod-multi_1.php; Chawla et al. 2013) were often misaligned with the winds, which rotate rapidly, La_t itself may overestimate the CL effects (Van Roekel et al. 2012). In addition, there are other wave effects not captured by the CL equations that make it difficult to conjecture about the impact of waves in this scenario. For example, one issue is that the peak significant wave height is 8 m (in the WaveWatch III model) in 35 m of water, and the wave dynamics are in the intermediate regime (with peak wave periods ranging from about 14 to 7 s) where they are substantially modified by the shallow bottom. Further, wave-driven bottom boundary layer dynamics may also impact the evolution of the mean profiles (Grant and Madsen 1979, 1986) in ways not accounted for in either the LES reported here or an analogous simulation of the CL equations.

2) Pressure gradient forces and large-scale circulation

A second mechanism that may cause the OSBL turbulence to differ in the real ocean compared to the LES is the large-scale dynamics. In comparison to the surface waves, the effect of this process on the OSBL turbulence is more indirect, although probably more significant for the mean profile evolution and fluxes. In particular, pressure-gradient-driven flows arise due to the interactions of the wind-driven flow with the coastal boundary (e.g., Kundu et al. 1983; Glenn et al. 2016; Kelly 2019). As reported by Glenn et al. (2016), this process is likely responsible for both the observed stronger bottom velocity and weaker surface velocity relative to LES. In addition, the strong bottom flow activates the bottom boundary layer. Hence, mixing of the thermocline will occur both from below and above. Since the pressure gradient flows can induce a baroclinic response, they can both increase and decrease the vertical shear at the thermocline and could therefore reduce or increase mixing. Future work might evaluate the impact of the lateral pressure gradient forces on the OSBL turbulence in this scenario by imposing these forces, as simulated in the ocean model of Glenn et al. (2016), on the LES, and thereby build on the surface fluxes imposed in the control integration discussed here.

6. Conclusions

Hurricane Irene passed over the New Jersey Shelf on 28 August 2011. Ahead of the eye, wind-driven turbulent mixing led to rapid cooling of the SST by over 4°C, which contributed to energy loss via air–sea heat flux from the hurricane to the ocean and the resulting rapid decay from category 3 to category 1 during 28 August (Glenn et al. 2016; Seroka et al. 2016). Here, we report a large-eddy simulation of the ocean turbulence at horizontal scales from 2 km to 1 m in a box of ocean just to the right of where the eye passed in the middle of the New Jersey shelf. The simulation was forced by our best estimates of the time-evolving air–sea heat and momentum fluxes during the storm and the analysis focuses on the period of time when the winds strengthen and then rapidly rotate as the storm approaches and passes; the poststorm period when the winds decay and the simulated surface boundary layer extends to the bottom is left for future work.

Despite the omission of surface gravity wave effects and large scale ocean circulation dynamics, the simulation captures the observed rapid ahead-of-eye cooling of SST and deepening of the surface mixed layer. The results show that the rapid ahead-of-eye cooling was due to two factors: 1) the shallow and sharp thermocline before the storm, which facilitates both a relatively rapid SST response for a given entrainment rate, as well as a relatively rapid entrainment rate for a given wind forcing, and 2) the magnitude of the wind stress, which supplies the energy for entrainment. However, the most striking feature of the simulation and the focus of the analysis is on ephemeral large coherent structures with aspect ratios ~10 that dominated the turbulent kinetic energy and buoyancy variance at various times and depths within the OSBL.

A descriptive analysis shows that the large-aspect-ratio structures have many similarities and some differences to the classic helical Ekman layer rolls in the top 5–10 m and Kelvin–Helmholtz billows just above the thermocline, both of which have been previously observed in the atmosphere and ocean and have a well-developed basis in linear instability theory. The simulated rolls have a peak characteristic speed of $\sim$10 cm s^{-1} and a wavelength of about 300 m just before the eye, only to be washed away by the rapid rotation of the wind as the eye passes. In addition, there is striking kilometer-scale spatial modulation of the KH billows in the thermocline, which are present to some degree at most times but have a growing dominant horizontal wavelength, are far from spatially ubiquitous, and have variable orientations and degrees of organization.

Analysis of the horizontal wavenumber spectra and cospectra allow us to separate and quantify the contribution of the large-scale structures to the turbulent kinetic energy and net vertical fluxes. We find that the large structures directly contribute more than half of the kinetic energy and buoyancy variance, ~10% of the total fluxes of momentum and buoyancy, and they may modify the turbulent Prandtl number by up to 50% (from say 1 to 1.5). Although these impacts on the mean profiles are substantial, the relatively small contribution of large scales to the total fluxes suggests that the large structures probably only modestly alter the mean profile evolution (by ~10%). Consistent with this suggestion, profiles of momentum flux, buoyancy flux, and the corresponding turbulent viscosity and diffusivity nearly collapse to time-independent profiles when appropriately nondimensionalized, despite the transient nature of the dynamics. Nevertheless, if the SST evolution in a similar model scenario is desired to within better than perhaps 0.5° (or about 10%), then the large-aspect-ratio structures are probably important to account for explicitly. The simulated large turbulent structures have some qualitative similarities to known linear instability models. Thus, these linear models may be a useful starting point for parameterization development, but future LES in other parts of parameter space are probably necessary to provide guidance and validation.

Finally, since this LES is an idealized process simulation, which omits potentially important surface gravity wave effects and larger-scale ocean circulation dynamics, caution should be exercised in extrapolating from these results to the real ocean. Although there are encouraging qualitative similarities between the LES and the observations of Gargett and Savidge (2020) of the coastal ocean response to a different hurricane, future simulations exploring the impacts of the missing processes in the LES as well as observational validation of the results presented here would be necessary to make robust conclusions about the dynamics of the large-aspect-ratio structures such as those simulated here under a hurricane. As mentioned above, such future efforts may be warranted if models of the SST evolution under a hurricane are desired to within 10% accuracy.

ABSTRACT

Underwater gliders allow efficient monitoring in oceanography. In contrast to buoys, which log oceanographic data at individual depths at only one location, gliders can log data over a period of up to one year by following predetermined routes. In addition to the logged data from the available sensors, usually a conductivity-temperature-depth (CTD) sensor, the depth-average velocity can also be estimated using the horizontal glider velocity and the GPS update in a dead-reckoning algorithm. The horizontal velocity is also used for navigation or planning a long-term glider mission. This paper presents an investigation to determine the horizontal glider velocity as accurately as possible. For this, Slocum glider flight models used in practice will be presented and compared. A glider model for a steady-state gliding motion based on this analysis is described in detail. The approach for estimating the individual model parameters using nonlinear regression will be presented. In this context, a robust method to accurately detect the angle of attack is presented and the requirements of the logged vehicle data for statistically verified model parameters are discussed. The approaches are verified using logged data from glider missions in the Indian Ocean from 2016 to 2018. It is shown that a good match between the logged and the modeled data requires a time-varying model, where the model parameters change with respect to time. A reason for the changes is biofouling, where organisms settle and grow on the glider. The proposed method for deciphering an accurate horizontal glider velocity could serve to improve the dead-reckoning algorithm used by the glider for calculating depth-average velocity and for understanding its errors. The depth-average velocity is used to compare ocean current models from CMEMS and HYCOM with the glider logged data.

1. Introduction

Today, underwater gliders are an inherent part of monitoring oceans. These platforms have proven their efficiency and robustness in the collection of oceanographic data in the last two decades [1–3]. The first operational underwater gliders, called “legacy gliders”, were the *Seaglider* [4] built by the University of Washington, the *Spray* [5] built at the Scripps Institution of Oceanography, and the *Slocum* [6] developed by the Webb Research Corporation. This paper focuses on the Slocum glider. It should be noted that the equations and methods presented are also applicable to other glider types. The data used are from the Center for Ocean Observing Leadership (COOL) at Rutgers University [7]. The Rutgers glider team started with the first Slocum glider missions in 2003 [8]. Since that time, the team has conducted 505 missions, which have mapped ocean properties over 252,944 km during 13,563 days at sea. The team is also involved in the Challenger Glider Mission, which is an international science effort to navigate a fleet of gliders on a global mission of discovery [9,10]. The gliders will retrace the path of the *HMS Challenger*, measuring temperature, salinity and current. The four-year voyage of the *HMS Challenger* that began in 1872 sought to answer significant questions about the world’s oceans. The measurements of the present day Challenger Glider Mission will be used to assess the capabilities of the most recent Ocean General Circulation Models. The Mission has completed the survey of the South Atlantic Ocean and is in the middle of the Indian Ocean leg as of publication. The data used in this paper is taken from the Indian Ocean transect.

Accurate determination of the glider states during a mission is a prerequisite for its control and the derivation of in-situ ocean current data. This requires an accurate glider model that should reflect the glider behavior in the current environmental conditions, such as salinity, temperature, pressure, bathymetry, and ocean current. The wing

configuration [11], the fitted sensors [12] and biofouling [13] also have an important influence on the glider model and should be considered.

The angle of attack is of crucial importance in glider modeling. It will be used for the calculation of the horizontal and vertical glider velocity. The horizontal glider velocity is required for dead-reckoning navigation during a mission [14] and for estimating the depth-average velocity [15]. The depth-average velocity results from the difference between the glider velocity over ground and the horizontal glider velocity through water. The horizontal velocity is also applied in the planning for long-term glider missions to find an optimal/passable path from a defined start to a goal and to get information about the feasibility of the mission with regards to energy consumption and the estimated arrival time at the goal [16]. The difference between the vertical glider velocity and the depth rate was used in [17] to determine the vertical current velocity.

Section 2 presents the glider flight model with relations and dependencies of the angle of attack and the horizontal glider velocity, which are based on the analysis of Slocum glider models presented in Section 3. The order of the sections (first: glider model used, second: relevant glider models) relates to the fact that many issues presented in Section 3 are explained in Section 2. Approaches to estimate the model parameters and to determine the angle of attack will be described in Section 4. Section 5 presents the results of the parameter identification for various parameter sets. Requirements regarding the logged data in order to determine trustworthy model parameters will be discussed. Horizontal glider velocities from a long-term mission are used in Section 6 to calculate the depth-average velocities which are used for the comparison of ocean current models from CMEMS [18] and HYCOM [19] with the glider data.

2. Glider flight model

A generally used glider model for a steady-state gliding motion will be described in the following sections.

2.1. Calculation of the horizontal glider velocity

Fig. 1 shows a schematic illustration of a glider with the defined reference frame, angles, velocities and forces.

It should be noted that the angle relations in Fig. 1 correspond to real glider conditions where a glider has a positive angle of attack α during the dive phase and a negative angle of attack during the climb phase.

The navigation of a glider, the planning of a long term glider mission or the in-situ estimation of the ocean current conditions during a mission require information about the correct horizontal glider velocity v_x. This velocity is dependent on the vertical glider velocity v_z and the glide path angle ξ, which is the result of the relation between the pitch angle θ and the angle of attack α

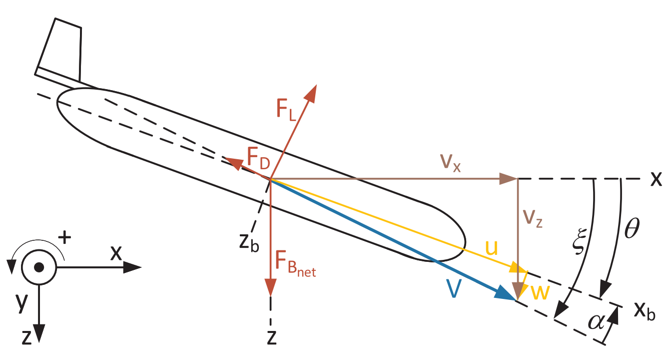

Fig. 1. Illustration of the defined reference frame, angles, velocities and forces for a glider.

$$\xi = \theta - \alpha \tag{1}$$

The angle of attack α is defined as the angle between the projection of the total velocity vector of the glider $\mathbf{V} = [u, v, w]$ onto a vertical plane, formed by the body-fixed x_b- and z_b-axes ($x_b - z_b$ plane), and the body-fixed x_b-axis. The angle α can be defined with the body-fixed velocities u and w as

$$\alpha = \tan^{-1}\left(\frac{w}{u}\right) \tag{2}$$

Assuming that the glider has zero roll and no yaw moment, this vertical plane can be used for a simplified glider flight model when the glider moves only in this plane. This assumption and the requirement for a symmetrical glider body will form the basis for the following modeling steps. This way, the resulting glide speed V can be calculated with the two body-fixed velocities u and w as

$$V = \sqrt{u^2 + w^2} \tag{3}$$

which can also be described with the horizontal and vertical glider velocity through water v_x, v_z as

$$V = \sqrt{{v_x}^2 + {v_z}^2} \tag{4}$$

and as function of the glide path angle ξ

$$V = -\frac{v_z}{\sin(\xi)} = -\frac{v_z}{\sin(\theta - \alpha)} \tag{5}$$

The horizontal glider velocity v_x, which is of interest, can be computed as

$$\begin{aligned} v_x &= -\frac{v_z}{\tan(\xi)} = -\frac{v_z}{\tan(\theta - \alpha)} \\ &= V\cos(\xi) = V\cos(\theta - \alpha) \end{aligned} \tag{6}$$

The vertical glider velocity (through water) v_z results from the difference between the depth rate (vertical velocity over ground) $\dot{z}$ and the vertical current velocity $v_{z_{current}}$, which is generally assumed to be zero

$$v_z = \dot{z} - v_{z_{current}} \overset{v_{z_{current}}=0}{\Rightarrow} v_z = \dot{z} \tag{7}$$

In contrast to the variables vertical glider velocity v_z and pitch angle θ, which can be directly derived from the logged glider data during the steady-state gliding, the angle of attack α has to be detected using additional glider parameters. The necessary steps and relationships for this are described below.

2.2. Force-velocity relations

The horizontal and vertical force equations for the glider in the vertical plane at equilibrium steady glides are

$$F_D\cos(\xi) + F_L\sin(\xi) = 0 \tag{8}$$

$$-F_D\sin(\xi) + F_L\cos(\xi) = F_{B_{net}} \tag{9}$$

where F_D is the drag force, F_L is the lift force, ξ is the glide path angle and $F_{B_{net}}$ is the net buoyancy force of the glider given by $F_{B_{net}} = m_0 g$, the product of the excess mass m_0 and the acceleration due to gravity g. The excess mass m_0 can be defined using the total vehicle mass m_v and the mass of displaced fluid m as $m_0 = m_v - m$. For a neutral buoyancy trimmed glider, m_0 corresponds to the variable ballast mass m_b. For safety reasons, a glider is often trimmed slightly light, so that it floats when the buoyancy engine is set to $m_b = 0$. Therefore, a buoyancy trim offset Δm_0 has to be added to the resulting excess mass:

$$m_0 = m_b + \Delta m_0 \tag{10}$$

Re-arranging Eqs. (8) and (9) into a separate description for F_D and F_L gives the buoyancy force components

$$F_D = -m_0 g\sin(\xi) \tag{11}$$

$$F_L = m_0 g\cos(\xi) \tag{12}$$

The hydrodynamic forces are modeled as

$$F_D = \frac{1}{2}\rho C_D(\alpha) A V^2 \tag{13}$$

$$F_L = \frac{1}{2}\rho C_L(\alpha) A V^2 \tag{14}$$

where C_D and C_L are the non-dimensional drag and the lift coefficients which refer to the reference area A, ρ is the density of water, and V is the glide speed.

2.3. Angle of Attack relations

The coefficients C_D and C_L are functions of the angle of attack α and will be generally modeled as

$$C_D = C_{D_0} + C_{D_2}\alpha^2 \tag{15}$$

$$C_L = C_{L_1}\alpha \tag{16}$$

Using the horizontal force Eq. (8) and the hydrodynamic force Eqs. (13) and (14), the glide path angle ξ can be calculated as

$$\tan(\xi) = \frac{\sin(\xi)}{\cos(\xi)} = \tan(\theta - \alpha) = -\frac{F_D}{F_L} = -\frac{C_D(\alpha)}{C_L(\alpha)} \tag{17}$$

The necessary steps to solve α numerically will be presented in Section 4.2.

A characteristic value to describe the gliding flight is the lift-to-drag ratio L/D which can be described using Eqs. (13)-(16) as

$$L/D = \frac{F_L}{F_D} = \frac{C_L(\alpha)}{C_D(\alpha)} = \frac{C_{L_1}\alpha}{C_{D_0} + C_{D_2}\alpha^2} \tag{18}$$

There is a maximum in L/D [20] at

$$\alpha_{(L/D)\max} = \pm\sqrt{\frac{C_{D_0}}{C_{D_2}}} \tag{19}$$

with a value of

$$(L/D)_{\max} = \frac{C_{L_1}}{2C_{D_0}}\sqrt{\frac{C_{D_0}}{C_{D_2}}} \tag{20}$$

The smallest glide angle $\xi_{\min}$ is at $(L/D)_{\max}$ and can be calculated as

$$\xi_{\min} = \xi_{(L/D)\max} = \pm\cot^{-1}\left(\frac{C_{L_1}}{2C_{D_0}}\sqrt{\frac{C_{D_0}}{C_{D_2}}}\right) \tag{21}$$

where $\cot^{-1}$ is the arccotangent.

Using Eq. (11) in (13) or (12) in (14), the glide speed V can be described as function of the related buoyancy force component to the hydrodynamic force as

$$V = \sqrt{-\frac{2m_0 g\sin(\xi)}{\rho A C_D(\alpha)}} \tag{22}$$

or

$$V = \sqrt{\frac{2m_0 g\cos(\xi)}{\rho A C_L(\alpha)}} \tag{23}$$

The vertical glider velocity v_z can be calculated by substituting Eq. (23) and a sine relation of the glide path angle ξ in Eq. (17) into Eq. (5)

$$v_z = \underbrace{\sqrt{\frac{2m_0 g\cos(\xi)}{\rho A C_L(\alpha)}}}_{V}\underbrace{\frac{C_D(\alpha)}{C_L(\alpha)}\cos(\xi)}_{-\sin(\xi)} = \sqrt{\frac{2m_0 g\cos(\xi)^3 C_D(\alpha)^2}{\rho A C_L(\alpha)^3}} \cong \sqrt{\frac{2m_0 g C_D(\alpha)^2}{\rho A C_L(\alpha)^3}} \tag{24}$$

Eq. (24) allows the calculation of the angle of attack for minimum vertical glider velocity $\alpha_{v_z,\min}$ by maximizing the term $C_L(\alpha)^3/C_D(\alpha)^2$ in the simplified equation, where the cosine term is ignored [21]. For typical, small glide angles ξ is the term $cos(\xi)^3$ close to one and constant. The solution of the extreme value problem

$$\frac{\partial}{\partial\alpha}\left(\frac{C_L(\alpha)^3}{C_D(\alpha)^2}\right) = \frac{\partial}{\partial\alpha}\left(\frac{{C_{L_1}}^3\alpha^3}{(C_{D_0} + C_{D_2}\alpha^2)^2}\right) = 0 \tag{25}$$

results in

$$\alpha_{v_z,\min} = \pm\sqrt{\frac{3C_{D_0}}{C_{D_2}}} \tag{26}$$

whereby the glide angle $\xi_{v_z,\min}$ can be calculated as

$$\xi_{v_z,\min} = \pm\cot^{-1}\left(\frac{C_{L_1}}{4C_{D_0}}\sqrt{\frac{3C_{D_0}}{C_{D_2}}}\right) \tag{27}$$

In analogy to the approach described above it is possible to determine the glide path angle where the horizontal glider velocity v_x has its maximum. Substitute Eq. (22) into (6)

$$v_x = \sqrt{-\frac{2m_0 g sin(\xi)}{\rho A C_D(\alpha)}}\cos(\xi) = \sqrt{-\frac{2m_0 g sin(\xi)\cos(\xi)^2}{\rho A C_D(\alpha)}} \cong \sqrt{-\frac{2m_0 g sin(\xi)\cos(\xi)^2}{\rho A C_{D_{const}}}} \tag{28}$$

and maximize the term $\sin(\xi)\cos(\xi)^2$ in the simplified Eq. (28), where the drag coefficient $C_D(\alpha)$ for small angles of attack is nearly constant. The extreme value problem for

$$\frac{\partial}{\partial\xi}(\sin(\xi)\cos(\xi)^2) = \cos(\xi)^2 - 2\sin(\xi)^2 = 0 \tag{29}$$

has one solution at

$$\xi_{v_x,\max} = \pm\cot^{-1}(\sqrt{2}) = \pm 35.3^\circ \tag{30}$$

The value $\xi_{v_x,\max} = 35.3^\circ$ is valid for all types of gliders and independent of hydrodynamic coefficients [22].

Fig. 2 shows a graphical representation of the glider velocities v_x and x_z for dive. This form of representation corresponds to the glide

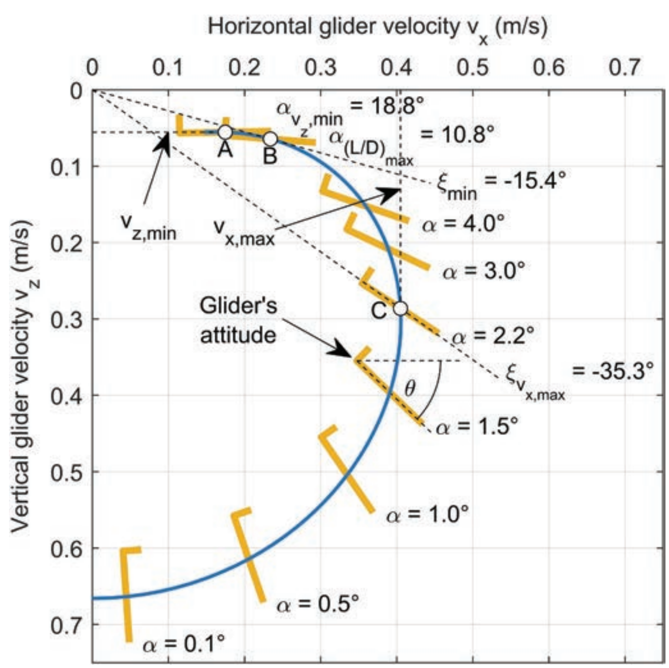

Fig. 2. Glide polar for a Slocum glider using the hydrodynamic coefficients of [14] for a excess mass $m_0 = 250g$. (A) minimum vertical glider velocity $v_{z,\min}$, (B) smallest glide angle $\xi_{\min}$, (C) maximum horizontal glider velocity $v_{x,\max}$.

polar of a sailplane [23] and can be used for graphical analysis and to determine the glider velocities v_x and v_z and angles α, ξ and θ for the operation point of interest. This plot is mirrored on the abscissa to the commonly used glide polar representation for a glider [22,24,25]. A glider should be flown within a glide angle range between $\xi_{\min}$ and $\xi_{x,\max}$ and between the operation points B and C. Here the slowest glide slope is defined at the maximum lift-to-drag ratio and results in the minimum specific energy consumption of the glider [22]. This slope is called stall glide slope in [25]. Flying at higher angles of attack will enable the lowest sink rate of a glider $v_{z,\ \min}$ in operation point A. Because the linear relation of the lift curve $C_L(\alpha)$ is not guaranteed for high angles of attack, this operation range should be avoided. The lift curve is dependent on the structural design of the glider and is mainly influenced by the shape of the wings. High angles of attack result in boundary layer separation and the wings stall [26].

3. Relevant work about slocum glider models

This section presents relevant work about the modeling of Slocum gliders. The interested reader will find information about model design, strategies to find the model parameters and relations between the individual models.

3.1. Relevant work

Vehicle Control Technologies, Inc. (VCT) [27] used computational fluid dynamics (CFD) computations to determine the coefficients C_D and C_L of the Slocum glider. These results are published in [24] and [26]. In this work, the coefficients C_D and C_L are normalized by the square length of the hull of 1.789 m. The reference area A is thus $(1.789\ \text{m})^2 = 3.2\ \text{m}^2$.

Graver [28] directly used the lift coefficient from [27] with a rescaling in his reference area, i.e. the frontal area of the vehicle for his glider flight model. With a glider diameter of 0.2127 m the reference area is $A = 0.0355\ \text{m}^2$. The drag coefficient was determined using the glider logging data and the given lift coefficient. An estimation of the buoyancy trim offset Δm_0 was necessary to avoid an asymmetrical drag coefficient curve.

Bhatta [29] used hydrodynamic force equations by analogy with Eqs. (37) and (38) so that the reference area definition could be omitted. Some parameters were estimated using glider logging data from sea trials in [28] and wind tunnel experiments in [26].

Williams et al. [30] used an iterative scheme to obtain estimates for the parameters C_{D_0}, C_{D_2} and C_{L_1} for the lift and drag coefficients. The individual parameters were determined sequentially in a loop using the logged glider data: pitch angle θ, vertical glider velocity v_z and the net buoyancy $F_{B_{net}}$. This loop is stopped when all parameters converge to a stable set. Here the reference area A is the frontal area of the glider. The values of the estimated parameters during dive are different from the values during climb. According to [30] this is due to the ballasting procedure. Williams's work also includes a detailed hydrodynamical analysis of a hull with a length-to-diameter ratio similar to a Slocum glider tested in a towing tank.

Merckelbach et al. [17] consider the hull and wings of a Slocum glider separately for the parameters of the lift and drag coefficients. The individual parameters for hull and wings are added together to give the total coefficients, so that they can be used in Eqs. (15) and (16). The buoyancy force calculation used considered the additional influences of water pressure P and water temperature T on the volume of the displaced fluid

$$F_B = g\rho\{V_g[1 - \varepsilon P + a_T(T - T_0)] + \Delta V_{bp}\} \tag{31}$$

where V_g is the glider volume at atmospheric pressure, ε is the compressibility of the hull, a_T is the thermal expansion coefficient, and ΔV_{bp} is the volume change resulting from the buoyancy engine. Therefore, the parameters V_g and ε are estimated using the logged glider data. An additional estimated parameter is C_{D_0} in Eq. (15). All other parameters in Eqs. (15) and (16) are the result of experiments or empirical formulas as described below. The determined parameters C_{D_2} and C_{L_1} from hull tow tests in Williams et al. [30] were used for the hull segment. Since these parameters refer to the frontal area A_F, rescaling is applied. The reference area in this work is the wing surface area $A_W = 0.1\ \text{m}^2$. The rescale factor is therefore $A_F/A_W = 0.038/0.1 = 0.38$. The parameter C_{L_1} for the lift coefficient of the wings is the result of a semiempirical formula [31] for a lift-curve slope using the aspect ratio $\mathcal{R}$, and the wing sweep angle Λ. (A detailed analysis and comparison of possible formulas for a lift-curve slope for a Slocum glider is given in [32].) Prandtl's lifting line theory was used for modeling the drag coefficient of the wings. In this theory the drag coefficient C_D has two terms, a parasitic drag C_{D_0} as a result of the form drag or pressure drag, the skin friction drag and the interference drag and an inducted drag C_{D_i} calculated using Prandtl's lifting-line theory

$$C_D = C_{D_0} + C_{D_i} = C_{D_0} + K{C_L}^2 \tag{32}$$

where

$$K = \frac{1}{\pi e \mathcal{R}} \tag{33}$$

The aspect ratio $\mathcal{R}$ is calculated as b^2/A_W, where b is the wing span and A_W is the wing area. The span efficiency parameter e in Eq. (33) allows the consideration of a real lift distribution, which is usually disturbed through the addition of fuselage, engine nacelles or other parts [33]. It should be noted that some of the relations used to describe the hydrodynamic vehicle behavior are based on aerodynamic studies where there is a wealth of experience. Another name for this factor is the Oswald efficiency factor. (A wide range of approaches to calculate this factor are presented in [34].)

Mahmoudian [35] also used Eq. (32) to describe the drag coefficient of the entire glider. The parameters used for the lift and drag coefficient in this model are from Bhatta [29].

Cooney [14] used exclusively empirical formulas from [33] to describe the glider behavior. Analogous to Merckelbach [17], a separate consideration of the hull and wings of a Slocum glider is conducted. The calculation of the drag coefficient is based on Eq. (32) where the parasitic drag C_{D_0} is exclusively the result of the pressure drag. The calculation of the pressure drag is based on Hoerner [33] (3–12 equation (25))

$$C_{D_0} = 0.44\frac{D}{L} + 4C_f(\text{Re})\frac{L}{D} + 4C_f(\text{Re})\sqrt{\frac{D}{L}} \tag{34}$$

where D is the hull diameter, L is the characteristic length and $C_f(\text{Re})$ is the skin-friction drag coefficient for a flat plate in laminar flow which is a function of Reynolds number Re

$$C_f = \frac{1.328}{\sqrt{\text{Re}}} \tag{35}$$

The Reynolds number Re represents the ratio of the dynamic forces relative to the friction forces [33] as

$$\text{Re} = \frac{VL}{\nu} \tag{36}$$

where V is the glide speed, L is the characteristic length and ν the fluid kinematic viscosity, which is taken to be $1.35\times 10^{-6}\ \text{m}^2/\text{s}$ at 10 °C. The speed-dependent behavior of the drag coefficient is a unique feature compared to the other models presented. Fig. 3 shows the pressure drag C_{D_0} as a function of glide speed V. Thus, a lower glide speed V leads to a greater drag coefficient C_D. The lift coefficient C_L due to the wings is determined using the lifting-line theory of swept wings. The parameters of the empirical formula are the aspect ratio $\mathcal{R}$ and the wing sweep angle Λ.

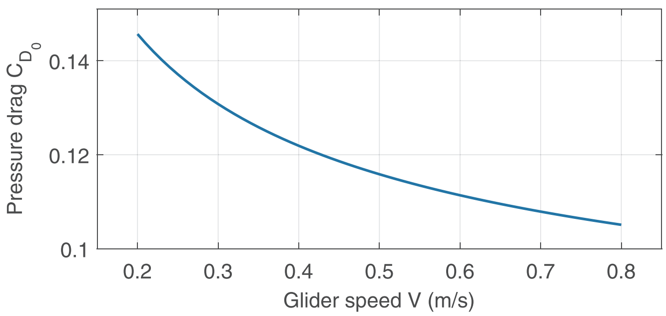

Fig. 3. Pressure drag C_{D_0} as function of glide speed V.

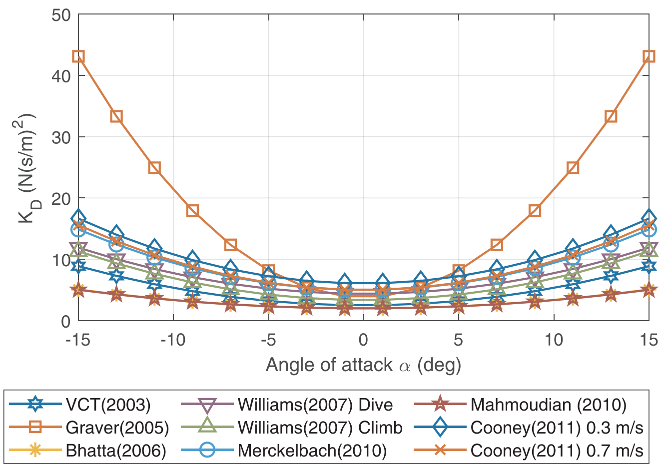

Fig. 4. Drag coefficient K_D of the individual models.

3.2. Comparison of the models

Although the models presented above describe the lift and drag coefficients for a Slocum glider, it is difficult to compare the individual parameters. The reasons for this are the different definition for the reference area A in Eqs. (13) and (14), different analytical equations to describe the drag and the lift coefficients, different types of Slocum glider and wing configurations. To compare the parameters used in the individual models, the following hydrodynamic force equations with the dimensioned lift and drag coefficients K_L and K_D will be used

$$F_D = \frac{\rho}{\rho_{fw}} K_D V^2 = \frac{\rho}{\rho_{fw}} \left(\underbrace{K_{D0}}_{\frac{1}{2}\rho_{fw} A C_{D0}} + \underbrace{K_{D_2}\alpha^2}_{\frac{1}{2}\rho_{fw} A C_{D_2}} \right) V^2 \tag{37}$$

$$F_L = \frac{\rho}{\rho_{fw}} K_L V^2 = \frac{\rho}{\rho_{fw}} \left(\underbrace{K_{L_1}}_{\frac{1}{2}\rho_{fw} A C_{L_1}} \alpha \right) V^2 \tag{38}$$

where p_{fw} is the density of freshwater 1000 kg/m^3. The relations of the dimensioned parameters K_{L_1}, K_{D_0} and K_{D_2} to the non-dimensioned parameters C_{L_1}, C_{D_0} and C_{D_2} in Eqs. (13) and (14) are located below the underbraces. This form of equation will also be used in this paper. Table 1 shows the individual parameters K_{L_1}, K_{D_0} and K_{D_2} and the characteristic values $\alpha_{(L/D)_{\max}}$, $(L/D)_{\max}$ and $\xi_{\min}$ calculated from it for the individual models.

It should be noted that the lift coefficient in VCT [27] and Graver [28] is defined as

$$C_L = C_{L_1}\alpha + C_{L_2}\alpha|\alpha| \tag{39}$$

which does not allow a direct comparison with the other models. In these cases, a linear regression can be used to estimate a linear coefficient C_{L_1} for Eq. (16). Therefore, the data points for α will be created ranging from 0° to 10°, which form the elements of the regression matrix $\mathcal{A}$. The lift coefficient values for Eq. (39) can now be calculated using these data points. These calculated values form the output variable y in the regression. This results in a parameter K_{L_1} equal to 219.93 ± 0.17 kg/m/rad for VCT and 219.43 ± 0.17 kg/m/rad for Graver.

To use a fixed drag coefficient for Cooney's work [14], two operating points, a glide speed $V = 0.3$ and $V = 0.7$ m/s, were chosen in Eq. (34). These give two K_{D_0} values of 6.06 and 5 kg/m which allow a direct comparison with the other models.

Table 1 shows a wide dispersion of the parameters and characteristic values. This also is evident in Figs. 4 and 5, which show the drag and lift coefficients as a function of α for the models. The curves of lift-to-drag ratio in Fig. 6 as well as the curves of glide path angle in Fig. 7 for dive, where the angle of attack α is positive show four characteristic groups (The curves for negative angles of attack are mirrored in the diagonal quadrant.). The corresponding group number is shown to the right of the curves.

The first group includes the work from VCT [27], Bhatta [29], Merckelbach [17] and Mahmoudian [35] where the maximum in L/D lies between 5.7 and 7.2 for α between 9.4° and 12.2°. The second group contains the results from Cooney [14] where the maximum in L/D lies between 3.5 and 3.8 for α between 10.3° and 11.3°. A third group contains the results of Williams [30]. The L/D curves for the dive and climb are similar, but the maximum in L/D lies at 1.8, which equals approximately one-third of the value of the first group. A reason for this could be in the initial configuration for the iterative scheme, which includes parameters only of the glider hull detected in the towing tank tests. The α values are again similar to the first group. The last group includes Graver's model. The maximum in L/D is 2.35 at an α of 4.7°. There is also a significant difference in the drag coefficient curve in Fig. 4 compared to the other models. Possible explanations for the high drag coefficient used by Graver [28] are complex geometry through wing deformation and a CTD sensor in real or bad data logging conditions due to a sideslip angle caused by a static roll.

Fig. 8 shows the determined angle of attack α and the resulting horizontal glider velocity v_x using mean values for the pitch angle θ and the vertical glider velocity v_z in Table 2 for all dives and climbs in the

period from 2018-09-05 to 2018-09-18 for the glider mission RU29-550 from Sri Lanka to Mauritius. As Fig. 8 shows, there is a maximal difference of 8% in the horizontal glider velocity in all models, except Williams. Although the models compared here have different parameters and L/D curves, the calculated horizontal vehicle velocities are close. The maximal difference in the horizontal glider velocity between Williams and the other models is around 20%.

4. Parameter identification

4.1. Background

This section describes an approach to estimating the parameters for the lift and drag coefficients to determine α which is used in Eq. (6) for calculating the horizontal glider velocity v_x. The idea is to minimize the difference between the logged vertical glider velocity v_z, derived from the depth z, and the modeled vertical glider velocity $\hat{v}_z$ using estimated parameters. The vertical force Eq. (9) is used for modeling the vertical glider velocity v_z. Combining Eqs. (5), (37) and (38) into (9) gives

$$- \sin(\xi)\frac{\rho}{\rho_{fw}}(K_{D_0} + K_{D_2}\alpha^2)\left(\frac{v_z}{\sin(\xi)}\right)^2 + \cos(\xi)\frac{\rho}{\rho_{fw}}(K_{L_1}\alpha)\left(\frac{v_z}{\sin(\xi)}\right)^2 = (m_b + \Delta m_0)g \tag{40}$$

Solving for $\hat{v}_z$ gives

$$\hat{v}_z = -\sin(\theta - \alpha)\sqrt{\frac{\rho_{fw}(m_b + \boldsymbol{\Delta m_0})g}{\rho((\boldsymbol{K_{L_1}}\alpha)\cos(\theta - \alpha) - (\boldsymbol{K_{D_0}} + \boldsymbol{K_{D_2}}\alpha^2)\sin(\theta - \alpha))}} \tag{41}$$

The estimated parameters are marked in bold and summarized in the parameter vector β

$$\boldsymbol{\beta} = \langle K_{L_1}, K_{D_0}, K_{D_2}, \Delta m_0 \rangle^T \tag{42}$$

In addition to the parameters for the lift and drag coefficients, the buoyancy trim offset Δm_0 is a further parameter to be estimated. This is necessary since the lift and drag coefficients are used for the modeled vertical glider velocity in both the dive and the climb. Without calibration of the buoyancy trim offset Δm_0, the modeled lift and drag coefficients for the individual dive and climb lie above or below the ideal lines. The parameter vector β can be estimated using a search method to minimize the cost function C given by

$$C(\beta) = \frac{1}{n}\sum_{i=1}^{n}(v_{z_i} - \hat{v}_{z_i})^2 \tag{43}$$

which corresponds to the mean squared error (MSE) where n is the number of all logged dives and climbs within a defined time period. The values ρ, θ and m_b used in Eq. (41) are average values computed for each dive and climb.

4.2. Determination of the angle of attack

The calculation of the lift and drag coefficient in Eq. (41) requires a known angle of attack α. This angle can be solved numerically by inserting Eqs. (37) and (38) into Eq. (17) to give

$$\tan(\theta - \alpha)(K_{L_1}\alpha) + (K_{D_0} + K_{D_2}\alpha^2) = 0 \tag{44}$$

A bisection or bracketing method can be used to solve this one-dimensional optimization task. A bracketing method works without derivatives and finds the minimum through iterative decreasing of the interval until the desired tolerance ϵ is achieved, where the minimum lies. In this approach the bisection method in MATLAB `fzero` and the bracketing methods Golden section search [36], Fibonacci search [37] and Brent's method [38] were tested. Brent's method was used as it requires lesser cost function calls compared to the other methods. On average, 7–9 cost function calls are needed to determine the angle of attack. The MATLAB function name for this bracketing method is `fminbnd`. This method requires a cost function $f(x)$ and a fixed interval $[xl, xu]$ wherein the search parameter x lies. The cost function is defined as

$$f(x) = (\tan(\theta - \alpha)(K_{L_1}\alpha) + (K_{D_0} + K_{D_2}\alpha^2))^2 \tag{45}$$

Good interval values can be found by using a quadratic approximation of Eq. (44) to determine α where the function $tan(x)$ is approximated with x

$$(\theta - \alpha)(K_{L_1}\alpha) + (K_{D_0} + K_{D_2}\alpha^2) = 0 \tag{46}$$

The resulting quadratic equation is therefore

$$\alpha^2 + \frac{K_{L_1}\theta}{(K_{D_2} - K_{L_1})}\alpha + \frac{K_{D_0}}{(K_{D_2} - K_{L_1})} = 0 \tag{47}$$

The approximated angle of attack α can be solved using the discriminant *disc*. An evaluation of the real roots gives

$$\begin{aligned}
&disc = \frac{K_{L_1}{}^2\theta^2}{4(K_{D_2}-K_{L_1})^2} - \frac{K_{D_0}}{(K_{D_2}-K_{L_1})}\\
&\text{if } (disc < 0) \text{ then } disc = 0\\
&\alpha_{1,2} = -\frac{K_{L_1}\theta}{2(K_{D_2}-K_{L_1})} \pm \sqrt{disc}\\
&\alpha = \min(|\alpha_1|, |\alpha_2|)
\end{aligned} \tag{48}$$

In cases that $|K_{D_2} - K_{L_1}| < 10^{-9}$, the quadratic Eq. (47) reduces to a linear equation, where α can be calculated using

$$\alpha = -\frac{K_{D_0}}{K_{L_1}\theta} \tag{49}$$

The resulting interval is calculated using α from Eq. (48) or (49) by

$$\begin{aligned} x_l &= \alpha - \Delta\alpha\\ x_u &= \alpha + \Delta\alpha \end{aligned} \tag{50}$$

where $\Delta\alpha$ was chosen as 3°. This value worked well for all examined glider missions. The cost function $C(\beta)$ in Eq. (43) thus includes an internal search procedure to detect the corresponding angle of attack α for every dive or climb.

4.3. Initial parameters setting

To guarantee a good convergence and to find the global minimum, initial parameters have to be defined. The parameters for the lift and drag coefficients K_{L_1}, K_{D_0}, and K_{D_2} from Cooney [14] were used as initial parameters in this paper (The parameter K_{D_0} corresponds to the mean value of this parameter in Table 1). The initial parameter for the buoyancy trim offset Δm_0 can be calculated by inserting Eq. (11) into Eq. (37) with the assumption of similar drag coefficients for all dives and climbs as follows

$$V_{dive} = \frac{v_{z\,dive}}{\sin(\xi_{dive})} \qquad V_{climb} = \frac{v_{z\,climb}}{\sin(\xi_{climb})} \tag{51}$$

$$\Delta m_0 = \frac{\bar{m}_{b_{\text{dive}}}\overline{\sin(\theta_{\text{dive}})}\bar{\rho}_{\text{climb}}\bar{V}_{\text{climb}}{}^2 - \bar{m}_{b_{\text{climb}}}\overline{\sin(\theta_{\text{climb}})}\bar{\rho}_{\text{dive}}\bar{V}_{\text{dive}}{}^2}{\overline{\sin(\theta_{\text{climb}})}\bar{\rho}_{\text{dive}}\bar{V}_{\text{dive}}{}^2 - \overline{\sin(\theta_{\text{dive}})}\bar{\rho}_{\text{climb}}\bar{V}_{\text{climb}}{}^2} \tag{52}$$

where the unknown parameter angle of attack α in ξ was set to zero and mean values of all dives and climbs were used.

5. Results

Logged glider data from the Challenger Glider Mission [9,10] was used to evaluate the parameter identification approach presented in Section 4. The goal is the accurate determination of the horizontal glider velocity v_x during a mission using the identified lift and drag coefficients K_{L_1}, K_{D_0} and K_{D_2}. The glider data used in Eq. (41) is the mean values of the water density ρ, the pitch angle θ and the variable ballast mass m_b computed for each dive and climb in the defined time period. The nonlinear regression function `nlinfit` from MATLAB was used to estimate the coefficients. This function uses the Levenberg-Marquardt nonlinear least squares algorithm and allows an easy determination of the confidence intervals for the coefficients using the MATLAB function `nlparci` after the minimization. The independent variable matrix **X**, the parameter vector $\boldsymbol{\beta}$ and the output vector **y** can be written as

$$\mathbf{X} = \begin{bmatrix} \theta_1 & m_{b_1} & \rho_1\\ \theta_2 & m_{b_2} & \rho_2\\ \vdots & \vdots & \vdots\\ \theta_n & m_{b_n} & \rho_n \end{bmatrix} \tag{53}$$

$$\boldsymbol{\beta} = \langle K_{L_1}, K_{D_0}, K_{D_2}, \Delta m_0\rangle^T \tag{54}$$

$$\mathbf{y} = \langle v_{z_1}, v_{z_2}, \ldots, v_{z_n}\rangle^T \tag{55}$$

5.1. Minimizations for different parameter sets

The first tests used data from the glider mission RU29-550 from Sri Lanka to Mauritius for a time period of two weeks from 2018-09-05 to 2018-09-18. The data of the glider state during the time period is shown in Fig. 9.

Five minimizations with different Parameter Sets *PS** to be minimized were executed. The placeholder character * includes the positions of the estimated parameters in the parameter vector in Eq. (54). For example - PS24 means only parameter K_{D_0} and Δm_0 will be estimated, parameter K_{L_1} and K_{D_2} have fixed values and will not be estimated. The estimated parameters and their 95% confidence intervals are shown as black text, while the unestimated parameters are shown in gray text in Table 3. An underlined parameter value represents a statistically insignificant value, where the corresponding confidence interval includes zero.

The unestimated parameters correspond to the parameters from Cooney [14]. The buoyancy trim offset Δm_0 was an estimated parameter in every minimization. The results for all minimizations is similar around −120 g (positively buoyant). This means that the glider is trimmed slightly light, which makes sense for safety reasons. The resulting drag and lift coefficients as a function of α for the individual minimizations are shown in Figs. 10 and 11.

All minimizations found solutions where the modeled vertical glider velocity $\hat{v}_z$ agrees well with the logged vertical glider velocity v_z, as

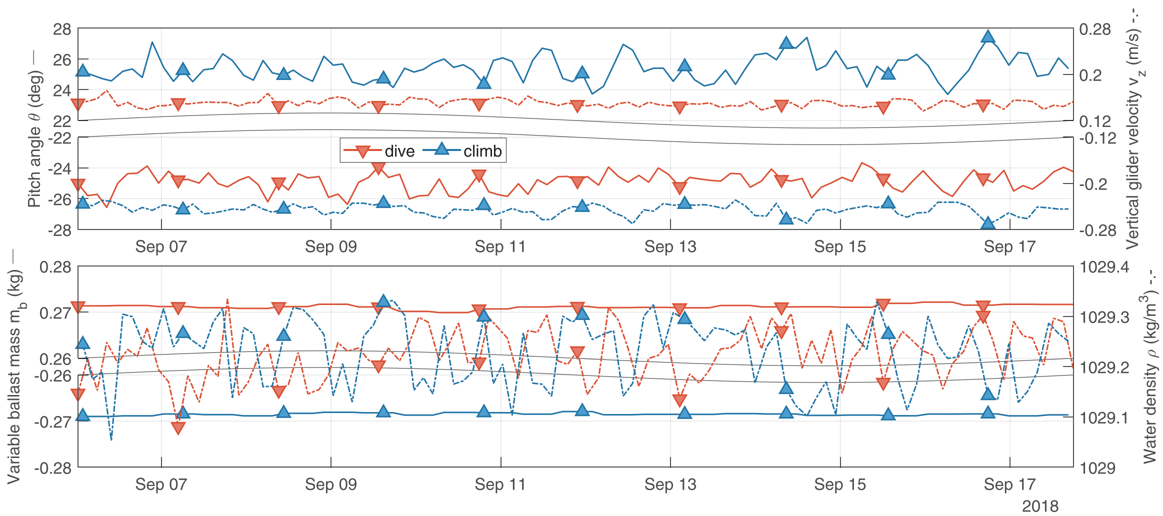

Fig. 9. Glider data used for the minimization: pitch angle θ, vertical glider velocity v_z, ballast mass m_b, water density ρ.

Table 3
Estimated parameters and their confidence intervals (CI).

Minimization	K_{L_1} (95% CI) (kg/m/rad)	K_{D0} (95% CI) (kg/m)	K_{D_2} (95% CI) (kg/m/rad^2)	Δm_0 (95% CI) (kg)
PS14	444.87 [416.67, 473.07]	5.53	154.39	−0.1197 [−0.1215, −0.1180]
PS24	212.28	6.30 [6.24, 6.35]	154.39	−0.1203 [−0.1220, −0.1186]
PS34	212.28	5.53	373.62 [360.63, 386.61]	−0.1198 [−0.1215, −0.1180]
PS234	212.28	7.21 [5.79, 8.63]	−109.54 [−519.36, 300.29]	−0.1207 [−0.1224, −0.1190]
PS1234	126.77 [-2100.06, 2353.59]	6.88 [1.52, 12.23]	169.90 [−1242.60, 1582.39]	−0.1207 [−0.1225, −0.1190]

shown in Fig. 12.

Likewise, the calculated drag and lift coefficients K_D and K_L, found using the logged glider data by substituting Eqs. (5) and (11) into Eq. (37)

$$K_D = -m_0 g \sin(\xi) \frac{\rho_{fw} \sin(\xi)^2}{\rho {v_z}^2} \tag{56}$$

and by substituting Eqs. (5) and (12) into Eq. (38)

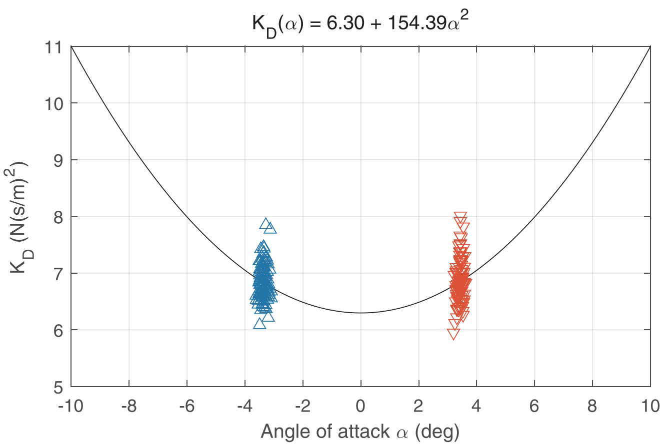

Fig. 13. Drag coefficient K_D estimated from PS24.

$$K_L = m_0 g \cos(\xi) \frac{\rho_{fw} \sin(\xi)^2}{\rho {v_z}^2} \tag{57}$$

lie along the fitted curves created by the estimated parameters for all minimizations. This can clearly be seen in Figs. 13 and 14, which show the results of the minimization PS24.

Although not all possible parameters were estimated in the first four minimizations, the good correlation between the logged and modeled data in Fig. 12 is remarkable. In addition to a good agreement between the chosen unestimated parameters and the real system parameters is another reason for the good correlation the cluster-like distribution of the logged data. This can be seen in Figs. 9, 18 and 19, where all logged data for the pitch angle θ and the vertical velocity v_z are concentrated around two individual points, one for the dives (θ = -24.922°, v_z = 0.15 m/s) and one for the climbs (θ = 25.397°, v_z = -0.246 m/s). For such a data constellation multiple settings exist for an angle of attack α to model these operating points. Figs. 15 and 16 show possible settings for the lift and drag coefficients for the dive operating point using Eqs. (56) and (57). In the case that the parameters of only one coefficient need to be optimized, the parameters result from the intersection of the given coefficient curve and the curve to describe possible settings of α for the operating point. This can be seen for the first minimization PS14 in Fig. 15, where the intersection of the given drag coefficient curve and the curve to describe possible settings of α results in an angle of attack α of around 1.46°. The three minimizations PS24, PS34 and PS234 use a given lift coefficient and estimate one or both parameters of the drag coefficient. This corresponds to Graver's work, where the lift coefficient was used from VCT [27] and only the drag coefficient was determined. Although the values found for K_{D_0} and K_{D_2} in Table 3 are

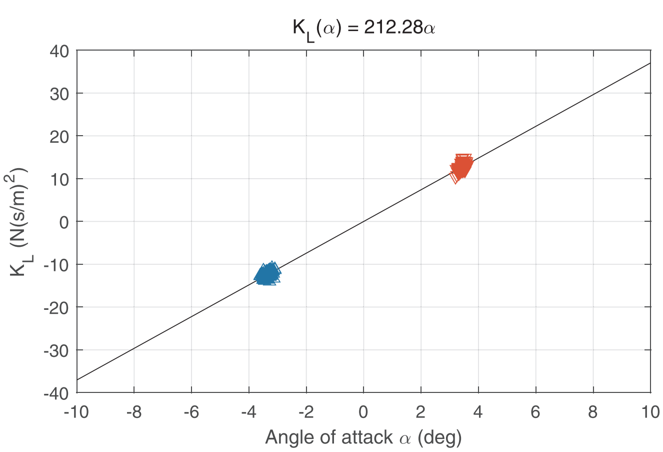

Fig. 14. Lift coefficient K_L estimated from PS24.

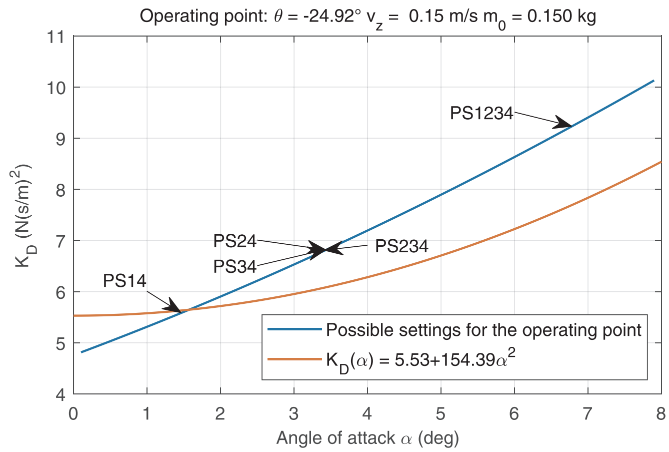

Fig. 15. Possible settings for the angle of attack α and the drag coefficient K_D for the defined operating point for dive.

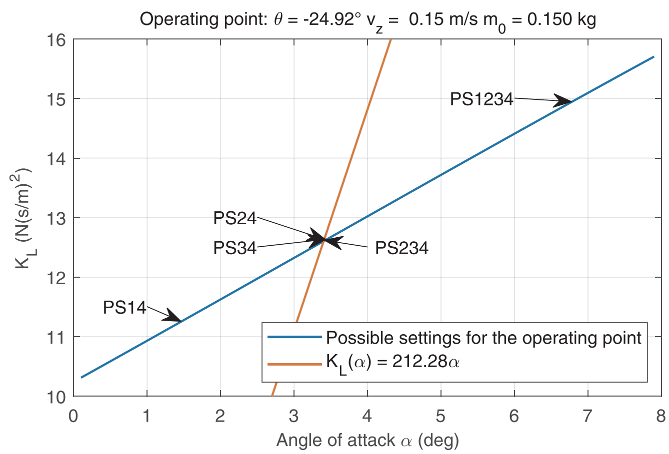

Fig. 16. Possible settings for the angle of attack α and the lift coefficient K_L for the defined operating point for dive.

very different, the calculated angles of attack α and the horizontal glider velocities v_x in Fig. 17 are similar.

The reason for this is the cluster-like distribution of the logged data, which leads to an operating point of α = 3.4° and K_D = 6.8 N(s/m)^2 using the intersection method for the lift coefficient in Fig. 16 described

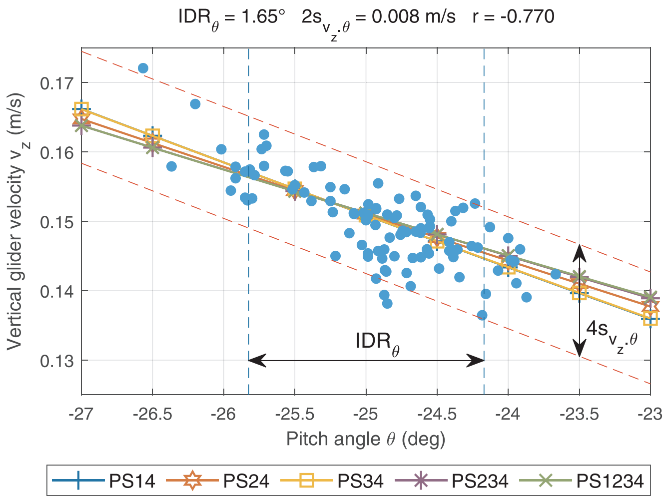

Fig. 18. Scatter plot of the logged pitch angle θ against vertical glider velocity v_z and the curves $v_z = f(\theta, K_{L_1}, K_{D0}, K_{D_2}, \Delta m_0)$ using the estimated parameters from minimizations in Eq. (41) for given pitch angles in the range [-27°, -23°] for dives.

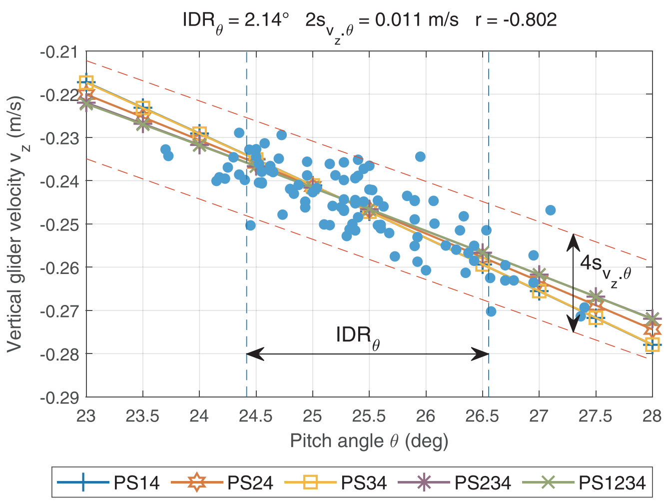

Fig. 19. Scatter plot of the logged pitch angle θ against vertical glider velocity v_z and the curves $v_z = f(\theta, K_{L_1}, K_{D0}, K_{D_2}, \Delta m_0)$ using the estimated parameters from minimizations in Eq. (41) for given pitch angles in the range [23°, 28°] for climbs.

above. This operating point can be modeled by various quadratic function curves, which is clearly shown in Fig. 10, where this operating point corresponds to the intersection point of the curves PS24, PS34 and PS234 (red circles). It should be noted that the negative value for the estimated parameter K_{D_2} obtained for minimization PS234 is a result of the cluster-like distribution of the logged data. A negative value for the parameter is impossible from the physical point of view, but it leads to the minimal cost for $C(\beta)$ in Eq. (43) using the logged data.

The minimization PS1234 has no limitations regarding the lift or drag coefficient curve used. This means that the lift and drag coefficients used to model the operating point are the result of a defined angle of attack α on the possible setting curves in Figs. 15 and 16. Multiple combinations for K_D and K_L are thus possible. The parameter set found leads to an angle of attack of around 6.8° for dives. This value is twice as high as the results of Cooney's approach (see Fig. 8) or the other minimizations (see Fig. 17) and is not trustworthy when using data with a cluster-like distribution around an operating point.

This data distribution is shown in Figs. 18 and 19 where the data samples are greatly scattered around the ideal curves.

The shape of these data distributions can be described by the scale parameters *interdecile range* (IDR) between the 10th and 90th percentiles for the pitch angle θ and the *residual standard deviation* of a linear regression $s_{y.x}$ for the vertical velocity v_z. A linear regression model $v_z = \beta_0 + \beta_1\theta$ is admissible for a pitch angle between $\pm$ 15° and $\pm$ 35° where the ideal curves in Figs. 18 and 19 can be assumed as linear. The using of IDR instead of a standard deviation results from the fact that the pitch angle data is not normally distributed and multimodal in practice. The MATLAB call for IDR is `IDR=diff(prctile(x,[10 90]))`. The residual standard deviation is defined as

$$s_{y.x} = \sqrt{\frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{n-2}} \tag{58}$$

where n is the sample size, y_i are the individual output data samples and $\hat{y}_i$ are the modeled output values from the regression. The lower and the upper bounds of the distribution are defined by two standard deviations $s_{y.x}$ from the regression line. Another possible parameter to describe these distributions is *Pearson's correlation coefficient r* [39]. This coefficient is a measure of the linear correlation between two variables x and y and is defined as

$$r_{xy} = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}} = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{(n-1)s_x s_y} \tag{59}$$

where n is the sample size, x_i and y_i are the individual data samples, $\bar{x}$ and $\bar{y}$ are the sample means and s_x and s_y are the standard deviations. The variables x and y correspond here to the pitch angle θ and the vertical glider velocity v_z. A linear relation between the vertical glider velocity v_z and the pitch angle θ leads to a correlation coefficient of -1. The calculated coefficients for the dives and climbs using the logged data are -0.77 and -0.802. A reason for these distributions could be an existing vertical current velocity $v_{z_{current}}$ in Eq. (7) caused by internal waves. This is also discussed in [15] as a possible influencing factor on the measurement accuracy of depth-average velocity.

5.2. Sensitivity and topographical analysis of the cost function

For a better understanding of the influence of the parameters β_i on the cost function $C(\beta)$ in Eq. (43), and thus on modeling the vertical glider velocity v_z in Eq. (41), a global sensitivity analysis is carried out. The method used is based on cumulative distribution functions (CDFs) and is described in detail in [40]. The key idea is to analyze the differences between the conditional and unconditional CDFs of the output y using the Kolmogorov-Smirnov (KS) statistic as a measure of their distances. This distance correlates to the sensitivity of the input x_i to the output y. The unconditional CDF is the result when all inputs vary simultaneously in defined ranges, whereas the conditional CDFs result when varying all inputs except x_i, which is fixed at a defined value. The KS statistic provides a curve of sensitivity over all defined fixed values of x_i. A new density-based sensitivity index, called PAWN was presented in [40], where a defined statistic such as the *maximum, mean* or *median* extracts a single value T_i from the KS curve for every input x_i. This value varies between 0 and 1. A low value of T_i implies a smaller influence of x_i on y.

In this paper, the inputs x_i of the sensitivity analysis are the parameters β_i and the output y is the cost function value $C(\beta)$. The data used corresponds to that of the previous section. The Sensitivity Analysis for Everybody (SAFE) Toolbox for MATLAB [41] was used for the analysis. The curves for the KS statistic in Fig. 20 show a high sensitivity for the parameters K_{D_0} and Δm_0. The parameters K_{L_1} and K_{D_2} have low sensitivity within the whole range and lie under the critical level for a confidence level α of 0.05. This can explain the large confidence intervals for these parameters in Table 3 and their uncertain estimation in Section 5.1. An interesting point is the increase in the middle of the KS curves of the parameters K_{D_0} and Δm_0 in Fig. 20 that correspond to the estimated parameters. These parameter areas show a higher sensitivity

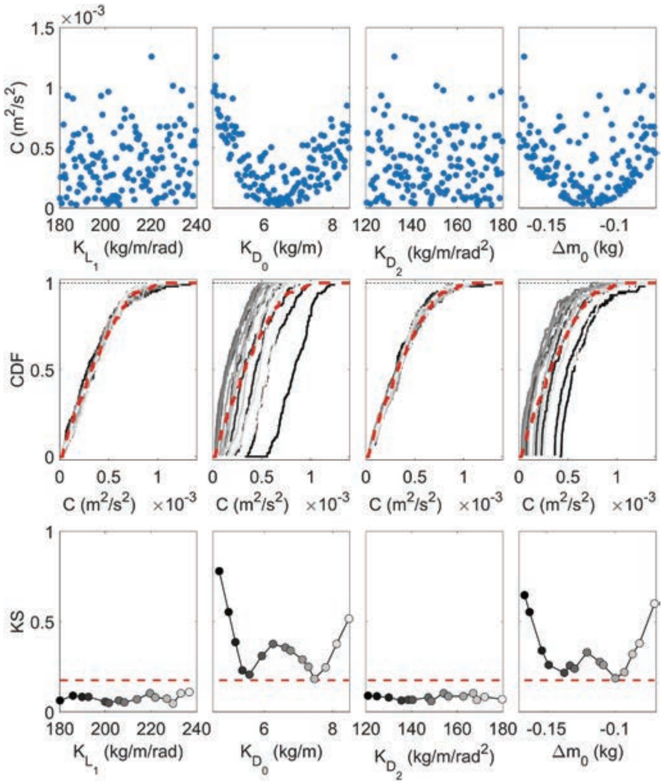

Fig. 20. *Top panels:* Scatter plots of the cost function $C(\beta)$ of Eq. (43) using the logged data from RU29-550 and the random samples of the parameters. *Middle panels:* Cumulative distribution functions (CDFs) of the cost function $C(\beta)$. The red dashed line is the empirical unconditional distribution function $\hat{F}_C(\cdot)$ of the cost function $C(\beta)$ and the gray lines are the empirical conditional distribution functions $\hat{F}_{C|\beta_i}(\cdot)$. *Bottom panels:* Kolmogorov-Smirnov statistic $\hat{KS}(\beta_i)$ at different conditioning values of β_i. The red dashed line is the critical level of the KS statistic for a confidence level of 0.05. [Experimental setup: sampling strategy: Latin Hypercube; number of samples used as conditioning values for the parameters β_i $n = 15$; number of samples used to create the empirical unconditional CDF $N_u = 150$; number of samples used to create the empirical conditional CDFs $N_c = 100$]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The middle lines show the mean value of the PAWN index. [Experimental setup: sampling strategy: Latin Hypercube; $n = 15$; $N_u = 150$; $N_c = 100$; number of bootstrap resamples: 100; statistic used in the PAWN index calculation: *maximum*].

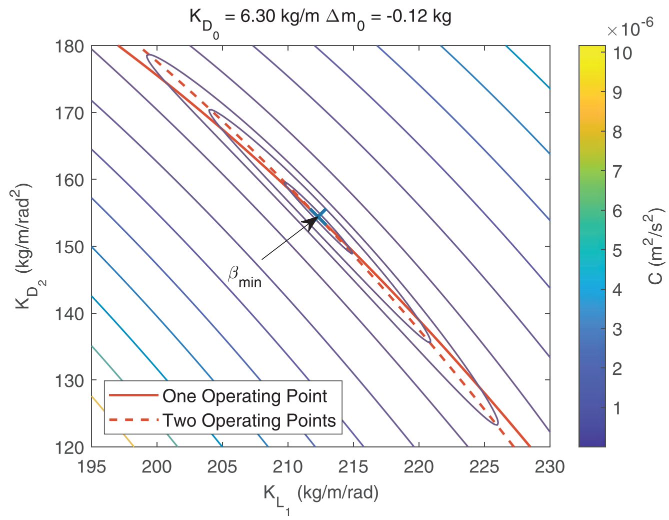

Fig. 22. Topology of the cost function with respect to the parameters K_{L_1} and K_{D_2} for the two operating points scenario. The parameters K_{D_0} and Δm_0 are fixed at their optimal value for the parameter set of minimization PS24. The red lines correspond to the minimum of the valley for a defined parameter K_{D_2} for one and two operating points. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

to the cost function because they characterize the area of the cost function minimum. Fig. 21 shows the resulting PAWN sensitivity indices for the four parameters and their confidence intervals. It shows clearly that the most influential parameters of the cost function $C(\beta)$ are K_{D_0} and Δm_0.

The analysis of the cost function topography may also shed light on the influence of the parameters β_i on the cost function $C(\beta)$. To additionally examine the influence of the data distribution on the cost function topography, simulated data was generated. The parameter set of minimization PS24 in Table 3 was used to calculate the vertical glider velocities v_z in Eq. (41) and define thus the minimum of the cost function. Two scenarios were examined. The first scenario includes one operating point for dive and climb where the pitch angles θ, the variable ballast masses m_b and the water density ρ in Table 2 were used for the calculations in Eq. (41). The second scenario includes an additional operating point where the pitch angles θ are 7° smaller than in the first scenario. Fig. 22 shows the contour plot for the cost function $C(\beta)$ with respect to the parameters K_{L_1} and K_{D_2} when the parameters K_{D_0} and Δm_0 are fixed at their optimal values for the two operating points scenario. The minimum lies inside a long flat valley. Using the cost function for one operating point results in a similar valley without significant minimumarea. This can clearly be seen in Fig. 23, which shows the parameter K_{L_1} and the minimum of the valley $C_{\min}$ with

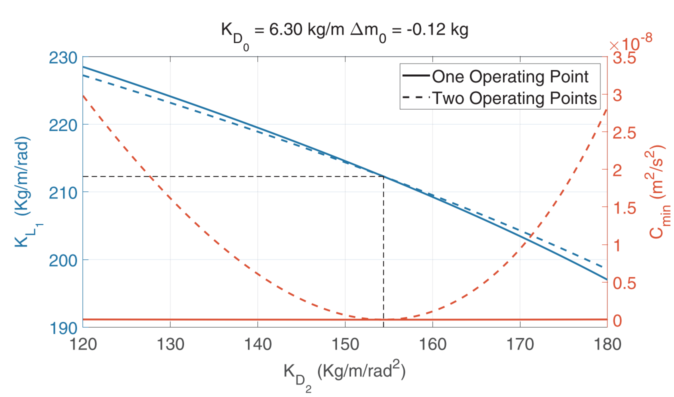

Fig. 23. Values for K_{L_1} and the minimum of the valley $C_{\min}$ with respect to the parameter K_{D_2} for one and two operating points.

respect to the parameter K_{D_2} for one and two operating points. The minimum of the valley $C_{\min}$ for two operating points shows a significant minimumarea, whereas the minimum curve $C_{\min}$ of one operating point is very flat, which makes it difficult or impossible to converge to the minimum. Multiple combinations of K_{L_1} and K_{D_2} are possible to fulfill the cost function requirement. This result is confirmed by the analysis of the minimization PS1234 in Section 5.1.

5.3. Requirements in parameter estimation

In order to detect the correct curve characteristics of the lift and the drag coefficient, it is necessary to use samples for dives and climbs which result in significantly variable angles of attack. This means using data with maximal informativeness about the system. This is a basic requirement in system identification or machine learning to create models which are valid for the whole operational area [42]. Tests with artificially generated noisy data using a parameter set assumed to be known in Eq. (41) and normally distributed pseudo-random numbers were carried out for minimization PS234 and PS1234.

These tests show that the minimization PS234 delivers significant parameters with a maximal 10% error to the given parameter K_{D_2} and a maximal 1% error to K_{D0} and Δm_0 with an interdecile range IDR_θ of at least 8° by two residual standard deviations $2s_{v_z,\theta}$ of 0.01 m/s corresponding to the logged data. In such a data distribution, the Pearson's correlation coefficient r is -0.99. Such a data distribution can be achieved by defining two operating points for the dives and climbs, where the pitch angles differ by about 7°. This is in line with [12] where three operating points $\theta = 16°, 19°, 27°$ for the dives and climbs were defined to detect the induced drag C_{D_2} in Eq. (15). Such a requirement contradicts the energy optimal control of a glider during long-term missions. A compromise has to be reached between the energy optimality and the correct estimation of all glider model parameters during a mission. It would be sufficient when the glider is operated with non optimal operation point for two or three days, to collect enough samples.

Finding significant parameters for all four parameters in minimization PS1234 requires in addition to an interdecile range IDR_θ of at least 8° a two residual standard deviations $2s_{v_z,\theta}$ of less than 0.001 m/s for the vertical velocity v_z which corresponds to a tenth of the observed deviation in the logged data. Pearson's correlation coefficient r is here -1.0. This requirement is difficult to realize in practice (existing vertical current velocity $v_{z_{current}}$ and measurement and detection errors in θ and v_z), which makes the estimation of all four parameters impossible. Another alternative is to use known model parameters and estimate the unknown ones, which is described in Section 5.4.1.

5.4. Depth-average velocity analysis for RU29-492

The logged data from the glider mission RU29-492 from Perth, Australia to Sri Lanka [47] for a time period of seven months from 2016-11-17 to 2017-06-24 was used to analyze the depth-average velocity during a long-term mission which is described in Section 6. The horizontal glider velocity required for this could be calculated with time-invariant and time-varying model parameters. The time-varying model allows the assessment of biofouling during the mission. The individual steps to determine the horizontal glider velocity v_x using a time-invariant and a time-varying model are shown in Fig. 24. The time-invariant model uses only one parameter set as result of the minimization of Eq. (43) using all logged glider data for the dives and climbs of the whole mission period, whereas the time-varying model estimates a parameter set for each dive and climb at time $t(i)$ using only logged glider data which lie in a sliding window defined by a time interval between $t(i) - 0.5t_{window}$ and $t(i) + 0.5t_{window}$. The length of the sliding window is t_{window}.

The data of the glider state during the time period is shown in Fig. 25. For most of this period, the glider was programmed to fly four

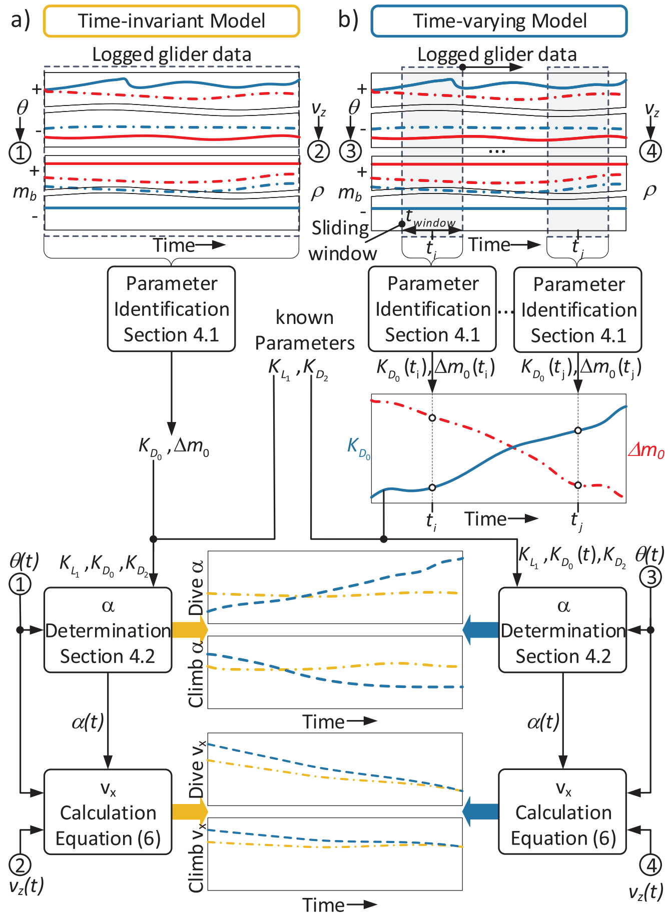

Fig. 24. Individual steps to determine the horizontal glider velocity v_x for a time-invariant (a) and a time-varying model (b).

yo profiles, starting from the surface and diving to 980 m, climbing to 100 m, diving again to 980 m, repeating this two additional times and returning to the surface. During the surface period of normally 10 min the glider sends the logged data via satellite to the Dockserver, the land- or ship-based glider communication center, and receives new instructions for command and control for the next dive period.

5.4.1. Parameter estimation

Due to the existing distribution of the logged data a reliable parameter estimation for all parameters in Eq. (41) is not appropriate (see Section 5.3). Therefore, the quadratic parameter K_{D_2} in drag coefficient Eq. (37) and the linear parameter K_{L_1} in lift coefficient Eq. (38) are assumed to be known and were used from Cooney [14] (see Table 1). This strategy is equivalent to the minimization set PS24 in Section 5.1 and corresponds to the works of Graver [28] and Merckelbach [17] where only a part of the model parameters were estimated. A close look at factors that influence both parameters shows that a change in value as a result of biofouling is unlikely. The linear parameter K_{L_1} only depends on constructive parameters/relations (aspect ratio $\mathcal{R}$, wing sweep angle Λ) where biofouling has no influence. Since in the lifting-line theory, the quadratic parameter K_{D_2} is calculated using the lift coefficient K_L (see Eqs. (32) and (33)) and the aspect ratio $\mathcal{R}$, a change in value as a result of biofouling is therefore also unlikely.

The approach described in Section 4.1 was used to estimate the unknown parameters K_{D0} and Δm_0. The first minimization estimates these two parameters using all logged data for the dives and climbs of the 7-month mission period in Eq. (43). This results in two single model parameters $K_{D0} = 7.355$ kg/m and $\Delta m_0 = -0.085$ g, which are time-invariant during the whole mission period. The modeled vertical glider

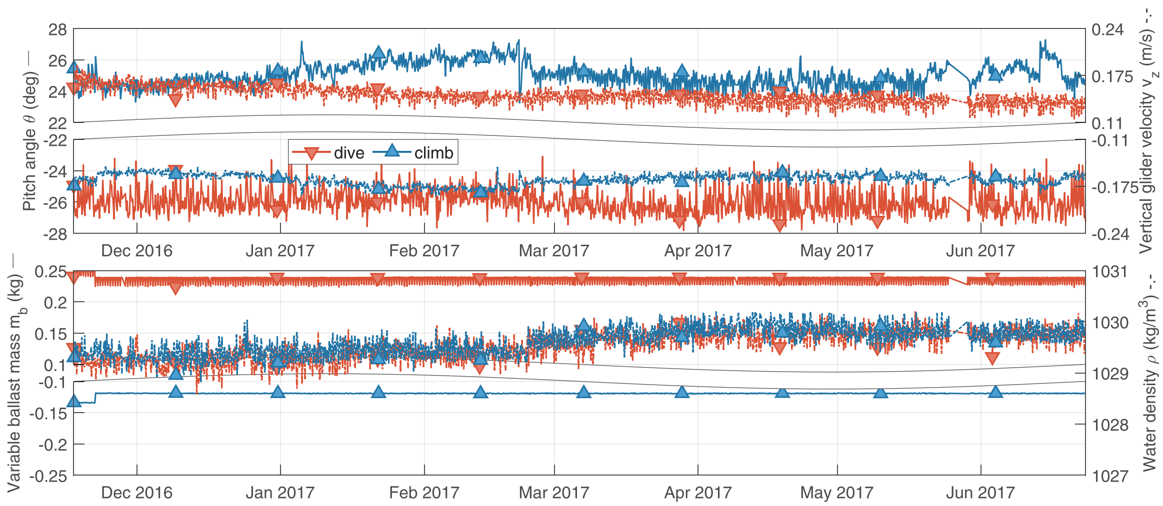

Fig. 25. Glider data used for the minimization: pitch angle θ, vertical glider velocity v_z, ballast mass m_b, water density ρ.

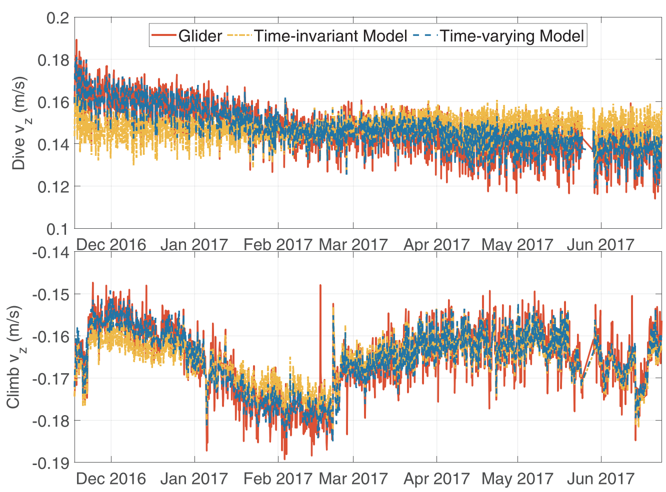

Fig. 26. Logged and modeled vertical glider velocity v_z for a time-invariant and time-varying model for dive and climb.

velocity v_z for dive and climb using these parameters in Eq. (41) are shown in curve “Time-invariant Model” in Fig. 26. The comparison of the logged and the modeled vertical glider velocity between dive and climb shows differences. There is a good match of the curves for climb for the whole mission period, where the vertical glider velocity is approximately equal to 0.16 m/s during the whole mission period. The modeled curve for the dive shows a relatively constant progression of 0.14 m/s, whereas the logged vertical glider velocity has larger values at the first half of the mission and smaller values in the second part of the mission. The real progression can be approximated as a linear slope starting at 0.17 m/s and ending at 0.14 m/s. The consistent commanded pitch angle θ and the variable ballast mass m_b (see Fig. 25) cannot explain the contradictory progression of the vertical glider velocity for the dive (time-varying progression) and the climb (time-invariant progression) during the mission.

To analyze the time-varying behavior of the vertical glider velocity for dive, an extended minimization process will be performed. In this process, the minimization will be executed for every mission day using the logged data over a sliding window of 3 weeks in Eq. (43). The resulting curves for the parameter K_{D_0} and Δm_0 are shown in Fig. 27. The glider was trimmed slightly, which results in a buoyancy trim offset of Δm_0 = -65 g at the start of the mission. This was necessary to compensate for the lower density of surface waters starting at Sumatra and most likely near Sri Lanka. The line “Time-varying Model” in Fig. 26 shows the course of the vertical glider velocity v_z using these parameters in Eq. (41).

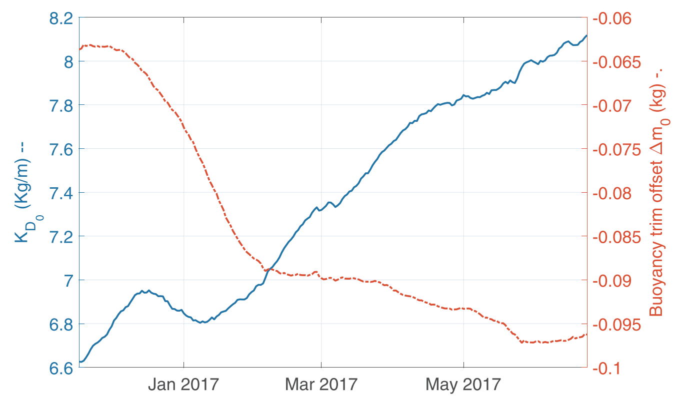

Fig. 27. Results of the moving minimization process for the parameters K_{D_0} and Δm_0.

Now both modeled curves for dive and climb match very well with the real glider behavior. The reason for this good match is the trends of the parameters K_{D_0} and Δm_0 during the mission. The parameter K_{D_0}, which corresponds to the parasitic drag coefficient and the negative buoyancy trim offset Δm_0 increase with time. Biofouling could be responsible for this behavior. The biofouling grows during the mission, which increases the skin friction drag and generates an additional buoyancy. This is also described in [13], where the influence of biofouling on the glider behavior during long-term missions is explained in detail. The 0.4 kg/m^3 increase in water density during the mission (see Fig. 25) can also explain the increase of Δm_0 by about 30 g. (The used glider had an extended energy bay, which results in a glider volume of 72.2 l. This volume leads to an additional buoyancy of 28.88 g = 0.4 kg/m^3 $\cdot$ 0.0722 m^3 during the mission.) These two effects, a larger drag coefficient and a larger negative buoyancy trim offset, add up during dive and reduce the glide speed. A larger negative buoyancy leads to a larger glide speed during climb. This effect will be compensated for by the larger drag coefficient, which decreases the glide speed. The result is an approximately equal glide speed for climb during the mission.

5.4.2. Resulting velocities

Fig. 28 shows the horizontal glider velocity and an estimated linear trend for dive and climb using the parameters from the time varying model. The estimated linear trend equations, computed with regression,

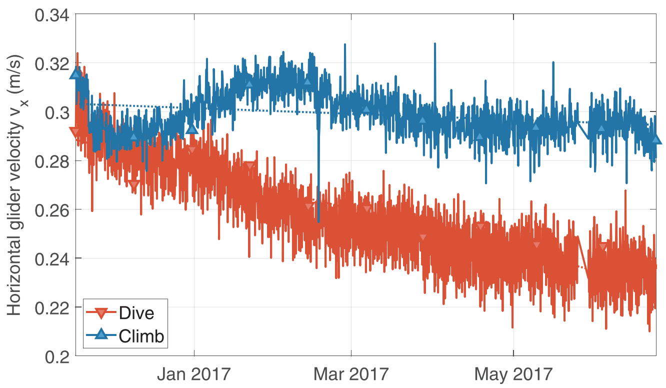

Fig. 28. Horizontal glider velocity v_x for dive and climb.

are

$$v_{x_{dive}} = 0.289\frac{m}{s} - 0.000275\frac{m}{s{\cdot}d}t_{mission} \tag{60}$$

$$v_{x_{climb}} = 0.303\frac{m}{s} - 0.0000396\frac{m}{s{\cdot}d}t_{mission} \tag{61}$$

where $t_{mission}$ is the mission duration in days. It is clear that the difference between the horizontal velocity for dive and climb will increase with increasing mission duration. The curves in Figs. 27 and 28 show three important facts which should be considered in connection with planning and navigation of long-term missions:

- The model parameter K_{D_0} and Δm_0 can be time-varying;
- The horizontal glider velocity v_x can decrease over the course of the mission;
- The horizontal glider velocity v_x for dive and climb can be different.

This means to obtain a similar horizontal glider velocity for dive and climb during the mission the current buoyancy trim offset Δm_0 needs to be detected as accurately as possible. A good estimate of this parameter can be achieved using Eq. (51). Fig. 29 shows the curves estimated using this approach ("Calculated Parameter") and the results of the moving minimization ("Estimated Parameter") as described above. The sliding window for the logged data is 3 weeks in both approaches. Since the maximum error between the curves is only 3.9 g, the calculated buoyancy trim offset is a good guide to determine the right variable balance mass m_b for climb and dive during the mission. A more accurate result can be achieved using an angle of attack α in Eq. (51).

Fig. 30 shows the calculated angle of attack courses using the model parameters from Cooney, a time-invariant and a time-varying model and the logged pitch angle θ in the angle of attack determination presented in Section 4.2. The angle of attack α is approximately equal to $\pm$ 4° during the mission using the parameters from the time-invariant

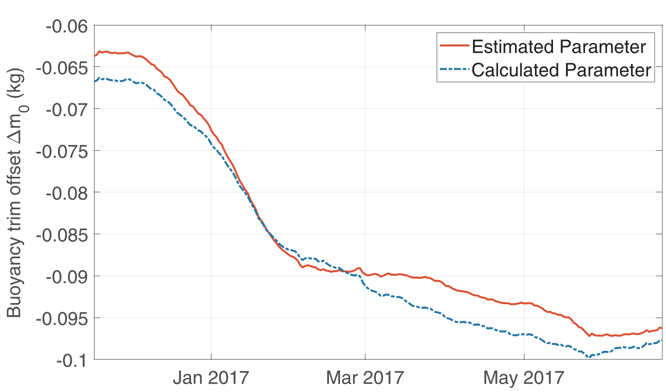

Fig. 29. Estimated and calculated buoyancy trim offset Δm_0.

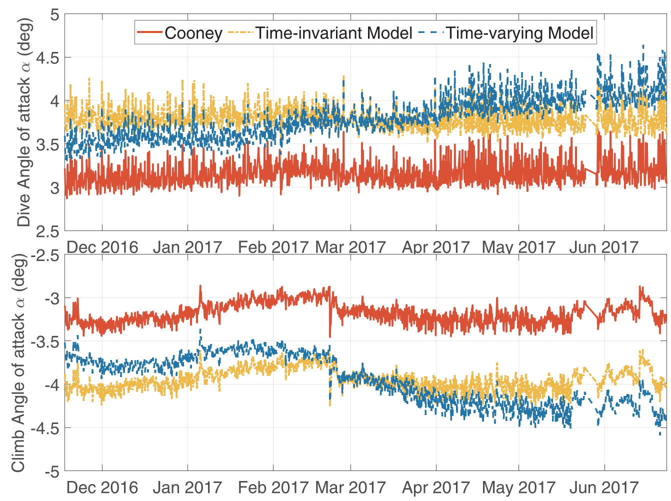

Fig. 30. Angle of attack α courses using the parameters from Cooney, a time-invariant and a time-varying model for dive and climb.

model. Using the time-varying model, the angle of attack will increase from $\pm$ 3.6° to $\pm$ 4.4° during the mission. Although Cooney's model does not include time-varying parameters a slight increase of the angle of attack α is observed for dives during the mission. The reason is the inclusion of the glide speed V in the pressure drag C_{D_0} calculation in Eq. (34), which is used in the angle of attack determination. The glide speed V is decreased for dives and remains constant for climbs during the mission.

Fig. 31 shows the calculated horizontal glider velocity v_x using the angles of attack in Fig. 30, the vertical glider velocity v_z and the pitch angle θ in Eq. (6). All curves have a similar trend, which is determined by the trend of the logged vertical glider velocity v_z for dive and climb. The calculated velocity values using Cooney's model are 0.005 to 0.015 m/s (1.7% to 5.0%) larger than the velocity values calculated with the time-varying model. The velocity values from the time-invariant model lie around the velocity curve of the time-varying model whereas the values are smaller in the first half of the mission ($-$0.005 to 0 m/s (1.7% to 0%)) and larger in the second part of the mission (0 to 0.005 m/s (0% to 1.7%)).

6. Evaluation of the depth-average velocity

The depth-average velocity is a unique calculated quantity in the

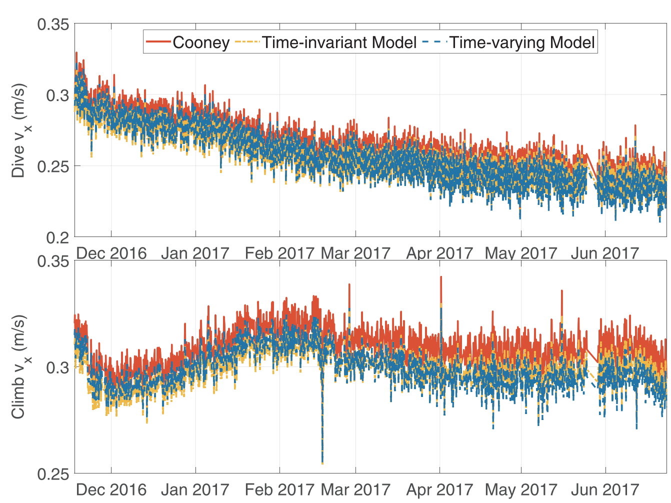

Fig. 31. Horizontal glider velocity v_x courses using the parameters from Cooney, a time-invariant and a time-varying model for dive and climb.

operating area of underwater gliders. It is used for glider navigation or as a score to evaluate the quality of ocean current models in and near the operating area of the glider. The evaluation of the ocean current models can help to choose a suitable current model for navigation during the mission. Another application for evaluation is the data post-processing, where the depth-average velocities of the individual dive segments in a mission will be compared with ocean current models. This evaluation can help to determine the confidence in new data sources, to improve the ocean models using the spatial and temporal anomalies between modeled and observed data, and to modify an ocean model with additional data/information from a glider or calculation methods from ocean models with a better correlation to the logged data. The individual steps for an evaluation process are presented below.

6.1. Calculation of depth-average velocity

To evaluate the depth-average velocity of an ocean current model with that of a glider requires their previous calculation. Both calculation methods for a glider and an ocean model will be described in detail below.

6.1.1. Depth-average velocity of a glider

The depth-average velocity of a glider $\mathbf{v}_{c_{Glider}}$ is the difference between the velocity over ground $\mathbf{v}_g$ and the horizontal glider velocity through water $\mathbf{v}_h$ [15]

$$\mathbf{v}_{c_{Glider}} = \mathbf{v}_g - \mathbf{v}_h \tag{62}$$

The velocity over ground $\mathbf{v}_g$ is the result of the GPS fixes at the beginning $\mathbf{x}_{start}$ and the end $\mathbf{x}_{end}$ of a dive segment and the time required for it

$$\mathbf{v}_g = \frac{\mathbf{x}_{end} - \mathbf{x}_{start}}{t_{end} - t_{start}} \tag{63}$$

The horizontal glider speed through water $\mathbf{v}_h$ can be described by its magnitude, the horizontal glider velocity v_x, and its direction, the logged glider heading ψ

$$\mathbf{v}_h = \begin{bmatrix} v_{east} \\ v_{north} \end{bmatrix} = \begin{bmatrix} v_x \cos(\psi) \\ v_x \sin(\psi) \end{bmatrix} \tag{64}$$

As shown in Section 5.4.1, there are two different horizontal glider velocities for dive $v_{x_{dive}}$ and climb $v_{x_{climb}}$. To calculate an exclusive horizontal velocity v_x used in Eq. (64) a temporal weighting where the velocities are active is necessary. The horizontal glider velocity for dive would be underestimated and the horizontal glider velocity for climb would be overestimated using a simple mean calculation, because the dive time period is larger than the climb time period. The vertical glider velocities $v_{z_{dive}}$ and $v_{z_{climb}}$ will be used for temporal weighting

$$v_x = \frac{|v_{z_{climb}}|}{v_{z_{dive}} + |v_{z_{climb}}|} v_{x_{dive}} + \frac{v_{z_{dive}}}{v_{z_{dive}} + |v_{z_{climb}}|} v_{x_{climb}} \tag{65}$$

6.1.2. Depth-average velocity of an ocean model

The depth-average velocity can be understood as the mean ocean current in the operation area of the glider during the time period for a considered dive segment. Such a segment can consist of one or more yo profiles. To calculate this value, the ocean current conditions $\mathbf{v}_c$ have to be detected at the position $\mathbf{x}_{start}$, at the time t_{start} and at the position $\mathbf{x}_{end}$, at the time t_{end} in several depth layers for the dive segment. Therefore, a defined number n of depth layers are equidistantly distributed between the surface and the dive-to depth which is shown in Fig. 32. The number n is taken to be 20. Finally, the mean value for all these ocean current components will be calculated according to the following equation

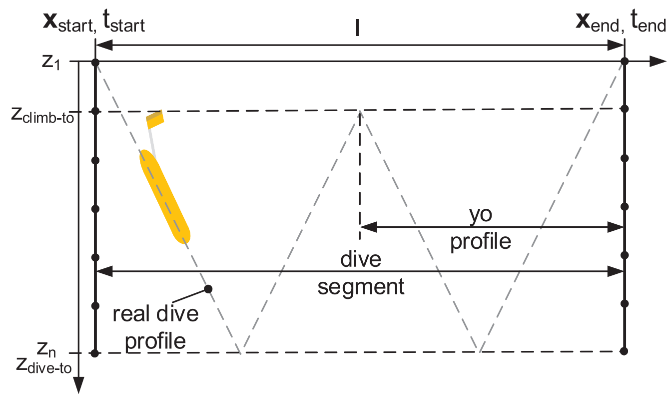

Fig. 32. Defined depth layers on the start and end position of a dive segment.

$$\mathbf{v}_{c_{Model}} = \frac{1}{2}\left(\begin{bmatrix} \mathbf{v}_c(\mathbf{x}_{start}, z_1, t_{start}) \\ \vdots \\ \mathbf{v}_c(\mathbf{x}_{start}, z_n, t_{start}) \end{bmatrix} + \begin{bmatrix} \mathbf{v}_c(\mathbf{x}_{end}, z_1, t_{end}) \\ \vdots \\ \mathbf{v}_c(\mathbf{x}_{end}, z_n, t_{end}) \end{bmatrix}\right) \tag{66}$$

Since the ocean current data, coming from the Ocean General Circulation Models (OGCM) as data files, will be provided only at discrete positions, depths and times with a nonlinear depth scale and a coarser time and length scale, so that the ocean current information cannot be taken directly from the files. Hence, a multi-dimensional interpolation scheme will be used to extract the desired ocean current data. Additional information about the interpolation scheme is presented in [16].

This approach is a simplification and works well for easy current conditions. In case of complex current conditions or to determine the depth-average velocity more accurately, a glider simulation should be used. Therefore, the exact yo movement of the glider in the current field of the ocean model using the commanded heading, pitch and dive profile for the dive segment will be simulated. The resulting surfacing position and the simulated horizontal glider velocity can then be used in Section 6.1.1 to determine the depth-average velocity.

6.2. Goodness-of-fit indicators

Two goodness-of-fit indicators were used for the evaluation. Both indicators use the distance information d between the calculated end positions using the depth-average velocity of the ocean model $\mathbf{v}_{c_{Model}}$ and the glider $\mathbf{v}_{c_{Glider}}$ after a defined time period Δt.

$$d = \|\mathbf{v}_{c_{Model}} - \mathbf{v}_{c_{Glider}}\|\Delta t \tag{67}$$

It should be noted that the horizontal glider velocity through water $\mathbf{v}_h$ has no influence on Eq. (67) because this vector will be used in both calculations for glider and for ocean model, and thus will be offset.

The first indicator is a non-dimensional skill score (ss) presented in [43]. This skill score was developed to compare simulated with observed drifter trajectories and has to be adapted for single dive segments. It has been applied in a variety of work [44–46] in the last decade. To overcome the difficulties with dive segments of different lengths a non-dimensional index s will be used to normalize the distance d with the length l of the dive segment

$$s = \frac{d}{l} \tag{68}$$

This index is used to calculate the skill score ss

$$ss = \begin{cases} 1 - \frac{s}{n}, & (s \leq n) \\ 0, & (s \geq n) \end{cases} \tag{69}$$

where n is a tolerance threshold. A skill score of 1 implies a perfect match between model and glider.

The second indicator is novel and uses a time period Δt of 24 hours in Eq. (67). The result of this indicator $Da24h$ is given in km. This makes

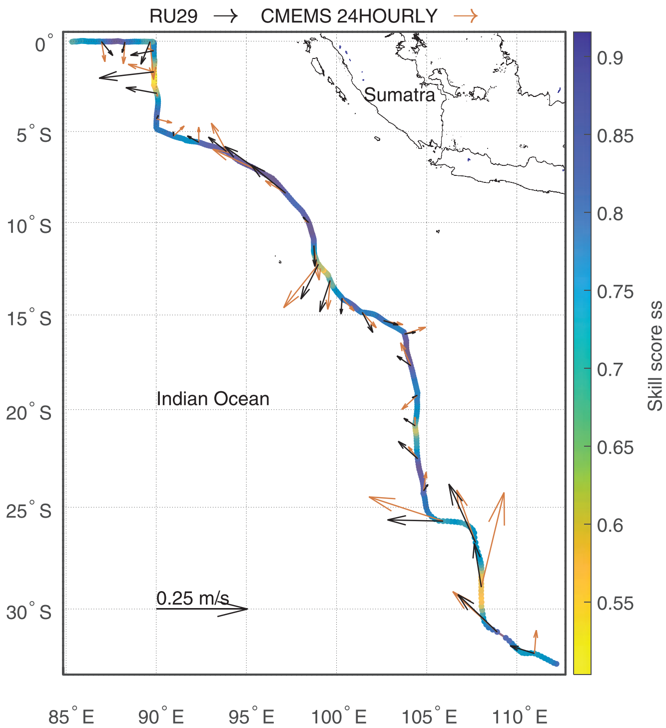

Fig. 33. Skill score *ss* and current vectors for the observed (RU29) and modeled (CMEMS 24HOURLY) depth-average velocities along the mission. The current vectors correspond to the weekly mean values.

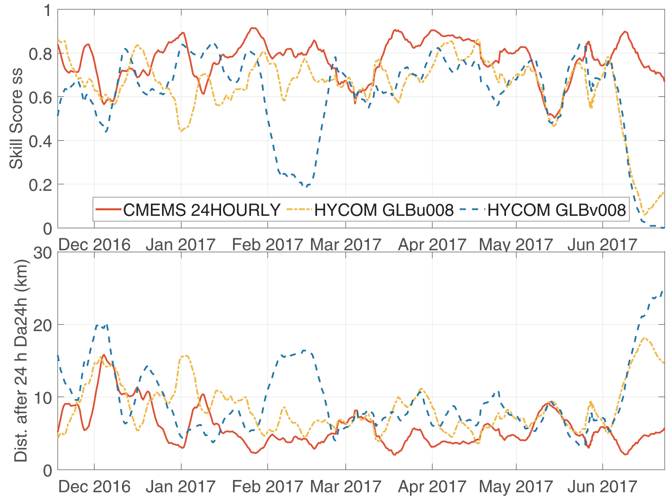

Fig. 34. Skill score *ss* and distance after 24h *Da24h* curves for the three ocean models: 24 hourly global-analysis-forecast-phys-001-024 model of CMEMS (CMEMS 24HOURLY), GLBu008 (HYCOM GlBu008) and GLBv008 (HYCOM GLBv008) of HYCOM.

it possible to overcome the difficulties with dive segments of different time periods. Likewise, this parameter can be imagined easily, as it corresponds to the distance between the modeled and the real surfacing position of the glider after 24 hours. A small distance means a good match between model and glider.

6.3. Evaluation

Three ocean current models were chosen for the comparison of the modeled with the observed depth-average velocities along the mission route. The models used are GLBu008 (GOFS 3.0) and GLBv008 (GOFS 3.1) of HYCOM [19] and the 24 hourly global-analysis-forecast-phys-001-024 model of the Copernicus Marine Environment Monitoring Service (CMEMS) [18]. Fig. 33 shows a map with the mission route of RU29-492 from Perth, Australia to Sri Lanka with the weekly mean depth-average velocity vectors from the glider RU29 (blue) using the calculated horizontal glider velocity v_x of the time-varying model and the 24 hourly CMEMS ocean model (red) for the several dive segments. This map includes additionally the smoothed skill score *ss* values for the several dive segments. A moving average algorithm with a sliding window of seven days was used for smoothing. There is a good match between the observed and modeled depth-average velocities for most of the mission period where the skill score *ss* is larger than 0.7. There are four regions during the mission with a bad evaluation:

- 28°-30°S and 108°E start of December 2016
- 21°S and 104°E start of January 2017
- 12.5°S and 99.25°E start of March 2017
- 2°S and 89.9°E middle of May 2017.

Fig. 34 shows the smoothed courses of the two goodness-of-fit indicators: skill score *ss* and distance after 24h *Da24h* for the three ocean current models using the calculated horizontal glider velocity v_x of the time-varying model. The distance after 24h *Da24h* shows an inverse behavior to the skill score *ss*. The HYCOM models show a worse evaluation in comparison to the CMEMS model. As shown in Table 4, which includes the mean values of the indicators, the GLBv008 model has a slightly worse evaluation in comparison to the GLBu008 model. The bad evaluation of the HYCOM models in the area are noticeable:

- 14.5°-15.5°S and 101°-103°E start of February 2017 (only GLBv008)
- 0°S and 85.5°-87°E middle of June 2017.

Table 4
Calculated mean values for skill score *ss* and distance after 24h *Da24h* for the three ocean models: 24 hourly global-analysis-forecast-phys-001-024 model of CMEMS, GLBu008 and GLBv008 of HYCOM and the three methods to detect the horizontal glider velocity v_x.

Score	Model	CMEMS	GLBu008	GLBv008
ss	Cooney	0.766	0.636	0.594
	Time-invariant	0.767	0.64	0.602
	Time-varying	0.768	0.641	0.603
Da24h (km)	Cooney	5.8	8.758	9.986
	Time-invariant	5.765	8.668	9.763
	Time-varying	5.762	8.646	9.754

Table 4 shows that the mean values of the two indicators for the methods used to detect horizontal glider velocity v_x are very similar. The higher model accuracy of the time-varying model does not lead to other significant results. The reason is the small differences in the calculated horizontal glider velocities in the individual methods (maximal 5%) (see Fig. 31). The CMEMS has a 20% better quality in *ss* and a 33% better quality in *Da24h* than the indicators of the HYCOM models. The GLBu008 shows a 6% better quality in *ss* and a 11% better quality in *Da24h* than the GLBv008 model.

7. Conclusions

This paper examines the need for an accurate glider model in navigation, control and data post-processing. A model which is generally used for a Slocum glider was presented in detail. The calculation of the horizontal glider velocity v_x based on an accurate angle of attack detection was discussed in this context. A robust minimization approach to detect the model parameters and its limitations due to the available logged glider data were described. The correct parameter estimation requires a large data distribution in the whole operation range of a glider which contradicts the energy optimal control of a glider during long-term missions. The analysis of RU29-492 from Perth, Australia to Sri Lanka shows an increase in the drag coefficient over the course of the mission caused by biofouling, which leads to an increase of the angle of attack of about 1° using similar pitch commands. In addition, an increase in the buoyancy trim offset as result of biofouling and changing salinity conditions during the mission could also be observed. This should be considered for the navigation and control of a glider through an online model parameter estimation during the mission. The decrease of the horizontal glider velocity from 0.3 to 0.26 m/s within 7 months should be considered in the global path planning.

The comparison of the depth-average velocity of ocean current models from CMEMS and HYCOM with the observed velocity from the glider using chosen goodness-of-fit indicators allows a spatial and temporal model evaluation along the mission route. In this context, one question arises: How should the evaluation results be processed so that they can be used in ocean model design?

Abstract

Nutrient and light availability regulate phytoplankton physiology and photosynthesis in the ocean. These physiological processes are difficult to sample in time and space over physiologically and ecologically relevant scales using traditional shipboard techniques. Gliders are changing the nature of data collection, by allowing a sustained presence at sea over regional scales, collecting data at resolution not possible using traditional techniques. The integration of a fluorescence induction and relaxation (FIRe) sensor in a Slocum glider allows autonomous high-resolution and vertically-resolved measurements of photosynthetic physiological variables together with oceanographic data. In situ measurements of variable fluorescence under ambient light allows a better understanding of the physical controls of primary production (PP). We demonstrate this capability in a laboratory setting and with several glider deployments in the Southern Ocean. Development of these approaches will allow for the in situ evaluation of phytoplankton light stress and photoacclimation mechanisms, as well as the role of vertical mixing in phytoplankton dynamics and the underlying physiology, especially in remote locations and for prolonged duration.

Phytoplankton are the foundation of all aquatic ecosystems and their photosynthetic activity and production of organic carbon not only supports highly productive ocean/lake ecosystems but also plays a significant role in shaping the chemistry of the Earth (Falkowski and Knoll 2007). Phytoplankton populations are highly dynamic with high turnover rates driven by a suite of environmental factors such as light, macronutrients, micronutrients, grazing and temperature (Falkowski and Raven 2007). Since the pioneering work by Lorenzen (1966), chlorophyll fluorometers have been widely adopted by the oceanographic community and provide sensitive non-intrusive estimates of phytoplankton biomass. While chlorophyll fluorescence is routinely used for estimating chlorophyll concentrations, conventional fluorometers do not provide insight into the physiological state of phytoplankton or their photosynthetic rates. The pump-and-probe technique (Kolber et al. 1988), the fast repetition rate (FRR) fluorometer (Kolber et al. 1998), and the fluorescence induction and relaxation (FIRe) sensors (Gorbunov and Falkowski 2005) have been developed to study phytoplankton physiology and evaluate the environmental controls of ocean primary production. Variable fluorescence signals provide a sensitive tool to measure the optical cross-sections for photosynthesis, the quantum yields of photochemistry, and rates of photosynthetic electron transfer in phytoplankton (Falkowski et al. 2004). Variable fluorescence measurements have allowed the oceanographic community to study the underlying mechanisms and factors regulating the physiological state and growth of phytoplankton (Suggett et al. 2010). However, the application of this technology has been largely limited to sampling from ships (Lin et al. 2016), airborne (Chekalyuk et al. 2000) or diving (Gorbunov et al. 2000; Gorbunov et al. 2001) approaches, which limits when, where and how much data is collected.

Observations of horizontal distributions of near-surface phytoplankton photosynthetic properties (such as the quantum yield for electron transport) using ship-based underway fluorometers (Lin et al. 2016) and LIDARs (Light Detection and Ranging) (Chekalyuk and Gorbunov 1993) have revealed horizontal variability in these properties on meso- to micro scales which are relevant to phytoplankton dynamics. This variability increases dramatically in highly dynamic and

*Correspondence: filipa.carvalho@noc.ac.uk

marine ecosystems, such as the coastal Southern Ocean (Lin et al. 2016). Although ship-based underway sampling was instrumental to document the variability and factors controlling photosynthetic rates in the near-surface layer, the use of underwater autonomous vehicles, such as gliders, provides an important practical tool to explore a high-resolution 3D structure of photosynthetic fluorescence properties in the water column. Airborne LIDAR fluorescence based techniques from planes and satellites can be used to overcome some of the gaps left by satellites, but data is limited on subsurface phytoplankton biomass (Churnside and Marchbanks 2015) or surface only photosynthetic characteristics (Chekalyuk et al. 2000).

Recent years have seen the rapid development of buoyancy-driven autonomous underwater vehicles (AUV) for oceanographic research (Griffiths et al. 2007). Some classes of the AUVs (buoyancy vehicles) can conduct sustained missions from weeks to a year (Schofield et al. 2007; Rudnick 2016) and are capable of carrying a wide range of sensors (Schofield et al. 2015). Here we report on the development of a variable fluorescence sensor for an autonomous buoyancy vehicle offering the potential for collecting phytoplankton photophysiology data remotely, in situ, under ambient light with high spatial and temporal resolution. This technology was demonstrated during a series of deployments (Haskins and Schofield 2015; Carvalho et al. 2016*a*) in the coastal waters off the West Antarctica Peninsula, a region which is experiencing a rapid environmental change (Schofield et al. 2010).

Integrating a FIRe sensor on a glider provides sampling advantages over ships. These include: (1) Gliders allow sampling at the very near surface where ships (especially large ones) have difficulty sampling. Thus gliders have the ability to measure the physiology of a natural population that can be used to ground-truth algorithms developed to evaluate phytoplankton physiology from space. (2) The small footprint of a glider allows the collection of data without the ship-shadow effect that is significant when collecting shipboard measurements using instruments on a wire. (3) Gliders can be used in a semi-Lagrangian, water mass tracking mode to evaluate in situ physiological response (e.g., photoacclimation) of a phytoplankton community to local physical forcing, such as a gradual or abrupt deepening of the mixed layer, and provides a relatively cheap and reliable way to follow a water mass, collecting physical and biogeochemical properties over time in the same population. Pairing these data with turbulence measurements (which gliders are also capable of collecting) allow further evaluation at microscales. (4) Sustained spatial physiological observations for long periods is cost-effective for gliders. Given the proven reliability of gliders to provide sustained observations for months at a time, a FIRe on a glider would allow the collection of 3D maps of phytoplankton physiology across different scales (time and space) allowing us to assess the physical drivers of phytoplankton physiology over meso- and micro-scales.

This work showcases the FIRe glider as a new tool that will complement shipboard phytoplankton physiological measurements. It highlights some of the advantages and capabilities of miniaturizing and integrating an already established FIRe sensor on an autonomous platform. We characterize the instrument by running a series of comparisons to a benchtop mini-FIRe instrument and present some field demonstration deployments in the West Antarctic Peninsula. Finally, we describe and suggest a series of best practices when deploying this instrument on the field.

Materials and procedures

Autonomous platform

Teledyne Webb Research (TWR) Slocum electric gliders are a robust AUV platform capable of mapping properties within the upper water column (Schofield et al. 2007) that are increasingly filling mesoscale sampling needs for ocean science. Gliders maneuver across the ocean at a forward speed of 20–30 cm s^{-1} in a triangle-shaped diving trajectory, deriving its forward propulsion by means of a buoyancy change and steering by means of a tail fin rudder. Pitch is regulated by shifting batteries back and forth within the glider. A depth sensor enables pre-programmed sampling of depth ranging from a minimum $\sim$2–3 m (about 10 for deep gliders) to 1000 m on the downcast or on multiple successive dives without surfacing. On single dives, and especially on the upcast, Slocum gliders are capable of sampling all the way to the surface. Sensors carried by the gliders continuously record data during the glider descents/ascents, and a typical mission can collect thousands of vertical profiles. This allows the glider to collect high-resolution data in both time and space. Another great advantage of gliders over ships is the ability to sample both in Lagrangian or Eulerian mode, on demand. The glider can be set in drift mode, following this way the same water mass and record changes over the same population or operate virtual mooring (Clark et al. 2020), where the glider station keeps at one location (see Section "*Field evaluation and applications*" for specifically designed missions for the FIRe glider).

Integrating variable fluorescence measurements into a glider

Bio-optical measurements of photosynthetic rates and physiological characteristics of phytoplankton are based on the use of variable fluorescence techniques (Huot and Babin 2010), including the FIRe technique (Gorbunov and Falkowski 2005). FIRe measurements are sensitive, fast, nondestructive, and can be performed in real-time (Gorbunov et al. 2020). The parameters (Table 1) derived from Kolber et al. (1998), are used to quantify the phytoplankton-specific photosynthetic performance in natural assemblages in aquatic ecosystems (Dubinsky and Schofield 2009) and provide a background for modeling the rates of primary production in the water column (Hughes et al. 2018; Ko et al. 2019).

Table 1. Notation of FIRe variables. See Cosgrove and Borowitzka (2010) for more details and synonyms.

Abr.	Description	Abr.	Description
σ_{PSII}	Functional absorption cross section of PSII in a dark-adapted state (Å^2)	σ_{PSII}'	Functional absorption cross section of PSII in a light-adapted state (Å^2)
F_o, F_m	Minimum and maximum yields of Chl *a* fluorescence (arbitrary units)	F_o', F', F_m'	Minimum, steady-state, and maximum of Chl *a* fluorescence measured under ambient light (arbitrary units)
F_v	Variable fluorescence, $F_m - F_o$	F_v'	Variable fluorescence measured under ambient light, $F_m' - F_o'$
F_v/F_m	Maximum quantum yield of photochemistry in PSII, measured in a dark-adapted state (dimensionless)	$\Delta F'/F_m'$	Quantum yield of photochemistry in PSII, measured under ambient light, $F_m' - F'/F_m'$ (dimensionless)
E_k	Light-saturation parameter (μmol quanta m^{-2} s^{-1})	$\Delta F'$	Change in the fluorescence yield measured under ambient light, $F_m' - F'$
$'$	Prime indicates that measurements are collected under ambient light	$\Delta F'/F_v'$	Coefficient of photochemical quenching characterizing the fraction of open reaction centres in a light-adapted state

Fluorescence signals are excited by flashes from 450 nm light emitting diodes (LEDs), isolated by a 680 nm interference filter and detected by a sensitive avalanche photodiode module (Gorbunov and Falkowski 2005). The computer-controlled LED driver delivers pulses with varied duration from 0.5 μs to 50 ms, which ensures fast saturation of PSII within a single photosynthetic turnover (STF, < 100 μs). In partnership with Teledyne Webb Research and Satlantic, a FIRe sensor was miniaturized and integrated into the Slocum glider science payload bay (Fig. 1), from now on referred to as a FIRe glider. Merging these two platforms allows for high-resolution continuous and vertically resolved mapping of phytoplankton physiological parameters in the water column. This prototype was integrated into a Slocum G1 glider, a "shallow glider" rated for 100 m. Given the slow speeds of a glider, during the STF protocol, the glider only moves about 0.02–0.03 mm, so it is a fair assumption to consider the excitation constrained to a fixed sample in space relative to the detector, so no artifacts should be introduced by this moving platform, as long as only parameters from the 100 μs burst are being used in the analyses.

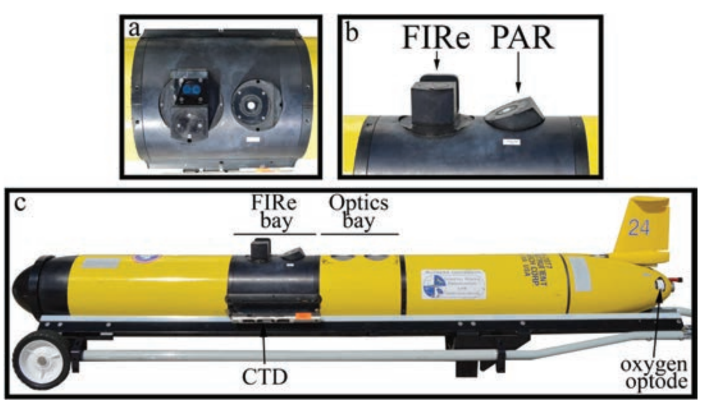

Fig. 1. Top **(a)** and side **(b)** view of the Fluorescence Induction and Relaxation (FIRe) and photosynthetic active radiation (PAR) sensors integrated into a Slocum glider FIRe bay (black section). (**c**) Extended Slocum glider with double science bay configuration with FIRe bay in front and optics bay with Seabird WET Labs ECO puck (measuring chlorophyll fluorescence, backscatter and/or colored dissolved organic matter), Seabird conductivity-temperature depth (CTD) sensor and Aanderaa dissolved oxygen optode in the aft. The glider is shown without its two lateral wings that connect to the black FIRe bay.

Other sensors

A photosynthetically active radiation (PAR) sensor is also incorporated in the FIRe science bay and is critical to the interpretation of the FIRe data. The standard Seabird Conductivity–Temperature–Depth (CTD) package in all gliders allows a high-resolution characterization of the physical setting, which provides critical data to relate physiological patterns associated with water column stability and mixed layer depth (Carvalho et al. 2017). The FIRe bay can be paired with an optional second science bay carrying a WET Labs Environmental Characterization Optics (ECO) pucks, measuring chlorophyll fluorescence, backscatter at several wavelengths, and/or colored dissolved organic matter (CDOM) fluorescence. Given the modular nature of Slocum gliders, other sensor pairings may be available on a second science bay or an extra stack-on bay, including extra energy bay to extend the deployment duration.

Assessment and discussion

Laboratory evaluation

Silsbe et al. (2015) highlights the importance of calibrations and understanding sensor behavior given the inherent variability within instruments. Bench testing was conducted to characterize this instrument and to understand how it compares to conventional benchtop instrument, i.e., mini-FIRe. We: (1) evaluated the relationship between the maximum fluorescence, F_m, and standard measurements of extracted chlorophyll concentration; (2) evaluated the effect of incident light on the measurement sensitivity and signal-to-noise; (3) characterized pure water, filtered seawater and deep in situ blanks; and (4) characterized instrument behavior in pure water.

Reference profile calibration

Like the bench-top FIRe instrument, the FIRe glider sensor requires a reference excitation profile, which is used to normalize the collected fluorescence intensities and to deduce fluorescence yields. This reference profile is acquired using a fluorescent dye (Rose Bengal) and is saved as a reference file. The reference profile reflects the actual shape of excitation intensity and has no variable fluorescence component. When processing the data collected during the deployment, the FIRe processing program will use this profile to calculate fluorescence yields. Given the high stability (< 0.5%) of this reference profile, due to the extremely stable and reproducible LEDs source, it is recommended the reference profile to be updated every 6 to 12 months.

Relationship between FIRe F_m and chlorophyll concentration

Like any fluorometer, the FIRe glider records fluorescence yields in arbitrary units. For these data to be used to assess phytoplankton biomass, maximum fluorescence yield (F_m) needs to be calibrated against standard extracted measurements of chlorophyll concentration (mg m^{-3}), to provide a proxy for phytoplankton biomass. These samples should be collected when and where the glider is being deployed as chlorophyll fluorescence yields may vary with community compositions.

Discrete samples were collected and evaluated in the (1) FIRe desktop, followed by the (2) FIRe glider, and finally (3) chlorophyll concentrations was estimated by filtering samples onto 25 mm Whatman GF/F filter and pigments extracted using 90% acetone, following the fluorometric method for phytoplankton chlorophyll determination (Yentsch and Menzel 1963). The filtered sample was then run again on both FIRe systems to evaluate blanks. A set of dilution experiments were conducted using water samples collected a few miles off Atlantic City (red, Fig. 2a,b) to increase the number of points and dynamic range in the F_m to chlorophyll concentration regression. Two sets of water sample calibrations from field deployments in the West Antarctic Peninsula were included in this analysis to add sample points with potentially different community compositions. F_m is less susceptible to variations in phytoplankton physiological state than F_o thus providing the best proxy for chlorophyll concentration. Comparison between FIRe glider measured F_m and chlorophyll concentrations is shown in Fig. 2a. Correlation between the two variables was evaluated using a Model-II geometric mean linear regression $y = 5.81x$ (5.44, 6.17) – 0.07 (–1.21, 1.06); $r^2 = 0.98$; $N = 43$).

To further characterize the custom-made glider integrated FIRe sensor, we ran the same discrete samples, in parallel, on the benchtop mini-FIRe, with filtered seawater (FSW) blank corrections applied for each system. To evaluate the correlation between F_v/F_m measured in each instrument, a model-2 major axis linear regression $y = 1.07$ (0.90, 1.24) - 0.10 (–0.22, 0.02), $r^2 = 0.92$ was calculated. Given that the order of the individual replicates in each system is not correlated (3 per sample in each system), only sample averages were used in this analysis. Nevertheless, standard errors are shown in error bars in Fig. 2c. Some of the variability may reflect that the FIRe system on the glider is significantly older then mini-FIRe which has been developed more recently, where increased sensitivity is due to the improvement of electronic circuitries and the use of a more sensitive detector (Gorbunov et al. 2020).

Blank correction

A “blank” is the background signal recorded from the sample, i.e., the signal associated with the absence of the property being studied, in this case, without chlorophyll fluorescence. In clear waters, the importance of blank collections has been highlighted (Cullen and Davis 2003; Bibby et al. 2008; Laney and Letelier 2008) because of fluorescence from dissolved organic matter (DOM) and phytoplankton degradation products (Benner and Strom 1993). In some instruments, electronic artifacts (Laney et al. 2001) and the effect of scatter by water itself (Laney et al. 2001) can present problems. The contribution of the latter two factors can be eliminated by improving the electronic and optical design. Although the magnitude and variability of the “blank” is usually small compared to chlorophyll fluorescence signals from phytoplankton in FIRe systems (Bibby et al. 2008), blanks should be routinely collected and subtracted from the fluorescence signals. However, in DOM-rich, low chlorophyll waters the blank correction may become critical for accurate retrievals of photosynthetic parameters (Bibby et al. 2008).

DI water blanks collected using this FIRe sensor integrated on the glider were overall very small (blank$_{\text{DI water}}$ = 39 ± 3.4, standard error), compared to the average chlorophyll fluorescence signal, corresponding to less than 3% of the lowest fluorescence recorded for a sample (i.e., F_m = 1200 a.u.). Furthermore, the amount of incident light did not affect the signal when exposing the DI water at varying irradiances. The “standard” blanks using filtered seawater (FSW) were collected to evaluate the effect of dissolved organic matter in the recorded fluorescence signal. Apart from the two lowest concentrations tested (chlorophyll concentration < 0.5 mg m^{-3}),

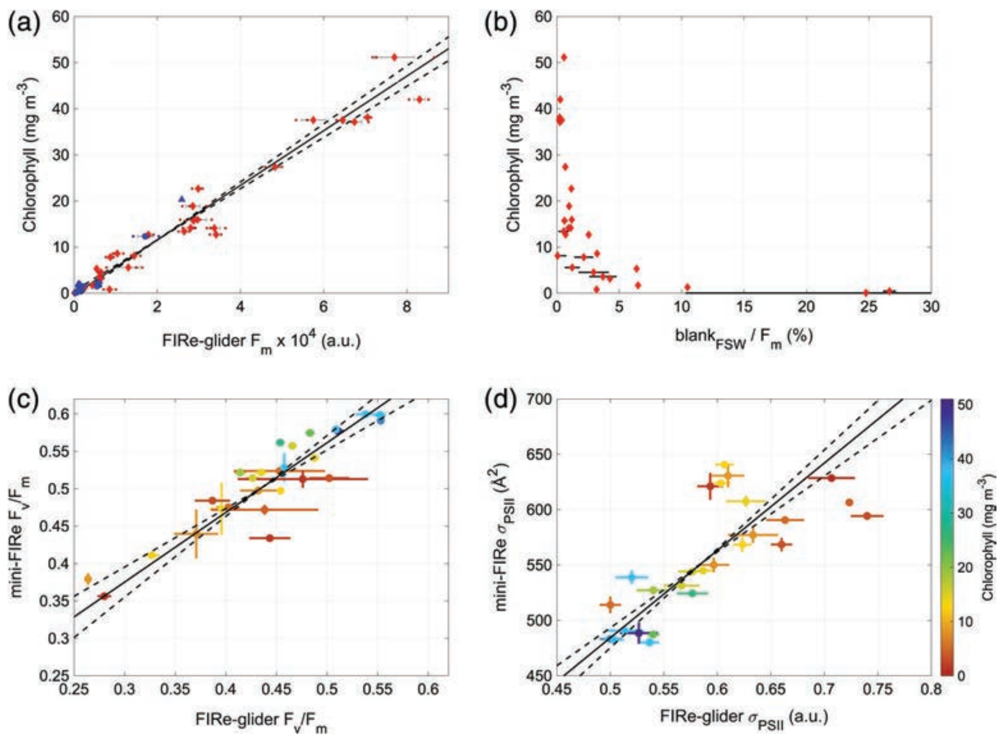

Fig. 2. Instrument calibration and characterization based on cross-comparison with the benchtop mini-FIRe instrument and discrete samples. (**a**) Relationship between maximum fluorescence (F_m' measured by the FIRe glider) and extracted chlorophyll concentration from in situ discrete samples. Different colors indicate different locations where water samples were collected (blue: West Antarctic Peninsula; red: New Jersey coastal waters). Individual measurements are shown in small colored dots, with averages shown in the large marker and standard errors for F_m in the horizontal bars. Model-II linear relationship (r^2 = 0.98) and slope uncertainty (2 standard errors) are shown in solid and dashed lines, respectively. Triple FIRe replicates were used individually against a single chlorophyll concentration from that sample (N = 43) for the regression analysis. (**b**) Ratio of freshwater (FSW) blank signal to F_m, against in situ chlorophyll concentration. Standard errors are shown in horizontal error bars. (**c**) Comparison of photosynthetic efficiency (F_v/F_m) measured using the mini-FIRe and the FIRe-glider. Model-II linear regression (r^2 = 0.92) and slope uncertainty (2 standard errors) of sample averages (N = 29) are shown in solid and dashed lines, respectively. Error bars indicate standard errors shown for each sample measured in each instrument and are colored based on chlorophyll concentration. (**d**) Cross-calibration of the functional absorption cross-section (σ_{PSII}). Comparison of sample averages (3 replicates each) between the FIRe-glider and the mini-FIRe with standard error bars for both instruments. Model-II linear regression (r^2 = 0.77) and 2 standard errors of the slope uncertainty shown in solid and dashed lines.

the magnitude of the fluorescence of the blank normalized to the F_m was less than 5% for average chlorophyll concentration found in the upper ocean (Fig. 2b).

While it is impossible to measure appropriate in situ blanks concurrently with the FIRe glider measurements during deployment, in situ discrete water samples should be collected and analyzed in the lab bench before and after deployment. This will allow the evaluation of region-specific blanks as well as potential effect of biofouling during long deployments. No significant signs of biofouling were found after up to 3-week long deployments in coastal Antarctica, even though the instrument does not use any anti-biofouling technology such as copper plating. Although biofouling itself is unavoidable during long-term deployments, the impact of biofouling on the measured signals is dramatically reduced by the improved optical design of the glider FIRe sensor. The optical design employs a two-window configuration, which includes excitation and emission windows. Thereby, the collimated excitation light does not reach the emission optical window and thus does not induce background fluorescence from biofouling material accumulated on this window. At the same time, fluorescence from biofouling accumulated on the excitation window does not reach the detector.

In all glider deployments conducted using the FIRe integration in coastal Antarctica, blanks corresponded to less than 1% of the chlorophyll fluorescence signal. Deep blanks, i.e., average signal in deep waters where we expect to find no phytoplankton, have been previously used when there is no chance to collect discrete in situ blanks. Using data from the field deployments, we found that the average "blank" signal at depth was higher (~ 450 a.u.) than the discrete blanks ran in the lab (~ 330 a.u.), likely due to the shallow profiling (100 m), constrained by the depth rating of the glider where this sensor was fitted to.

Functional absorption cross-section calibration

The functional absorption cross-section of Photosystem II (σ_{PSII}) is a product of the optical absorption cross section of

PSII (i.e., the size of the PSII antennae) and the quantum yield of photochemistry in PSII (Falkowski et al. 2004). This biophysical parameter is controlled by photoacclimation status and nutrient availability, as well as affected by the community composition (Suggett et al. 2009). σ_{PSII} is calculated from the rate of fluorescence rise during the single turnover flash (STF), as this rate is proportional to the product of σ_{PSII} and the excitation intensity (Gorbunov and Falkowski 2005). Accurate calibration of the excitation intensity within the sounding volume of the FIRe sensor is critical for retrievals of σ_{PSII} in absolute units, Angstrom squared (Å^2). Such calibration is conducted as part of the standard calibration procedure of the FIRe sensor. Because the spatial distribution of excitation intensity in the sounding volume of the underwater glider FIRe sensor is less uniform than that in the benchtop instrument, the benchtop instrument is much easier and more accurate to be calibrated. To convert the measured σ_{PSII}, collected in relative units, into absolute units, angstrom squared (Å^2), a correction coefficient must be determined by cross-calibrating the FIRe glider sensor against a "standard" calibrated benchtop FIRe instrument. A model-II linear regression $y = 789.2x$ (581.02, 997.45) + 89.66 (−33.25, 212.56) was calculated, with $r^2 = 0.77$ (Fig. 2d).

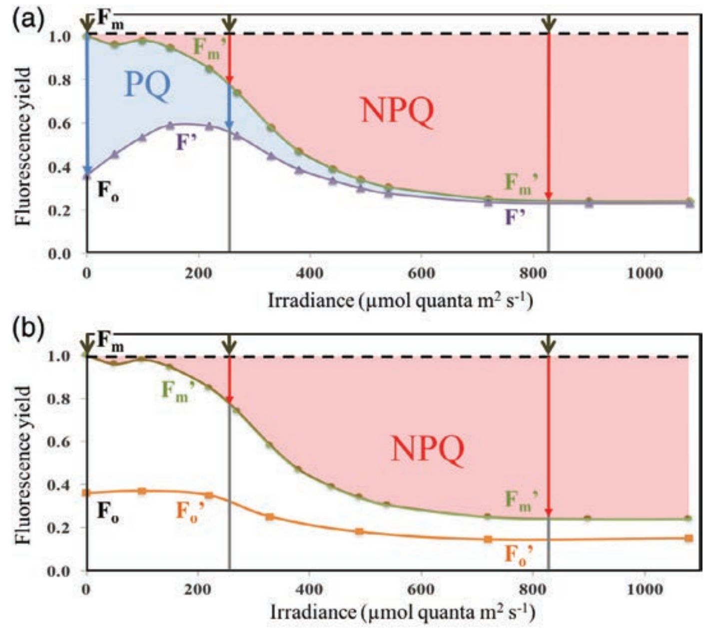

Fig. 3. Schematic of irradiance dependence of chlorophyll fluorescence yields. Measurements in: (**a**) light-adapted state, i.e., during daytime and (**b**) dark-adapted state, i.e., during night time. F_o and F_m are minimum (open reaction centres) and maximum (closed reaction centres) fluorescence yields measured in dark-adapted cells. F_o' and F_m' are the minimum and maximum fluorescence yields in a light adapted state. F' is the actual fluorescence yield measured under ambient light. PQ and NPQ are photochemical quenching and non-photochemical quenching, respectively. Top gray arrows indicate example irradiances and its corresponding fraction of NPQ and PQ.

Field evaluation and applications

The FIRe glider capabilities were evaluated in the field by three coastal deployments off the West Antarctic Peninsula (Fig. 5), in Palmer Deep Canyon (Carvalho et al. 2016*b*) near Palmer Station. The following sub-sections demonstrate some of the applications of such integration, some field experiments and some operational recommendations.

Non-Photochemical quenching (NPQ)

One of the biggest advantages of the FIRe integration on a glider is the ability to make measurements under ambient light. Daytime profiles reflect the physiological status resulting from high light during peak irradiance hours while night-time profiles can be used as a dark-adapted state. While capturing a "true" dark-adapted state is usually a problem in many FRRf studies, the sampling under ambient light by the FIRe glider allows the evaluation of the gradual relaxation of NPQ, but also understand when the true reversal of the daytime inactivation caused by supra-optimal irradiances. The physiological characteristics available under these two conditions are presented in Fig. 3 and described in Table 1.

In this situation, nutrient stress can be assessed using night-time profiles only and both Non-Photochemical Quenching (NPQ), a physiological mechanism to protect the photosynthetic apparatus from photodamage, where excess energy is dissipated as heat (Muller et al. 2001; Milligan et al. 2012) and Photochemical Quenching (PQ) can be evaluated throughout the deployment. The NPQ parameter (Bilger and Bjorkman 1990) gives a straightforward estimate of the portion of thermally dissipated photon flux (i.e., the quantum yield of nonphotochemical quenching).

To determine F_m we can use the night-time profile where F_m' is maximal (finding the maximum F_m' between 22:00 and 6:00) the night immediately before or after the daytime period being considered. This relies on the assumption that the glider has not moved into a different water mass, which is more valid when sampling in a Lagrangian way, which gliders are capable of. A specific semi-Lagrangian mission designed for the FIRe glider is further detailed in section "Evaluate the physiological responses of the same phytoplankton community to changes in water column dynamics".

The high resolution capability of gliders allows not only the timeseries analysis of NPQ at a particular depth (Fig. 4, left panels, in this case at 8 m depth), but also the characterization of a depth-resolved NPQ (Fig. 4, middle and right), important in situations where potentially different physiological communities react differently to varying irradiance. The two quenching components, non-photochemical quenching component (qN) and photochemical quenching component (qP), are defined in Kooten and Snel (1990). While the data is lacking in the upper 5-7 m for this example due to the deployment setup, the glider does have the capability to sample this

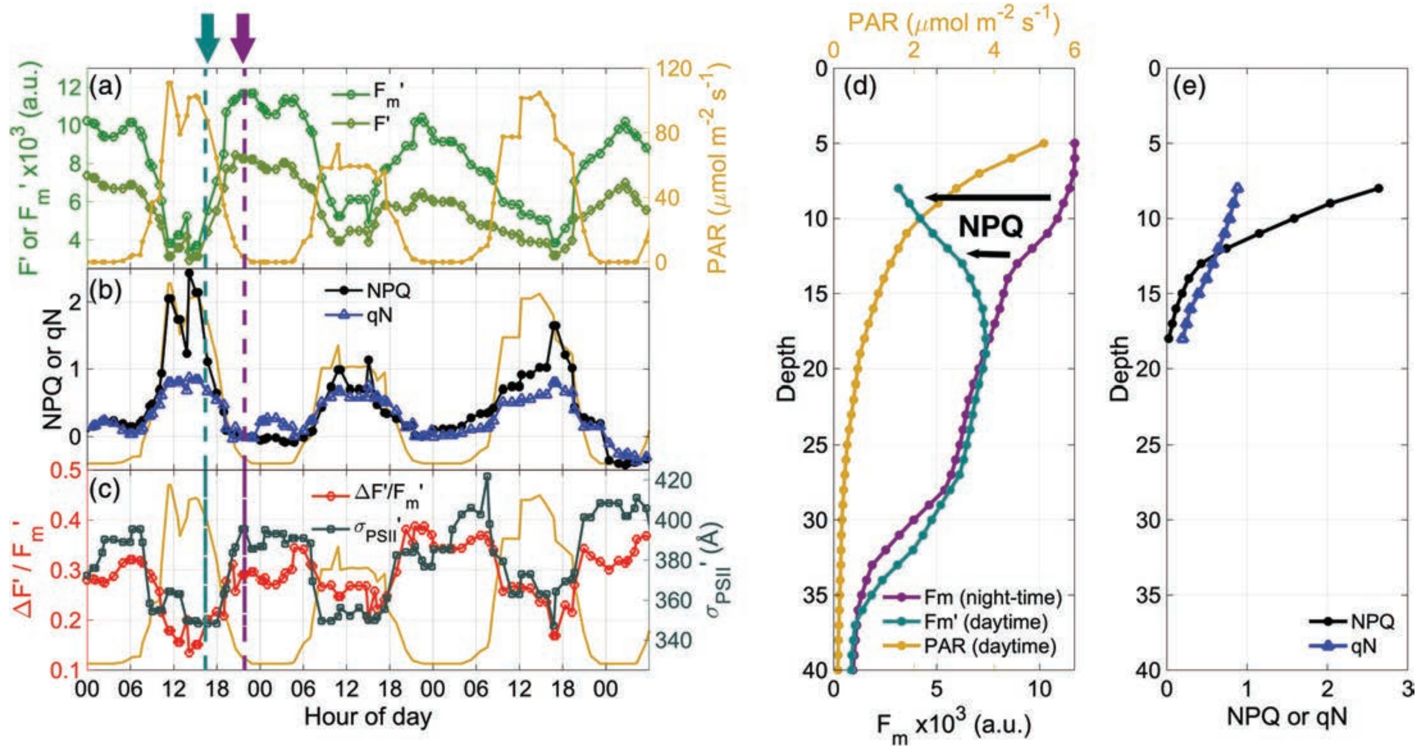

Fig. 4. Three diel cycles from a coastal deployment off the West Antarctic peninsula at 8 m depth of (**a**) fluorescence at steady-state (F', light green) and maximum (F_m', dark green) levels with factory calibrated photosynthetic active radiation (PAR, gold), (**b**) non-photochemical quenching (NPQ, black) and NPQ component (qN, blue); (**c**) the quantum yield of photochemistry in PSII ($\Delta F'/F_m'$, red) and functional absorption cross section for PSII (σ_{PSII}', gray). layer and better inform the fluorescence kinetics where irradiance is highest.

Performance under low phytoplankton biomass conditions

Data collected over three different deployments in the West Antarctic Peninsula was used to evaluate the sensor sensitivity as a function of chlorophyll. Maximum fluorescence (F_m') was converted to chlorophyll using in situ discrete samples collected before and after deployments. For lower values of chlorophyll, there was more scatter, predominantly toward the negative values in F_v/F_m as, under low biomass (i.e., low signal-noise ratio), it gets increasingly difficult to distinguish first F_o, then F_m, from zero. Under low chlorophyll concentrations, poor fits of the biophysical model to the data were observed during the processing using the supplied Satlantic/Seabird software, resulting in still accurate F_m values (as shown by the good F_m:chl regression fit in Fig. 2a), but less certain estimates of F_o, where in most cases, F_o becomes negative. We will further on refer to these as "bad points," but note that it is due to the poor model fit and not bad data collected. To further assess the minimum chlorophyll concentration in which we can accurately collect physiological data, bad points (7% of the data, of a total of 41,445 data points) were identified when $F_v/F_m < 0$ (i.e., F_o was either higher than F_m or negative) or F_v/F_m was higher than is commonly found in natural populations ($F_v/F_m > 0.66$). Theoretically, F_o cannot be higher than F_m as in the scenario where the reaction centres are fully closed, F_o would equal F_m. Most "bad points" corresponded to $F_v/F_m < 0$ (94%, matching low chlorophyll concentrations), while only a very small percentage corresponded to $F_v/F_m > 0.66$ (6%). Fewer points in the scatter cloud were collected under high irradiance, with the majority being found below 50 m, under low light and where the signal-to-noise ratio was low. Applying a simple 3-point median filter to remove spikes resulted in a decrease of the "bad points" to 3.6% where a higher percentage (98.7%) corresponded to $F_v/F_m < 0$. Minimum chlorophyll concentration was calculated assuming different percentages of acceptable "bad points": when considering 10% "bad points" acceptable using untreated/raw data (data with median filter applied in parenthesis), minimum chlorophyll concentration is 0.26 (0.23) mg m^{-3}, while for 5 and 1% are 0.32 (0.26) and 0.44 (0.38) mg m^{-3}, respectively, with results improving with a larger window on the median filter. While these results could be indicative of low sensitivity of the instrument, after a careful visual analysis of the output of the fitting software under low concentrations, we believe the increasing number of bad

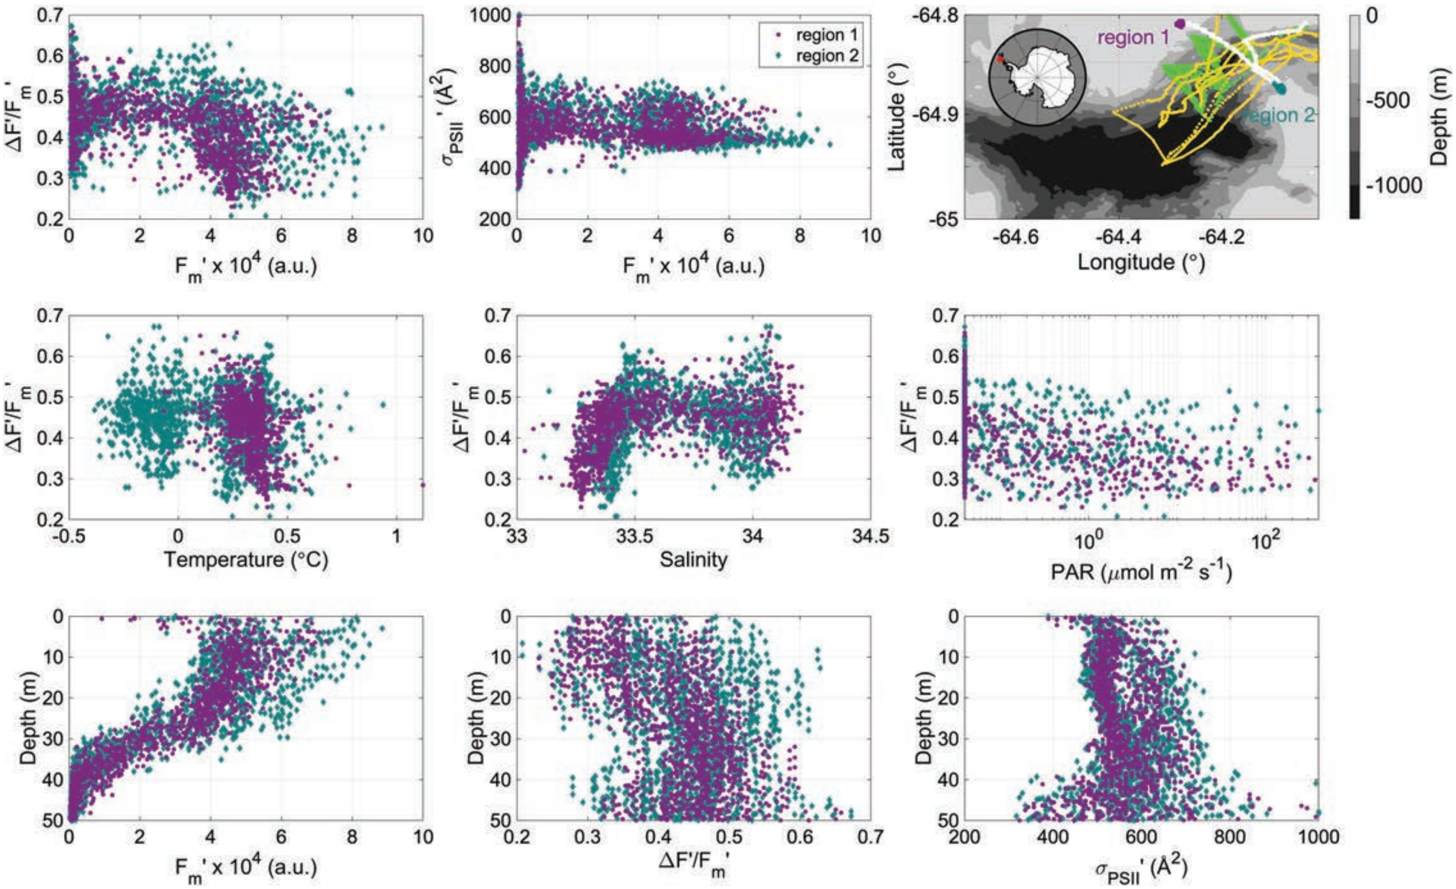

Fig. 5. Location of the three coastal deployments off the West Antarctic Peninsula shown in this manuscript, illustrating the station keeping mission (white, purple and teal for transit, region 1 and region 2, respectively), drift mission (yellow) and a zigzag mission (green). Scatter plots from the station keeping mission from Fig. 6 with the two diel cycles from each region showing different physiological responses to physical forcing: (top) Photosynthetic efficiency ($\Delta F'/F_m'$) and functional absorption cross-section of PSII (σ_{PSII}') as a function of phytoplankton biomass (F_m'); (middle) $\Delta F'/F_m'$ as a functional of temperature, salinity, and PAR; (bottom) depth profiles of F_m', $\Delta F'/F_m'$ and σ_{PSII}' for the two regions.

points at low concentrations are due to the poor curve fitting using the provided processing software. We believe this "sensitivity" can be further improved, if data is fitted manually (i.e., not using the provided software), as we found that misfits often resulted from just one potential outlier in the fluorescence induction curve. Unfortunately, the raw data files collected by the glider-integrated FIRe system are in a proprietary binary format which we were incapable of decoding, despite several unsuccessful attempts to interface with both Satlantic/Seabird, the commercial FIRe manufacturer, and Teledyne Webb Research, the glider manufacturer. Each file is individually processed on the software, where FIRe variables (Table 1) are derived; however, no statistics are reported for the quality fit of the biophysical model, so we are unable to fully characterize the robustness of the model fit. Given this constraint we were not able to demonstrate the reason for the poorer results low chlorophyll concentrations is not the instrument itself, instead it reflected issues with the proprietary software provided by Satlantic. Despite this problem, it represented only a small proportion of the data (7% of the raw data) and future development efforts will be should be able to resolve this issue. However, given the high-resolution capabilities of the gliders, under low chlorophyll concentration, signal can be isolated from scatter/noise by averaging and using low-pass filters, as shown previously. The amount of data points from the glider would still surpass, by far, the ones collected manually, using discrete samples.

Two missions have been designed to evaluate physiological responses at different temporal and spatial scales: (1) compare and contrast physiological responses of phytoplankton to different physical forcing settings using Eulerian sampling ("station keeping mission"), white, purple and teal dots in the map from Fig. 5) and (2) evaluate the physiological responses of the same phytoplankton community to changes in water column dynamics ("drift mission", yellow dots in the map from Fig. 5). A third mission was also conducted at the same location in a zigzag pattern (green dots in the map from Fig. 5) to increase the number of data points in the field assessment analyses.

Compare and contrast physiological responses of phytoplankton to different physical forcing ("station keeping mission")

Often, the irradiance regime experienced by phytoplankton is a result of the complex interaction between incident irradiation, turbulent mixing and variations in the water column vertical structure (i.e., changes in the water column stability and MLD due to varying wind stress and water mass types as well as heat from insolation) (Neale et al. 2003). For a given temperature and nutrient status, phytoplankton regulate photosynthetic rates based on their light field by altering their photosynthetic apparatus. For example, the cellular chlorophyll content is usually higher when the cells have been growing under low light (Lewis et al. 1984; MacIntyre et al. 2000). It is then informative to analyze phytoplankton physiology in the context of their physical setting (Hughes et al. 2020).

The ability of the FIRe glider to collect, at high resolution, physiological data together with physical oceanographic parameters allows further analyses on the physical drivers of primary production. Gliders also offer an advantage compared to other oceanographic platforms in providing more flexibility in how, when and where they sample. It is sometimes beneficial to use gliders as virtual moorings when the scientific question involves a spatial comparison. An Eulerian approach allows data collection that isolates the temporal signal by removing space from the equation. Deploying the FIRe glider in station keeping (virtual mooring) mode in locations with different physical settings, one can infer how environmental variables are associated with phytoplankton physiology over time (Fig. 6). The degree with which the same population is being sampled depends on the local circulation. This mission was conducted in an area where physical and biological regional differences had been previously documented (Carvalho et al. 2016*b*; Kohut et al. 2018). Different water masses and degrees of stratification can be identified between the two regions (Figs. 5, 6), where overall higher $\Delta F'/F_m'$, F_m' and σ_{PSII}' can be observed in region 2, an area with lower temperatures, increased PAR and higher salinity. Together with higher $\Delta F'/F_m'$ across all PAR range, a clear diel signal is evident in σ_{PSII}' (showing high values during night-time and a decrease during daytime, Fig. 6). Ranges of measured σ_{PSII}' are shown in Figs. 5, 6 are in accordance with previous studies (Behrenfeld and Kolber 1999; Suggett et al. 2009; Alderkamp et al. 2015).

Evaluate the physiological responses of the same phytoplankton community to changes in water column dynamics ("drift mission")

The properties of phytoplankton community structure, such as cell size and taxonomy, influence photosynthetic rates and therefore variable fluorescence signals (Suggett et al. 2009). When evaluating the temporal pattern (e.g., diel cycles) in the photosynthetic efficiency of a phytoplankton community in situ, it is important to make sure that the measurements are constrained to the same phytoplankton community. The best way to accomplish this in situ is to use a Lagrangian approach and follow the same water mass over time. While gliders are a platform capable of collecting a large amount of high-resolution profiles autonomously, one of its main constraints is the active movement into a potentially different water mass as they fly through the water column on their standard flight configuration. To stay within the same water mass and evaluate physiological changes of a phytoplankton community through time, a new mission was designed to avoid actively changing water masses. A glider cycle ("yo," including a dive and a climb back to the surface) takes around 20 min. On this custom mission design, a "yo" was done every hour, where the rudder (steering) was set all the way to one side, resulting in a corkscrew dive and climb. The remaining time, in between the hourly dives, the glider would drift at the surface following the phytoplankton community present in the same water mass. This setup allows the collection of at least 24 profiles to characterize a diel cycle within the same water mass.

Stratification, mixed layer depth (MLD) and rates of vertical mixing have been identified as controls on primary production and phytoplankton dynamics (Lewis et al. 1984; Mitchell and Holm-Hansen 1991; MacIntyre et al. 2000). In a strongly mixed surface layer, phytoplankton acclimate to light levels averaged over the MLD (Lewis et al. 1984), so a relatively stable light environment as a result of a shallow MLD allows phytoplankton to photoacclimate on timescales of 1–2 d (Schofield et al. 1995). During intense mixing events, dim-light adapted phytoplankton may be brought toward the surface where they are exposed to supra-optimal irradiances, which leads to a decrease in both F_m' and $\Delta F'/F_m'$.

Photoadaptive parameters respond to changes in irradiance at different rates. Photoinhibition can be assessed in the fluorescence signal on time-scales of seconds to minutes while it takes several hours for the photosynthetic capacity to be compromised (Lewis et al. 1984). Effects of high irradiance periods (hours 10–16) shown by the yellow colors in the Photosynthetically Active Radiation (Fig. 7, bottom) are evident by the low values seen in the photosynthetic efficiency ($\Delta F'/F_m'$, Fig. 7) maximum fluorescence (F_m' or proxy for chlorophyll concentration (Fig. 7), and in the functional absorption cross-section (σ_{PSII}', Fig. 7). This is evidence of NPQ, with the deepest penetration occurring during peak irradiance (hour 13–14). Increased fluorescence signal was found under shallower MLD. NPQ was more marked in the deeper MLD (lower F_m', Fig. 7) regime where phytoplankton are acclimated to lower light. The collection of high-resolution photo-physiology parameters over a diel cycle permits the evaluation of NPQ under supra-irradiances as seen by a decrease in $\Delta F'/F_m'$, F_m', and σ_{PSII}', as compared to their dark-adapted values.

Light-induced mechanisms used to prevent photodamage under high irradiance, such as NPQ, result in changes in the functional absorption cross-section of PSII (σ_{PSII}') (Krause and Weis 1991; Falkowski et al. 1994). This decrease in σ_{PSII} can be

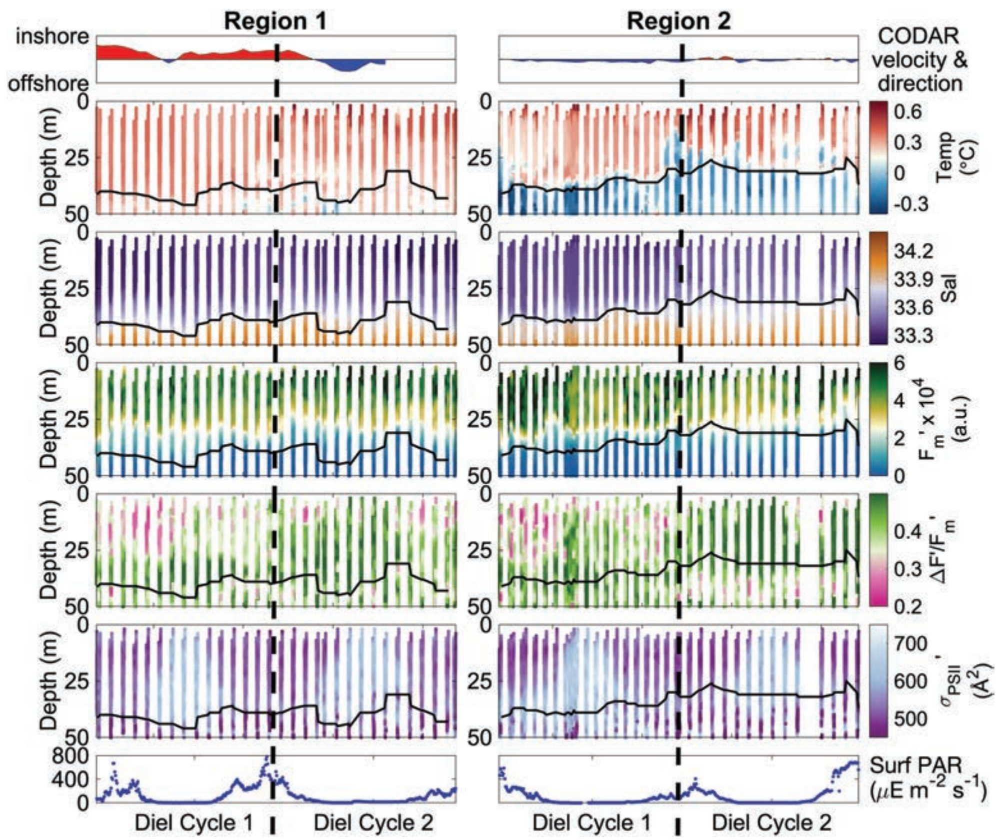

Fig. 6. Two diel cycles separated by the black vertical dotted line (as outlined in the surface PAR, bottom) collected in two regions with different oceanographic conditions. Direction and magnitude of the dominant surface currents (top, from HF radars) are in part responsible for changes in the vertical structure of the water column as demonstrated by the temperature and salinity panels and the depth of the mixed layer (black line). Remaining rows report FIRe measurements—F_m' (relative units), $\Delta F'/F_m'$ (dimensionless) and σ_{PSII}' (functional absorption cross-section of PSII, Å^2). Adapted from Carvalho et al. (2016a).

close to 50%, implying a matching reduction in the excitation delivery to the reaction centres of Photosystem II and a shift of E_k to higher values as seen in left σ_{PSII}' panel in Fig. 7 and left panels in Fig. 8.

Photoacclimation mechanisms evaluation

To cope with high light-induced stresses (i.e., to optimize light absorption under low light conditions or even to reduce total photon utilization under supra-optimal irradiances) phytoplankton have developed a suite of photoadaptation mechanisms. Using the drift mission data, we can compare the different photoacclimation responses to MLD dynamics (e.g., shallow vs. deep mixed layer). When cells photoacclimate, they adjust their photosynthetic machinery to operate at the highest quantum yield possible that allows for the maximal rate of photosynthesis. This occurs at the inflection point in the photosynthesis irradiance curve, the light saturation parameter (E_k) (Dubinsky and Schofield 2009). Bio-optical models (Webb et al. 1974; Jassby and Platt 1976) describe the relationship between photosynthesis and irradiance. The hyperbolic tangent model has become one of the most widely used models for predicting photosynthetic rates in natural phytoplankton assemblages. The photosynthetic rates (P) as a function of PAR are described by the following equation (Jassby and Platt 1976):

$$P = P_{\max}\left[\tanh\left(\frac{\text{PAR}}{E_k}\right)\right] \tag{1}$$

where PAR is photosynthetically active radiation, $P_{\max}$ is the maximum rate achieved at saturating light, and E_k is the light saturation parameter. The quantum yield ($\Delta F'/F_m'$) is, by definition, proportional to the ratio of P to PAR:

$$\frac{\Delta F'}{F_m'} = c\,\frac{E_k}{\text{PAR}}\left[\tanh\left(\frac{\text{PAR}}{E_k}\right)\right] \tag{2}$$

where $\Delta F'/F_m'$ is the quantum yield of photochemistry in PSII, measured under ambient light and c is a constant that corresponds to F_v/F_m measured in a dark-adapted state at PAR = 0, essentially α in a P–E curve. Changes in E_k values provide insight on photoacclimation regimes due to a combination of

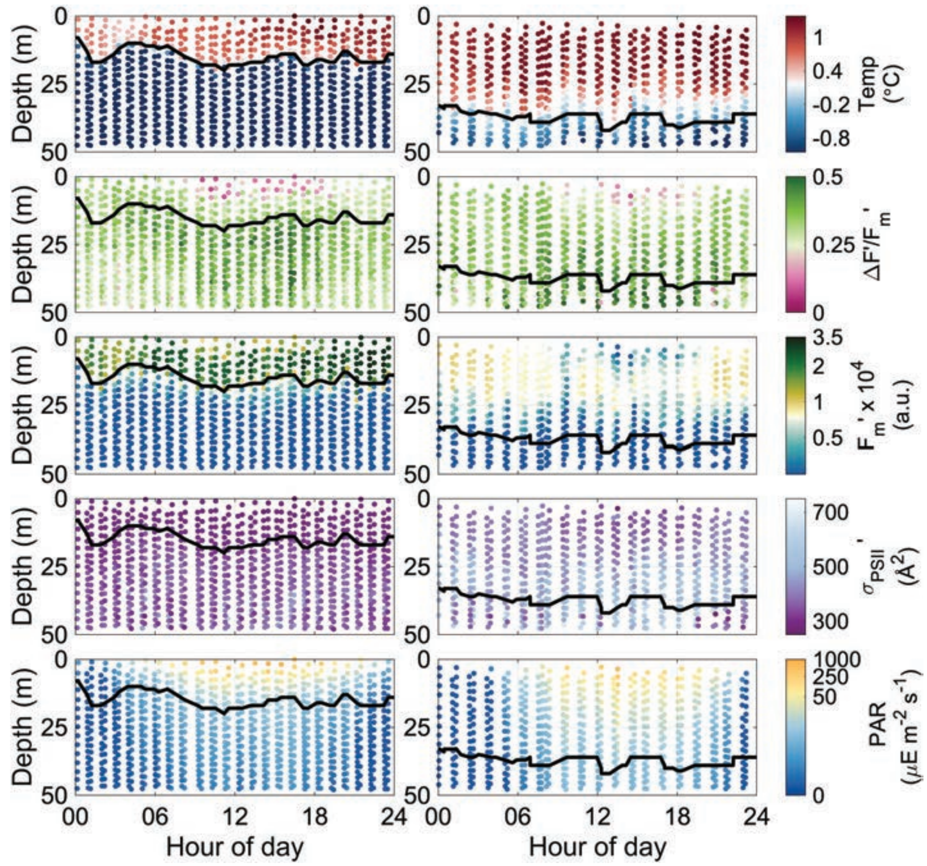

Fig. 7. Example of diel cycles collected during the drift mission for shallow (left panels) and deeper (right panels) mixing regimes. The depth of the mixed layer is shown with a black line. Gaps in data show times where glider was drifting at the surface. One profile was collected every hour. Effects of high irradiance periods (hours 10–16) shown in yellow in the Photosynthetically active radiation panels are evident by the low values seen in $\Delta F'/F_m'$ (photosynthetic efficiency), F_m' (proxy for biomass) and σ_{PSII}' (functional absorption cross-section). A warming of the upper ocean (temperature) is also seen during the highest irradiances. Adapted from Carvalho et al. (2016a).

the light field that phytoplankton are exposed and the mixing scales that can dominate the kinetics of primary productivity over the time-course of a day. This method can also be useful to evaluate the role of mixing in the competition between algal species (Falkowski and Woodhead 2013).

Applying this model (Eq. 2) to the high-resolution data from the FIRe glider during the drift mission we can estimate E_k and explain photoacclimatory responses of phytoplankton to changes in different MLD dynamics regimes (Figs. 7, 8).

Under a shallow MLD regime (Figs. 7, 8, left panel), where the light penetration reaches closer to the bottom of the ML, there is likelihood of two potential different physiological communities (i.e., communities with different photoacclimation regimes) as evaluated by the different E_k (compare orange and purple layers in Fig. 8). The much higher E_k seen at the surface gives an indication of phytoplankton acclimated to high irradiances while the lower E_k seen below the MLD shows lower light acclimation. Under deeper MLD conditions, E_k values are much closer (compare orange with purple box within the same MLD regime) indicating photoacclimation is similar between the two layers (Fig. 8). These measurements and the derived depth dependent variability of the light saturation parameter are difficult to measure using standard ship-based sampling strategies and cannot provide sustained measurements over time. The glider approach allows for these processes to be directly measured under ambient light and data collected over the deployment allows the rates of photoacclimation for natural populations to be measured as the physical features, such as the mixed layer depth, evolve over time, which are important controls on primary production.

The current configuration of the glider FIRe prototype allows the collection of an average induction curve every 2.5–3 m. This vertical resolution is constrained by the maximum sampling rate and by fixed pitch flying due to the configuration of the PAR sensor. Only upcast data are used for accurate PAR measurements, since the mounted PAR sensor is upward looking angled at -20° (Fig. 1). Multiple profiles are needed to increase the signal-to-noise ratio and provide a statistically significant fit to estimate E_k. For this dataset it required a

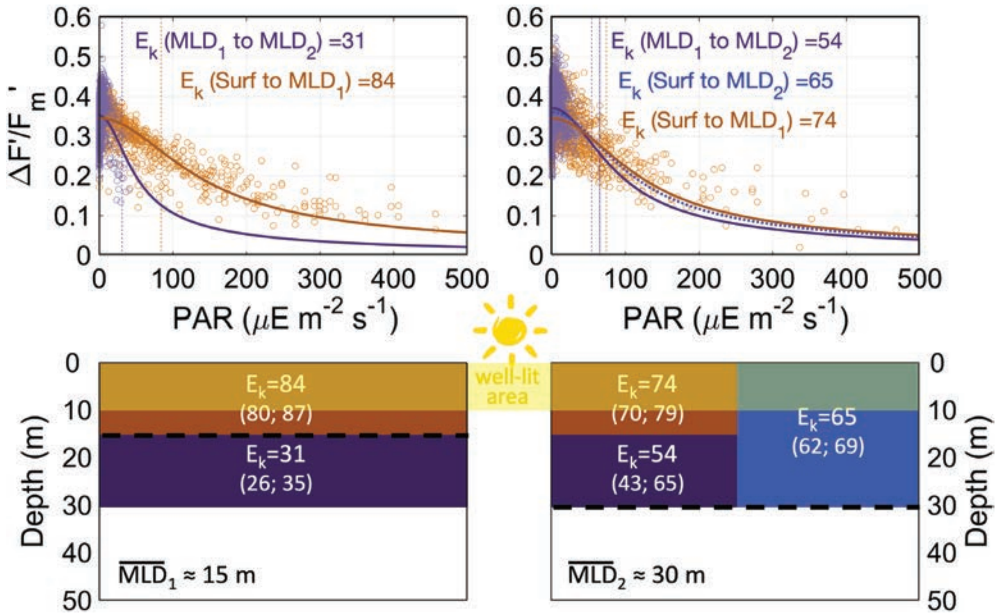

Fig. 8. (Top) Scatter plots of $\Delta F'/F_m'$ and PAR with curve fits (Eq. 2) for the two MLD regimes collected during the drift mission shown on Fig. 7 (upcast data only), highlighting the effect of MLD on phytoplankton photoacclimation. (left) average MLD$_1$ is 15 m, i.e., shallower. (right) average MLD$_2$ is 30 m, i.e., deeper. Three depth bins (surface to MLD$_1$—Orange, MLD$_1$ to MLD$_2$—purple, and surface to MLD$_2$—blue) were created to evaluate potential different phytoplankton photoacclimation regimes. Light saturation parameters, E_k, for each fitting are also presented. (bottom) Simple box model schematic with different depth bins, highlighting the different photoacclimation regimes presented in the plots on top, by comparing the E_k in each box, in relation to the MLD (black dashed line). Given PAR profiles from the glider, well-lit region of the upper ocean is shaded in yellow (top 10 m). 95% confidence intervals are presented in brackets for the E_k parameter estimation.

minimum of ~ 700 points, which corresponds to ~ 20 profiles using the current setup, all collected over a single diel cycle, to estimate a robust depth resolved E_k value. This number was obtained by evaluating the minimum number of points necessary to include in the analysis for the E_k to converge to a stable estimate.

Operational recommendations

Note that power is probably the biggest constrain when fitting a FIRe sensor on a glider. The factory estimated power consumption of the sensor is 5.88 W, but field data shows power consumption closer to 5.5 W, depending on the sampling rate, whether the instrument is on all the time and other fitted sensors. From our field experience, a deployment with the FIRe integration, where the sensors are kept always on, lasts about 10 and 36 d, using an alkaline and a lithium primary battery pack, respectively. In practice, given that shallow gliders collect one profile every 10–15 min, a reduction in profile frequency can extend the deployment length and maximize data collection. Sampling just on the upcast (as downcasts lack FIRe data in the upper 6-8 m given the time needed for the instrument to turn on and given the positioning of the PAR sensor), or even every other upcast still provides 2–3 profiles every hour and can double the deployment length. Depending on the science focus, namely nutrient limitation studies, sampling only during night-time can make a big difference in power consumption. Our planned station-keeping mission meant, contrary to the drift mission, that the glider is flying and collecting physical data continuously. A FIRe "yo" (upcast and downcast) every hour or so is a good compromise between the collection of high-resolution diel cycles of phytoplankton physiology and the mission longevity. Keep in mind, the ability to communicate with the glider means the duty cycle can be adjusted during the mission.

Comments and recommendations

Underwater gliders have proven to be a robust technology for autonomous high-resolution collection of oceanographic data. The integration of a FIRe sensor in a Slocum glider allows the evaluation of phytoplankton physiology in relation to the physical conditions. It also has the additional advantage of collecting in situ data under ambient light. Such data is fundamental for modeling instantaneous rates of primary production and the water-column integrated primary production (Ko et al. 2019). Using variable chlorophyll fluorescence, physiological parameters can be used to assess environmental factors controlling phytoplankton productivity. Gliders offer an added sampling flexibility in terms of both steering and endurance, by providing an opportunity to design missions to target specific scientific goals such as assessing the progression of a phytoplankton population through time or evaluating how different physical settings influence physiological responses. The high-resolution capabilities in both time and space permit the collection of diel cycles that allow a better understanding how phytoplankton react to variations in irradiance over different timescales.

Analysis of the irradiance dependencies of variable fluorescence signals provides insight into photoacclimation responses of phytoplankton to variations in vertical mixing regimes. While we realize that analyzing data from this FIRe sensor integration entails several assumptions and comes from a prototype, this study demonstrates the potential applications of this technology in autonomous platforms. Future plans include improving the sensor sensitivity to allow the use of the FIRe glider in oligotrophic regions. Increased flexibility to sample from different sensors independently from the FIRe sensor would be another helpful modification as it would allow extra data to be collected. The current integrated PAR sensor restricts the amount of data points collected during the profile as we cannot change the pitch to slow down the glider. Integrating a scalar irradiance PAR response would allow not only downcast sampling, but changing the pitch to slow the glider resulting in increased vertical resolution of photoacclimation parameters. Still, at a rate of ~ 0.4 measurements per metre, in a single 2-week mission, 592 profiles of FIRe data were collected, including over 17,000 induction curves, which corresponds to about 30 points per 100 m profile.

Another improvement would be integration of an ultra-high sensitive multi-color FIRe sensor (Gorbunov et al. 2020) onto the glider that allows selective excitation of different functional groups of phytoplankton, spectrally resolved functional absorption cross-sections of PSII. Such an integration would offer the potential to enhance sampling resolution, as well as to monitor changes in taxonomic composition of phytoplankton communities.

Key Points:
- A Slocum glider with an integrated deep-sea pH sensor collected high-resolution carbonate chemistry data in the Mid-Atlantic Bight
- Highest pH occurred in winter shelf and fall shelf break water, while lowest pH was seen in nearshore surface and Cold Pool bottom water
- Seasonal and spatial carbonate chemistry dynamics were influenced by stratification, freshwater input, biology, and water mass mixing

Abstract Ocean acidification alters the oceanic carbonate system, increasing potential for ecological, economic, and cultural losses. Historically, productive coastal oceans lack vertically resolved high-resolution carbonate system measurements on time scales relevant to organism ecology and life history. The recent development of a deep ion-sensitive field-effect transistor (ISFET)-based pH sensor system integrated into a Slocum glider has provided a platform for achieving high-resolution carbonate system profiles. From May 2018 to November 2019, seasonal deployments of the pH glider were conducted in the central Mid-Atlantic Bight. Simultaneous measurements from the glider's pH and salinity sensors enabled the derivation of total alkalinity and calculation of other carbonate system parameters including aragonite saturation state. Carbonate system parameters were then mapped against other variables, such as temperature, dissolved oxygen, and chlorophyll, over space and time. The seasonal dynamics of carbonate chemistry presented here provide a baseline to begin identifying drivers of acidification in this vital economic zone.

Plain Language Summary Seawater chemistry affects the ability of organisms to survive in the ocean. Past monitoring of seawater chemistry has missed key times and locations that are important to natural life cycles. In order to fill in those gaps, we put a chemical sensor into a deep-sea robot that we can control from land. This robot, called a Slocum glider, glides from the top of the ocean down to 200-m depth and collects ocean chemistry data along the way. We used our Slocum glider to measure how seawater chemistry differs between seasons in the Mid-Atlantic, which will help us understand how organisms might be affected by water conditions.

1. Introduction

Ocean acidification (OA) results from the uptake of atmospheric carbon dioxide (CO_2), which alters oceanic carbonate chemistry (Doney et al., 2009; Gledhill et al., 2015; Orr et al., 2005). The ocean has absorbed approximately one third of the CO_2 emitted by human activities since the Industrial Revolution (Gruber et al., 2019). During this time, atmospheric CO_2 has risen from approximately 280 parts per million (ppm) to 410 ppm (Dlugokencky & Tans, 2020). When CO_2 is absorbed by the ocean, it reacts with seawater and results in complex chemical reactions that reduce seawater pH and calcium carbonate saturation state, Ω. Saturation states governing the formation and dissolution of the two mineral forms of calcium carbonate, calcite and aragonite, are expressed as Ω_{cal} and Ω_{arag}, respectively. A saturation state above 1 indicates carbonate supersaturation and thermodynamic favorability of carbonate calcification, while a saturation state below 1 indicates carbonate undersaturation and thermodynamic favorability of carbonate dissolution. However, carbonate saturation states approaching 1, and as high as 1.92, have been shown to cause negative impacts on calcifying organisms, despite carbonate supersaturation (Gazeau et al., 2007; Gledhill et al., 2015; Gobler & Talmage, 2013, 2014; Hettinger et al., 2012; Talmage & Gobler, 2009, 2010; Waldbusser et al., 2014), likely due to impacts on metabolism and increases in the energetic cost of mitigating stress (Melzner et al., 2019; Miller et al., 2009; Pan et al., 2015).

The rate of oceanic uptake of atmospheric CO_2 has increased in the last two decades due to increasing levels of atmospheric CO_2 (Intergovernmental Panel on Climate Change [IPCC], 2019). The global ocean is acidifying at unprecedented rates, with open ocean surface water pH decreasing by 0.017–0.027 pH units per decade since the late 1980s (Gledhill et al., 2015; IPCC, 2019; Sutton et al., 2016; Zeebe, 2012). Global surface ocean pH is predicted to decline by up to 0.29 pH units by 2081–2100 relative to 2006–2015 under RCP8.5 (IPCC, 2019). In addition to global changes in pH, the rate of change in global Ω_{arag} since the Industrial Revolution has been 5 times greater than natural variability over the last millennium (Friedrich et al., 2012; Gattuso et al., 2015). Under RCP8.5, there will be no ocean water with Ω_{arag} greater than 3.0, and the total volume of water with Ω_{arag} less than 1.0 will increase from 76% (1990 value) to 91%, by 2100 (Gattuso et al., 2015).

In coastal oceans, carbonate chemistry is influenced by a range of drivers including productivity-respiration cycles, nutrient loading, freshwater inputs, and other coastal processes (Gledhill et al., 2015; Saba, Goldsmith, et al., 2019). Because of its multiple contributors, acidification in coastal zones can be highly variable and episodic both spatially and temporally (Baumann & Smith, 2017). The hydrodynamic and biological processes influencing coastal environments can vary on the order of minutes to days (Runcie et al., 2018; Xu et al., 2017). These extreme short-term events likely have a more immediate impact on carbonate-dependent organisms compared to gradual change due to increases in atmospheric CO_2 (Baumann & Smith, 2017; Cai et al., 2011; Waldbusser & Salisbury, 2014). However, a global increase in atmospheric CO_2 will increase the frequency of extreme acidification events, pushing organisms past critical survival thresholds more regularly (Gledhill et al., 2015). Furthermore, acidification can cooccur with other metabolic stressors, including low dissolved oxygen (DO) and warm temperatures (Cai et al., 2011, 2017; Saba, Goldsmith, et al., 2019).

The Mid-Atlantic Bight (MAB), located within the U.S. Northeast Shelf (NES), is an ecologically and economically vital coastal zone. This region is home to some of the most profitable commercial and recreational fisheries in the United States (Colvocoresses & Musick, 1984; Hare et al., 2016; NEFSC, 2020), ecosystems that protect coastal communities from inundation, storms, and erosion (NRC, 2010), and offshore wind energy development sites (Musial et al., 2013; NEFSC, 2020). The MAB is prone to acidification due to freshwater sources (primarily riverine), eutrophication and photosynthesis-respiration cycles, coastal upwelling, and other influences. Coastal inputs and biological activity alter carbonate chemistry more quickly than gas equilibrium and therefore play a major role in determining the carbonate system, specifically the partial pressure of CO_2 (pCO_2) and pH (Cai et al., 2020). Mid-Atlantic coastal waters are acutely affected by seasonal changes in temperature and inputs from shore. Because MAB oceanography is highly variable between seasons, it is necessary to monitor changes in the carbonate system seasonally (Huret et al., 2018). While there may be no net change in pH or Ω_{arag} over a full annual cycle, seasonal changes operate under a time scale that could affect biological processes in the nearshore (Gledhill et al., 2015; Waldbusser & Salisbury, 2014). Monitoring seasonal changes also provide a basis for identifying long-term changes in carbonate chemistry due to shifts in salinity, temperature, atmospheric CO_2, and coastal inputs (Gledhill et al., 2015; Goldsmith et al., 2019; Xu et al., 2020).

Acidification monitoring efforts to date are limited in temporal and spatial resolution and lacking in economically important coastal regions including the MAB (Goldsmith et al., 2019). Traditionally, monitoring in the MAB has been conducted through large field campaigns every few years. These ship-based surveys depict large spatial variability and decadal changes of surface water carbonate chemistry in the U.S. NES but lack seasonal resolution across the system (Cai et al., 2020; Z. A. Wang et al., 2013; Wanninkhof et al., 2015). In addition to cruise campaigns, there are few fixed (moored) stations monitoring carbonate system parameters on the MAB shelf. These fixed stations are capable of characterizing temporal changes in carbonate chemistry but lack spatial resolution in terms of location and depth. Additionally, many existing MAB monitoring stations measure only one of the four carbonate system parameters (pH, dissolved inorganic carbon [DIC], total alkalinity [TA], and pCO_2), two of which are necessary to fully characterize the carbonate system (Pimenta & Grear, 2018). Along with cruise campaigns and surface-fixed stations, satellite imagery can be used to estimate a suite of surface water carbon system factors, including biological productivity, pCO_2, salinity-derived carbonate parameters, and large-scale coastal inputs (Salisbury et al., 2015; H. Wang et al., 2017).

The ability to monitor carbonate chemistry in high resolution throughout the water column is critical in order to detect low pH in water masses and to derive relationships between physical, biological, and carbonate system variability. Autonomous underwater gliders, capable of collecting data in highly variable

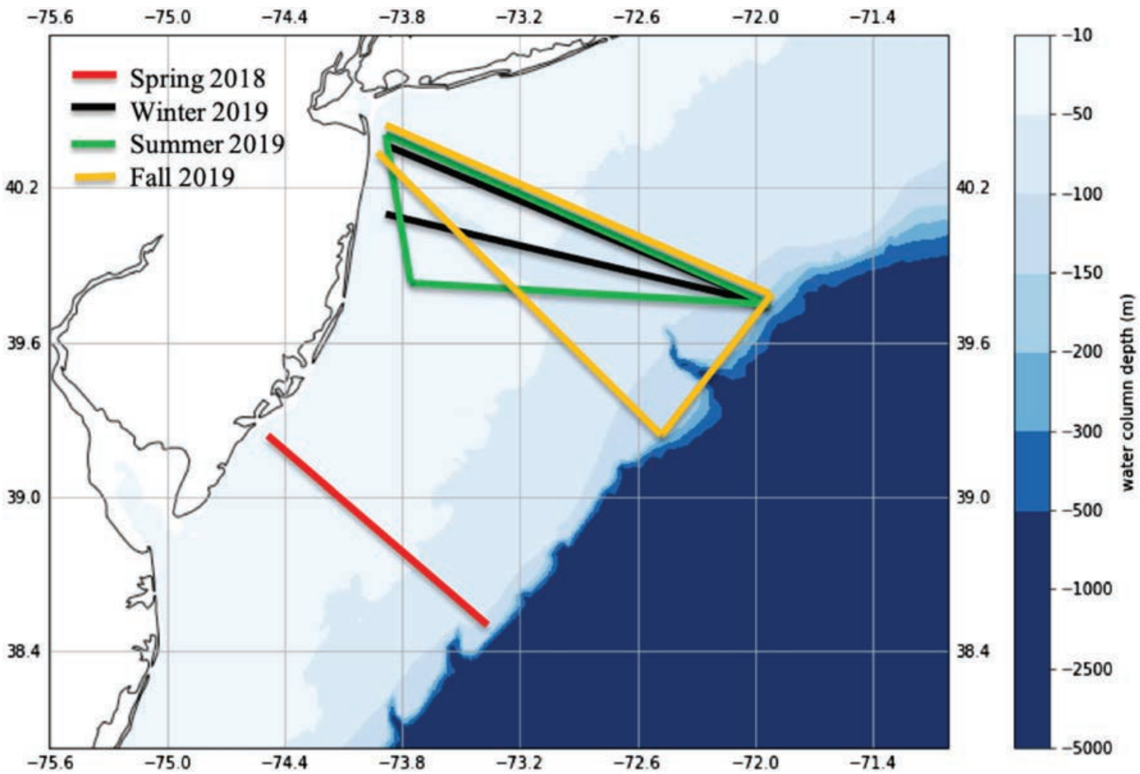

Figure 1. Seasonal glider deployments completed between May 2018 and November 2019.

currents in water depths up to 1,000 m, are a reliable platform that fulfill this role (Rudnick, 2016; Schofield et al., 2007). A deep ion-sensitive field-effect transistor (ISFET) pH sensor was recently developed and integrated into a Teledyne-Webb Slocum G2 glider (Saba, Wright-Fairbanks, et al., 2019). In addition to measuring pH, this glider has a suite of sensors that provide profiles of conductivity, temperature, DO, chlorophyll fluorescence, and spectral backscatter. This allows users to compare seawater pH to other ocean properties and conduct salinity-based estimates of TA in order to constrain the carbonate system. Here, we present data from four seasonal deployments of the pH glider in the central MAB, which have produced the first spatially and temporally high-resolution characterization of seasonal carbonate system dynamics in this region.

2. Materials and Methods

2.1. Seasonal Deployments

The pH glider was deployed on four seasonal missions in the MAB (2–22 May 2018 [spring], 1–19 February 2019 [winter], 17 July to 12 August 2019 [summer], and 15 October to 6 November 2019 [fall]; Figure 1). Before deployment, the glider pH sensor was fully conditioned following the guidelines described in Saba, Wright-Fairbanks, et al. (2019). After deployment from the small vessel R/V Rutgers, the glider was sent on a shallow mission during discrete water sample collection (see below). Once discrete sampling was completed, the glider was sent to its first offshore waypoint. The winter, summer, and fall missions followed a cross-shelf transect starting ~15 km off Sandy Hook, New Jersey, traveling 200 km eastward to the shelf break. The glider then completed various transects and triangles back to shore, covering a total of 469.6 km in winter, 503.5 km in summer, and 471.4 km in fall. The spring mission followed an established glider observation line from Atlantic City, New Jersey, 140 km eastward to the shelf break and back, for a total of 317.0 km.

Timing for sensor repairs and recalibrations prevented four sequential seasonal deployments on the Sandy Hook transect line. A mission planned for spring of 2019 on the Sandy Hook line was postponed due to technological difficulties and rough seas, and the postponed mission was terminated within hours of deployment due to a glider pump failure. The spring deployment was rescheduled for April 2020 but was canceled due to research restrictions during the coronavirus disease 2019 (COVID-19) pandemic.

Upon each deployment and recovery of the pH glider, discrete water samples were collected following best practice guidelines for autonomous pH measurements with DuraFET sensors (Bresnahan et al., 2014; Johnson et al., 2016; Martz et al., 2015; Saba, Wright-Fairbanks, et al., 2019). Discrete samples were collected near the glider at various depths either by a hand-lowered 5-L Niskin (spring and winter; within 5 m of glider) or using an SBE55 6-bottle rosette with an SBE19 conductivity, temperature, and depth sensor (CTD) attached (summer and fall; within 100 m of glider). Samples were collected into 250-ml borosilicate glass bottles and preserved with 50 μl of saturated mercuric chloride then transported to the Cai laboratory (University of Delaware) for analysis (section 2.2.3).

2.2. Sensor QA/QC

2.2.1. Glider CTD, Oxygen, and Chlorophyll Sensors

The glider was equipped with a pumped CTD modified for integration with an ISFET pH sensor, an Aanderaa oxygen optode, and a Sea-Bird Scientific BB2FL ECO puck to measure chlorophyll fluorescence, colored dissolved organic matter (CDOM), and optical backscatter. The CTD and DO data were run through quality assurance/quality control (QA/QC) guidelines outlined in an Environmental Protection Agency (EPA) QA Project Plan for glider deployments along the coast of New Jersey (Kohut et al., 2014). Both sensors are factory calibrated annually, and data were verified predeployment and postdeployment (Saba, Wright-Fairbanks, et al., 2019). The BB2FL ECO puck is factory calibrated by WET labs every 1–2 years. Between each seasonal deployment, the integrated CTD/pH sensor was cleaned and recalibrated by the manufacturer (Sea-Bird Scientific).

2.2.2. Glider pH Sensor

Each time the glider surfaced throughout a mission, a subset of collected data was sent to shore via an Iridium satellite phone located in the tail of the glider. This allowed for preliminary inspection of all science data and software metrics to assess glider functionality. Full data sets were collected postrecovery from memory cards stored in the glider. Data were processed using Slocum Power Tools (https://github.com/kerfoot/spt/) and analyzed using MATLAB data analysis software (version R2019a).

pH data were initially inspected for sensor time lags, which were identified as skewed upcast and downcast profiles in pH reference voltage data and were often associated with areas of steep gradients in salinity or temperature. To correct for sensor lag, upcast and downcast pairs were run through potential time shifts from 0 to 60 s at 1-s intervals. The optimal time shift minimized the difference between reference voltage at a certain depth in an upcast/downcast pair (Saba, Wright-Fairbanks, et al., 2019).

After time shifts were applied, pH data were run through QA/QC measures based on the Integrated Ocean Observing System (IOOS) Manual for Real-Time Quality Control of pH Data Observations (IOOS, 2019). pH reference voltage data were flagged and removed in instances where more than 1 hr has passed between observations ($\ll$1% of observations) or in instances without a valid time stamp (~20% of observations). Next, observations of other scientific variables without both a corresponding pH reference voltage and pressure value were removed (~40% of observations). Observations outside of the latitude and longitude bounds of the MAB were flagged and removed ($\ll$1% of observations). pH values were validated in a gross range test, flagging and removing values outside the calibration bounds of the glider pH sensor (pH $<$ 6.5 and pH $>$ 9; $\ll$1% of observations). As more deployments of the pH glider provide a mean climatology for the MAB, the gross range test can be restricted to a user-specified local or seasonal pH range. Next, a spike test identified and removed single value spikes in pH reference voltage observations ($\ll$1% of observations). Lastly, data were inspected visually for unrealistic rates of change, flat-lining, and attenuated signals, which would indicate sensor failure. Tests for multivariate failure and comparisons to nearby pH sensors were not applicable to these deployments, but should be considered in future pH glider deployments.

2.2.3. Discrete Samples

Discrete sample pH was measured spectrophotometrically at 25°C using purified *meta*-Cresol Purple dye (Clayton & Byrne, 1993; Liu et al., 2011). pH accuracy was determined against Tris buffers (DelValls & Dickson, 1998; Millero, 1986). Additionally, discrete TA and DIC measurements were used to calculate pH and check the internal accuracy of spectrophotometric measurements. TA titrations were run via open cell Gran titration on an Apollo Scitech TA titrator AS_ALK2 (Cai et al., 2010; B. Chen et al., 2015;

Huang et al., 2012). DIC was quantified using a nondispersive infrared method on an Apollo Scitech DIC Analyzer AS-C3 (B. Chen et al., 2015; Huang et al., 2012). TA and DIC accuracies were determined using certified reference materials (CRMs) from Andrew Dickson's group at the Scripps Institution of Oceanography.

Discrete pH measurements were converted to in situ pH values using in situ, depth-specific temperature and salinity measured by SBE19 CTD. Discrete pH was then compared to glider ISFET measurements at the same, or closest, depth from the glider's first profile at deployment and its last profile before recovery. Groundtruthing offsets were determined as glider pH—discrete pH at each depth. Glider agreement was calculated as the average absolute offset between all depths at deployment or recovery. Uncertainty in glider agreement was calculated as one standard deviation between glider pH measurements in the surface layer during the discrete sampling period. Because there was little variation in temperature and salinity in the surface layer over a short period of time, variation in glider pH introduced by the environment was small. Glider pH science bays were sent to SeaBird Scientific for postdeployment analysis, cleaning, and recalibration between deployments.

2.3. Data Analysis

Salinity was calculated based on glider-measured conductivity, temperature, and pressure. TA and salinity exhibit a conservative relationship in U.S. East Coast waters (Cai et al., 2010; Z. A. Wang et al., 2013); thus, TA is estimated using glider-derived salinity (Saba, Wright-Fairbanks, et al., 2019). In each season, a linear regression to estimate TA from salinity was derived from a combination of discrete samples taken at glider deployment/recovery and discrete samples from transects across the U.S. NES during the East Coast Ocean Acidification (ECOA)-1 cruise in summer 2015 (supporting information Text S1). Discrete samples from glider deployments and the ECOA-1 cruise were both analyzed by the Cai group using the same method. Sampling during glider deployments and recoveries took place only in relatively low salinity nearshore waters (Figure S1). Conversely, the ECOA-1 cruise sampled across the entire shelf to the shelf break but missed lower salinity areas. Using both seasonal discrete samples and shelf-wide ECOA samples ensured that seasonal TA-salinity regressions accounted for the entire scope of salinities the glider encountered in the MAB while minimizing uncertainty due to seasonal differences in TA-salinity relationships. Full-deployment salinity-estimated TA was also compared to TA derived using the CANYON-B algorithm, which is trained on GLODAPv2 and GO-SHIP bottle samples, and calculates carbonate system parameters using measured latitude, longitude, time, depth, temperature, salinity, and oxygen (Bittig et al., 2018).

Glider pH was calculated on the total hydrogen concentration scale using glider-measured reference voltage, salinity, pressure, temperature, and sensor-specific calibration coefficients (Johnson et al., 2017; Saba, Wright-Fairbanks, et al., 2019). The remaining carbonate system parameters were calculated using CO2SYS for MATLAB (v3.0) with glider temperature, salinity, pressure, pH, and salinity-derived TA as inputs (Lewis & Wallace, 1998; Sharp et al., 2020; van Heuven et al., 2011). Other CO2SYS inputs included total pH scale (mol kg^{-1}-SW), K_1 and K_2 constants of Mehrbach et al. (1973) with refits by Dickson and Millero (1987), KSO_4 dissociation constant of Dickson (1990), KHF dissociation constant of Uppstrom (1974), and borate-to-salinity ratio of Perez and Fraga (1987). Carbonate system parameters reported here are pH, Ω_{arag}, and ratio of TA to DIC (TA:DIC). TA:DIC provides context for the CO_2 buffering capacity of seawater. Oceanic buffering capacity for CO_2 reaches a minimum at TA:DIC = 1, meaning water with TA:DIC closest to 1 is most susceptible to acidification (Cai et al., 2020; Egleston et al., 2010; Z. A. Wang et al., 2013).

Slocum gliders are propelled by purposeful changes in buoyancy, allowing the glider to dive and climb in a sawtooth pattern from surface to bottom waters. The pH glider system used here was equipped with a 200-m pump, allowing it to operate in depths as shallow as 4 m and as deep as 200 m. Coastal gliders travel approximately 20 km day^{-1} horizontally, while profiling vertically at 10–15 cm s^{-1}. Sensors sample at 0.5 Hz, providing observations at 20- to 30-cm intervals vertically. All measured and derived variables were bin-averaged into 1-m depth by 1-km-distance bins. At a sampling rate of 0.5 Hz and vertical profiling velocity of 10–15 cm s^{-1}, a 1-m depth average incorporated three to five measurements, minimizing the effect of small-scale physical and biological water column dynamics. At a horizontal speed of 20 km day^{-1}, a 1-km-distance bin averaged 1.2 hr of data, which could include between 3 and 30 individual profiles depending on water column depth.

Brunt-Vaisala frequency squared (N^2) was calculated between adjacent 1-m layers in each depth- and distance-binned profile. The mixed-layer depth (MLD) for each binned profile was determined as the depth of maximum N^2 ($\max(N^2)$) (Carvalho et al., 2017). Each profile's mixed layer was assigned a quality index (QI), which indicates the significance of the stratification index based on relative homogeneity in and below the mixed layer (Carvalho et al., 2017; Lorbacher et al., 2006). Profiles with QI < 0.5 were considered well mixed and removed from MLD analysis.

For analysis, deployment data were split into spatial and depth-defined regions. Distinctions between surface and bottom waters were made using the mean MLD in each season, with surface waters defined as surface to MLD, and bottom waters from MLD to the bottom. During winter, there was no significant MLD (QI < 0.5). Therefore, winter surface and bottom parameters were represented by an average of the top 5 m and bottom 5 m of the water column, respectively. The nearshore region was defined as extending from shore to the 35-m isobath, where sea slope begins to increase in the central MAB, or 1–40 km offshore (Levin et al., 2018). Midshelf was defined from the 35- to 100-m isobaths or 40–160 km offshore (40–120 km offshore in the spring). The shelf break was defined as beyond the continental shelf (>160 km offshore or >120 km offshore in spring), where depth increases to >100 m.

Significances of regional and seasonal comparisons of measured and derived variables were calculated using a Kruskal-Wallis analysis with Dunn post hoc, unless otherwise noted. Significance is reported as a p value, with $p < 0.05$ demonstrating a significant difference between the values being compared. All averages are presented as mean ±1 standard deviation, and a table of averages is included in the supporting information (Table S1). Along with being depth-averaged into 1-m bins, chlorophyll and oxygen concentrations were integrated to 35-m depth to analyze mixed layer productivity. Integration to 35 m, as opposed to full-water column integration, ensured that the majority of mixed layer productivity in each season was captured while minimizing skewed integrations that could arise due to seasonal differences in profile depths. The 35-m integrated chlorophyll and oxygen are presented along with 1-m depth-averaged chlorophyll and oxygen.

To visualize the spread of data in each season, box-and-whisker plots displaying medians, 25th and 75th percentiles, minimums, and maximums were created for glider-measured and derived variables. To summarize carbonate system interactions with the development and degradation of seasonal stratification and chlorophyll maxima, physical, biological, and carbonate system properties from the first cross-shelf transect of each deployment were plotted on common color axes. Finally, full-deployment carbonate parameters were plotted as a function of distance from shore and season in order to visualize spatial differences in carbonate system seasonality.

3. Results

3.1. Sensor Performance

A full record of groundtruthing offsets is available in Tables S2 and S3. Seasonal mean glider agreement ranged from 0.005 to 0.042 pH units and within-mixed-layer variability ranged from 0.001 to 0.027 pH units. Given these observations, we believe that glider pH measurements are accurate to better than 0.05 pH units, which agrees with the manufacturer accuracy specification for this sensor (±0.05 pH units). Short-term reproducibility is likely significantly better than 0.03 because the source of error is short-term, within-mixed layer repeatability. This conclusion is supported by the manufacturer precision specification for this sensor (±0.001 pH units), which implies that spatial variability along a section can be resolved to ±0.001 pH units. Therefore, pH is reported here to the third decimal place.

pH sensor time lag varied seasonally. No shift was necessary for the winter mission, while 47- and 30-s shifts were applied to the spring mission, a 36-s shift was applied to the summer mission, and a 45-s shift was applied to the fall mission. Spring required two lag corrections because of a shift in the sensor lag between the first third and last two thirds of deployment, likely due to a shift in water column structure (Saba, Wright-Fairbanks, et al., 2019).

The magnitude of uncertainty in derived variables varied based on the accuracy of TA estimation. Average absolute differences between discrete TA and estimated TA ranged from 5.5 (winter) to 27.4 μmol kg^{-1} (summer). Average uncertainty in Ω_{arag} and TA:DIC due to TA offsets ranged from 0.005 to 0.024 and 0.0001 to 0.0003, respectively (Table S4). A full analysis of TA offsets, as well as a list of seasonal

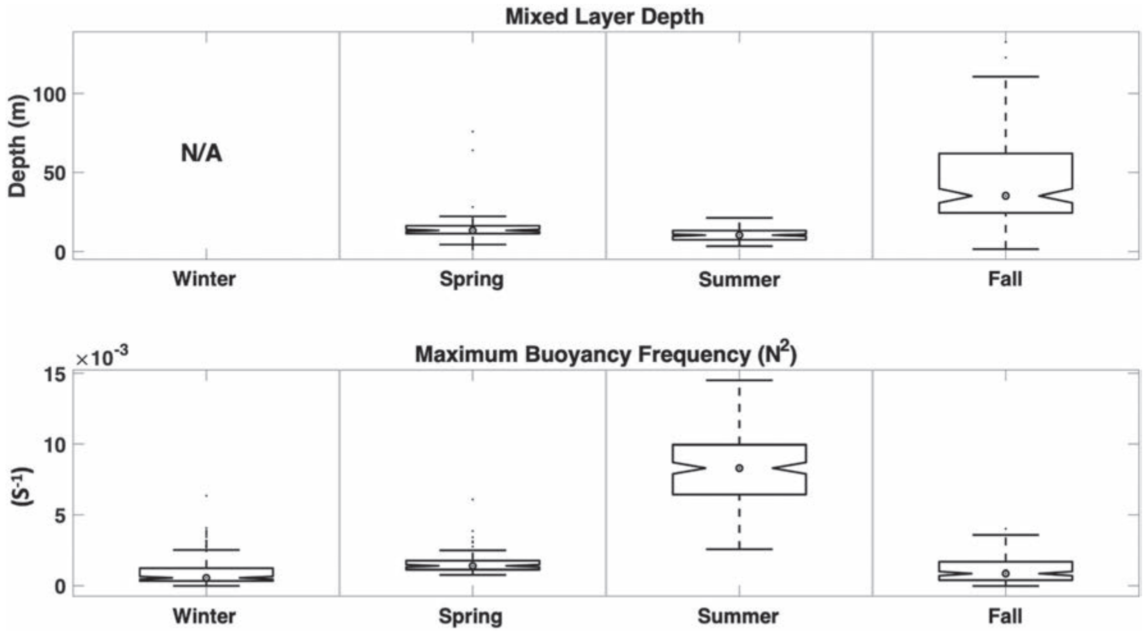

Figure 2. Comparisons of mixed layer depth (MLD) and maximum buoyancy frequency (max(N^2)) during seasonal glider deployments. Targets indicate median values, box limits indicate the 25th to 75th percentiles, and whiskers represent the full range of data. Data points beyond 1.5 times the interquartile range away from the top or bottom of the box were identified as outliers and are shown as black dots extending from the whiskers. Notches depict the 95% confidence interval around the median. If notches do not overlap, there is 95% confidence that the medians are different ($p < 0.05$). Winter had a well-mixed water column with insignificant MLD QI values; thus, no data are shown for winter MLD.

TA-salinity regressions, can be found in the supporting information (Text S1 and Tables S4 and S5). Full-deployment salinity-derived TA was similar to CANYON-B algorithm estimates of TA, differing at most by a seasonal average of 2.0 ± 4.3 μmol kg^{-1} (~0.1%).

3.2. Seasonal and Spatial Water Column Dynamics

The winter mission collected 4,933 profiles of science data over 19 days, spring collected 6,426 profiles over 20 days, summer collected 6,948 profiles over 26 days, and fall collected 5,333 profiles over 22 days. On average, about 270 profiles were generated per day. Although the four seasonal deployments were not sequential, they highlight stratification and mixing patterns typical of the MAB, revealing seasonal transitions in physical, biological, and chemical characteristics described in detail below.

3.2.1. Physical Dynamics

Seasonal changes in stratification occurred in the MAB (Figures 2 and 3). The winter water column was cold (<13°C) and well mixed, with no significant MLD (QI < 0.5) and the lowest observed max(N^2) (0.0010 ± 0.0010 s^{-1}, $n = 187$, $p < 0.001$). Surface waters were warmer in the spring compared to winter ($p < 0.001$), resulting in stronger stratification (max(N^2) = 0.0015 ± 0.0005 s^{-1}, $n = 129$, $p < 0.001$) and MLD of 14.4 ± 8.2 m ($n = 129$). Surface temperature peaked in the summer (23.64 ± 1.13°C, $n = 188$, $p < 0.001$), while bottom waters remained cold, resulting in continued shoaling of MLD to 10.4 ± 3.7 m ($n = 188$) and the greatest max(N^2) observed seasonally (0.0082 ± 0.0025 s^{-1}, $n = 188$, $p < 0.001$). Strong stratification in the spring and summer trapped a cold (<12°C) water mass below the mixed layer, which was consistent with the well-known summer Cold Pool (Z. Chen et al., 2018; Houghton et al., 1982). Surface waters cooled in the fall, causing a lower max(N^2) (0.0011 ± 0.0009, $n = 358$), and a deep MLD (44.7 ± 27.7 m, $n = 180$).

Surface and bottom water salinity were significantly lower in the nearshore than at the shelf break in every season ($p < 0.001$; Figures 3 and 4). With the exception of spring (full water column) and summer bottom water, surface and bottom temperature also increased from nearshore to the shelf break in each season ($p < 0.004$; Figures 3 and 4). The lowest salinities were recorded in nearshore summer surface waters ($p < 0.001$), averaging 30.06 ± 0.37 PSU ($n = 28$). In the summer, midshelf surface waters were also significantly fresher than the other seasons ($p < 0.001$), due to heavy rainfall during the mission. The highest

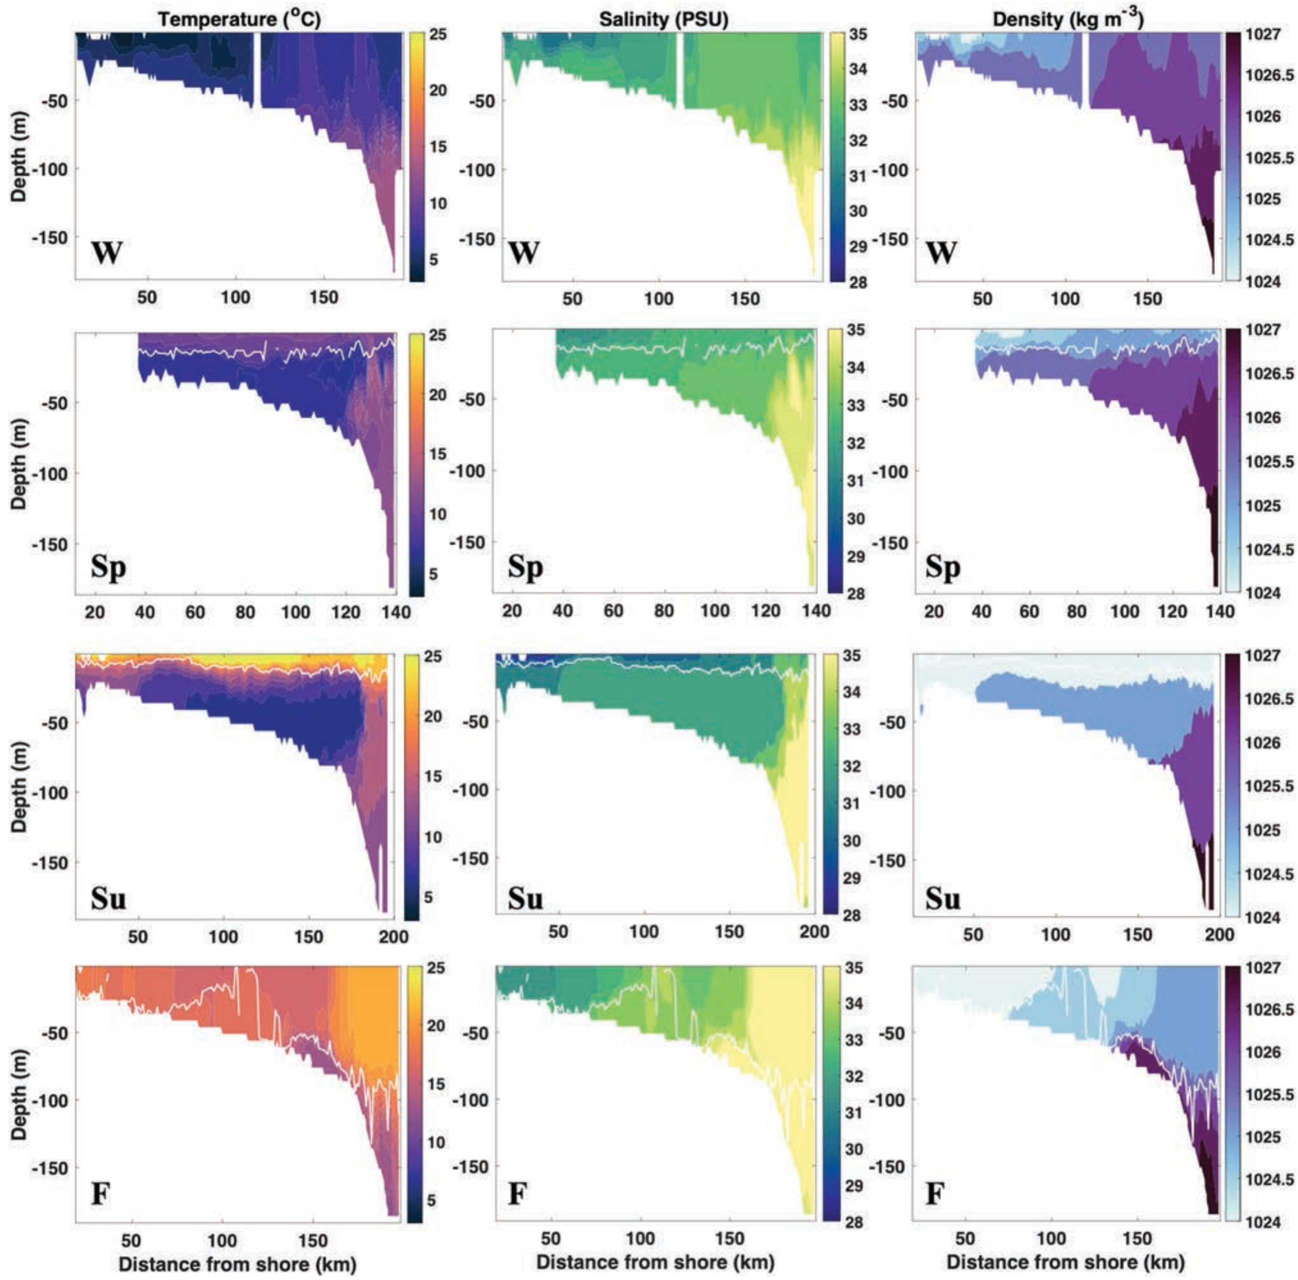

Figure 3. Contour plots of temperature, salinity, and density from four seasonal glider deployments in the MAB (W = winter, Sp = spring, Su = summer, and F = fall). Data shown are from the first cross-shelf transect of each deployment. Mixed layer depth (MLD) for each binned profile is plotted in white. Winter had no significant mixed layer. The nearshore region was defined as 1–40 km offshore, midshelf was 40–160 km offshore (40–120 km in spring), and the shelf break was >160 km offshore (>120 km offshore in spring).

salinities were recorded in fall shelf break surface and bottom waters ($p < 0.001$), averaging 35.66 ± 0.26 PSU ($n = 38$) and 35.37 ± 0.17 PSU ($n = 38$).

3.2.2. Biological Characteristics

Phytoplankton biomass varied seasonally as water column structure changed in the MAB (Figures 4 and 5). The deeply mixed fall water column and the productive spring water column had the highest 35-m integrated chlorophyll concentrations of 43.39 ± 11.23 mg m^{-2} ($n = 180$) and 42.82 ± 19.79 mg m^{-2} ($n = 129$), respectively ($p < 0.001$). Fall and spring integrated chlorophyll levels were not significantly different from one another. Winter and summer had significantly lower 35-m integrated chlorophyll concentrations than the seasons preceding them ($p < 0.001$).

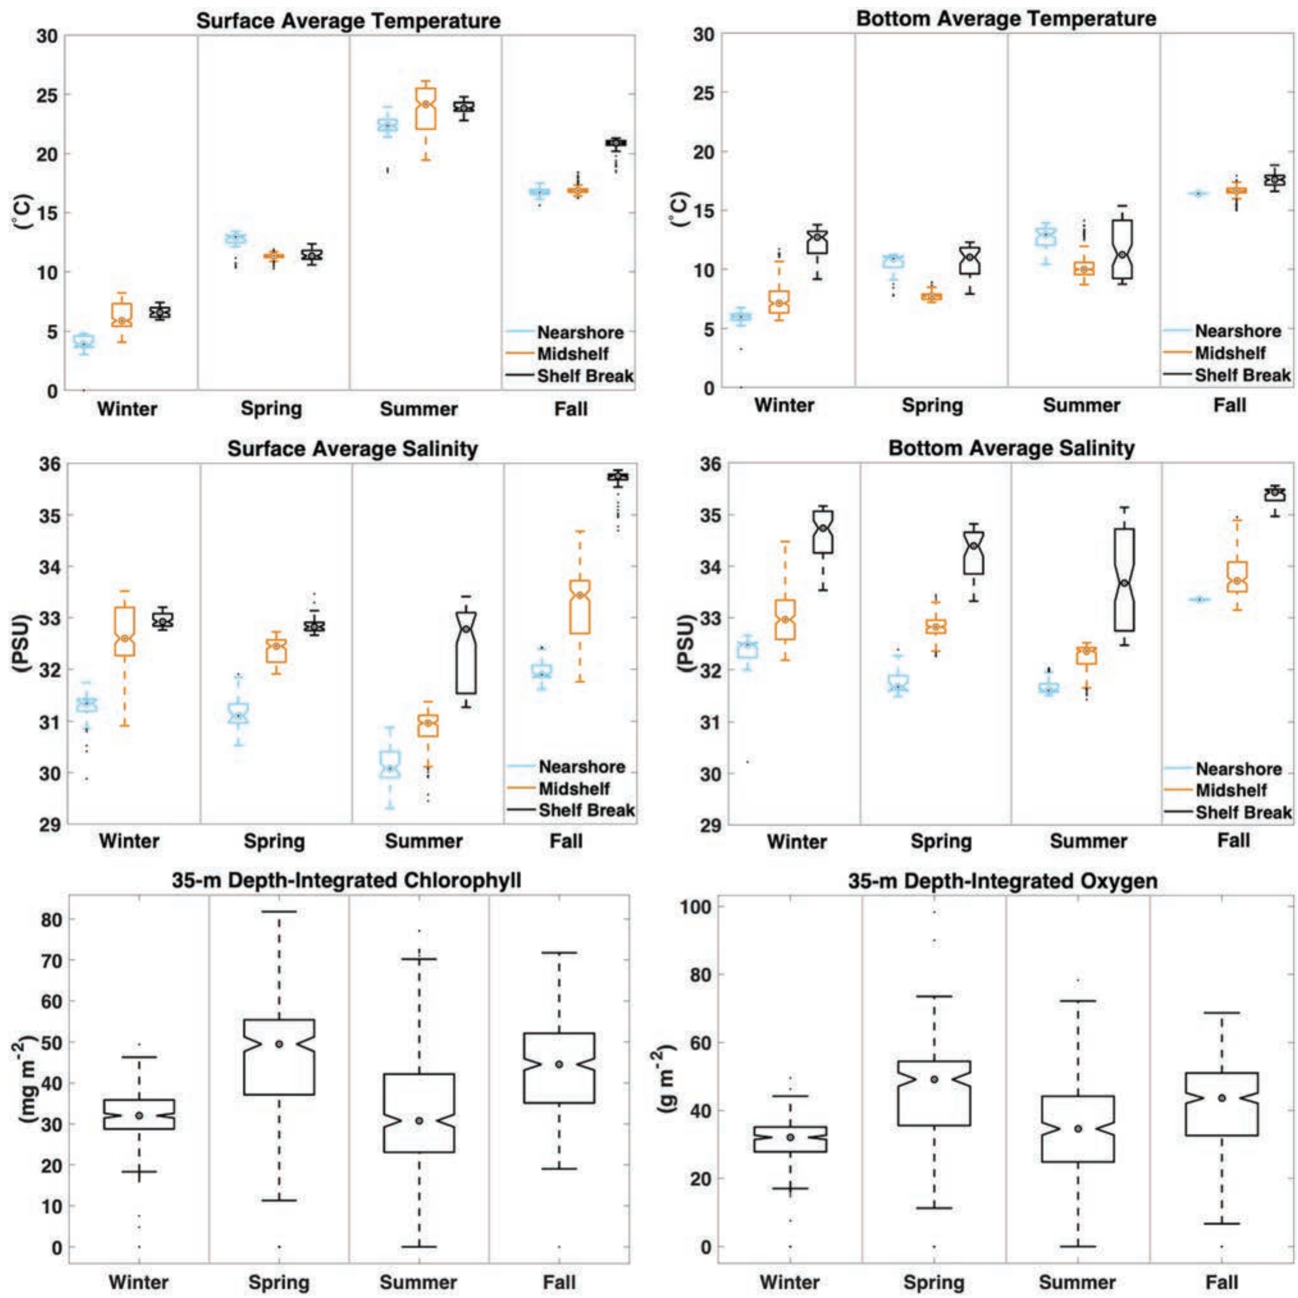

Figure 4. Comparisons of physical, biological, and chemical ocean properties during seasonal glider deployments. Targets indicate median values, box limits indicate the 25th to 75th percentiles, and whiskers represent the full range of data. Data points beyond 1.5 times the interquartile range away from the top or bottom of the box were identified as outliers, and are shown as black dots extending from the whiskers. Notches depict the 95% confidence interval around the median. If notches do not overlap, there is 95% confidence that the medians are different ($p < 0.05$).

In each binned profile, the chlorophyll maximum was identified as the 1-m depth bin with the highest 1-m depth-averaged chlorophyll concentration. Depth-averaged chlorophyll concentrations at the chlorophyll maximum were 1.55 ± 0.48 mg m^{-3} ($n = 187$) in winter, 3.35 ± 2.16 mg m^{-3} ($n = 129$) in spring, 2.52 ± 0.88 mg m^{-3} ($n = 188$) in summer, and 1.80 ± 0.58 ($n = 180$) mg m^{-3} in fall.

In each season, surface and bottom depth-averaged chlorophyll was highest in the nearshore and lowest at the shelf break ($p < 0.001$), except in fall bottom water which saw no significant spatial change (Figure 5). The highest depth-averaged chlorophyll concentrations occurred in nearshore spring bottom water (2.86 ± 0.49 mg m^{-3}, $n = 13$, $p < 0.001$), which captured the spring chlorophyll maximum layer. High

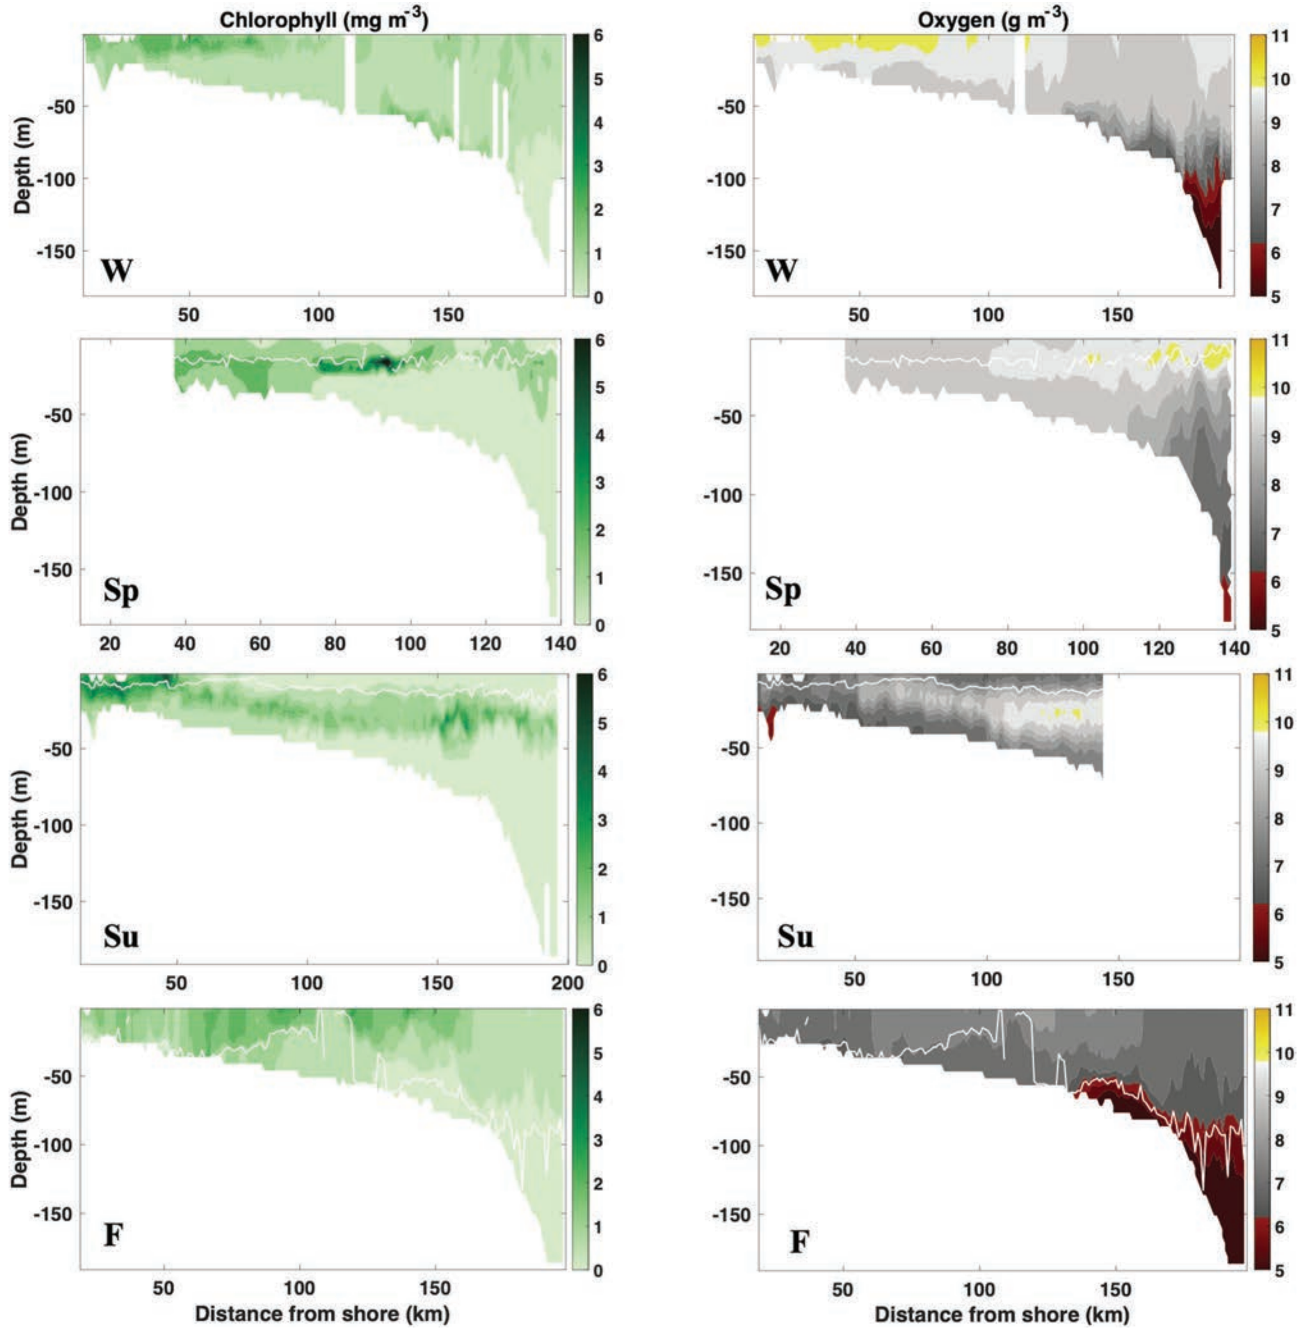

Figure 5. Contour plots of depth-averaged chlorophyll and oxygen from four seasonal glider deployments in the MAB (W = winter, Sp = spring, Su = summer, and F = fall). Data shown are from the first cross-shelf transect of each deployment. Mixed layer depth (MLD) for each binned profile is plotted in white. Winter had no significant mixed layer. The nearshore region was defined as 1–40 km offshore, midshelf was 40–160 km offshore (40–120 km in spring), and the shelf break was >160 km offshore (>120 km offshore in spring).

depth-averaged chlorophyll was also present in spring and summer nearshore surface waters, averaging 2.13 ± 0.71 mg m^{-3} ($n = 13$) and 2.30 ± 0.45 mg m^{-3} ($n = 28$), respectively.

3.2.3. Chemical Dynamics

3.2.3.1. Oxygen

The chlorophyll-rich, stratified spring and deeply mixed fall water columns exhibited the highest 35-m integrated DO concentrations of 41.55 ± 20.12 g m^{-2} ($n = 129$) and 41.86 ± 12.46 g m^{-2} ($n = 180$) ($p < 0.001$;

Figures 4 and 5). Like chlorophyll concentration, winter and summer 35 m integrated oxygen levels were significantly lower than both fall and spring ($p < 0.001$).

In spring, summer, and fall, high depth-averaged DO was observed at the chlorophyll maximum depth (Figure 5). Shelf break bottom waters exhibited the lowest depth-averaged DO concentrations in winter, spring, and fall ($p < 0.001$), averaging 6.20 ± 0.88 g m^{-3} ($n = 35$), 8.20 ± 0.49 g m^{-3} ($n = 20$), and 6.32 ± 0.36 g m^{-3} ($n = 39$), respectively. The DO optode malfunctioned shortly after summer deployment, so summer shelf break measurements are not available.

3.2.3.2. Carbonate System

Figures 6 and 7 display seasonal and spatial differences in the carbonate system. Full water column pH ranged from 7.701 to 8.166 throughout all seasons, while Ω_{arag} ranged from 0.83 to 3.72, and TA:DIC ranged from 1.019 to 1.180. Deployment-averaged pH was highest in winter and lowest in summer (Table S6). Deployment-averaged Ω_{arag} and TA:DIC were highest in fall and lowest in summer (Table S6). Areas that differed from the means were localized in space and time. For example, areas of high pH were associated with the chlorophyll maximum in spring and summer, and areas of high pH, Ω_{arag}, and TA:DIC were found at the shelf break in all seasons (Figure 6). Conversely, areas of low pH, Ω_{arag}, and TA:DIC were associated with the nearshore region in spring, summer, and fall, and with shelf bottom waters in the summer (Figure 6).

In summer and fall, surface and bottom pH, Ω_{arag}, and TA:DIC were lowest in the nearshore and significantly higher at the shelf break ($p < 0.001$; Figure 7). The highest spring pH, Ω_{arag}, and TA:DIC values were also present at the shelf break ($p < 0.005$, Figure 7). Winter followed a different spatial pattern, with surface and bottom pH highest in the nearshore and significantly lower at the shelf break ($p < 0.001$). Winter surface Ω_{arag} and TA:DIC were highest in the midshelf region ($p < 0.05$), while bottom Ω_{arag} and TA:DIC increased from nearshore to shelf break ($p < 0.002$).

In the nearshore, surface and bottom pH were highest in winter, averaging 8.124 ± 0.007 ($n = 31$) and 8.080 ± 0.014 (n = 31) respectively ($p < 0.005$; Figures 6 and 7). The lowest nearshore pH occurred in summer bottom waters ($p < 0.001$), averaging 7.827 ± 0.029 ($n = 28$). Bottom waters also reached a minimum in Ω_{arag} and TA:DIC in summer ($p < 0.03$), averaging 1.29 ± 0.11 and 1.048 ± 0.007 respectively ($n = 28$). Contrary to seasonal patterns in pH, nearshore surface water saw the highest Ω_{arag} and TA:DIC in the summer/fall and lowest in the winter/spring ($p < 0.001$).

In the midshelf, the highest seasonal pH occurred in well mixed, cold winter surface water ($p < 0.002$; Figures 3, 6, and 7). Average winter midshelf surface pH was 8.107 ± 0.013 ($n = 121$). Conversely, winter midshelf surface waters had low Ω_{arag} and TA:DIC, averaging 1.84 ± 0.09 and 1.082 ± 0.004, respectively ($n = 121$). The lowest midshelf pH occurred in summer surface and bottom water, averaging 7.934 ± 0.016 in the surface and 7.922 ± 0.053 in the bottom ($p < 0.001$, $n = 120$). Low pH summer bottom water was associated with the Cold Pool bottom water mass and also exhibited the lowest Ω_{arag} and TA:DIC in the midshelf (1.47 ± 0.15 and 1.059 ± 0.009, respectively; $p < 0.001$; $n = 120$). While summer midshelf bottom water had the lowest seasonal Ω_{arag} and TA:DIC, summer midshelf surface water had the highest values in the region, averaging 2.30 ± 0.18 and 1.101 ± 0.008 respectively ($p < 0.001$, $n = 120$), though these values were not significantly different than fall.

At the shelf break, a warm, salty water mass persisted throughout all four seasons (Figure 3). The highest shelf break Ω_{arag} and TA:DIC occurred in fall ($p < 0.001$), when this water mass mixed into the surface layer (Figure 6). There, Ω_{arag} averaged 3.13 ± 0.12 ($n = 39$) and TA:DIC averaged 1.138 ± 0.006 ($n = 39$). The lowest shelf break Ω_{arag} and TA:DIC occurred in winter surface waters ($p < 0.05$), averaging 1.73 ± 0.06 and 1.075 ± 0.003 ($n = 35$), respectively. The lowest seasonal shelf break pH occurred in summer surface waters ($p < 0.001$), averaging 7.969 ± 0.014 ($n = 39$).

4. Discussion

High-resolution data resulting from deployments of a glider equipped with novel pH sensor technology highlight seasonal and spatial carbonate chemistry dynamics in the MAB for the first time. Results underscore the importance of seasonality, water mass mixing, biological production, and freshwater inputs in controlling the carbonate system in the MAB.

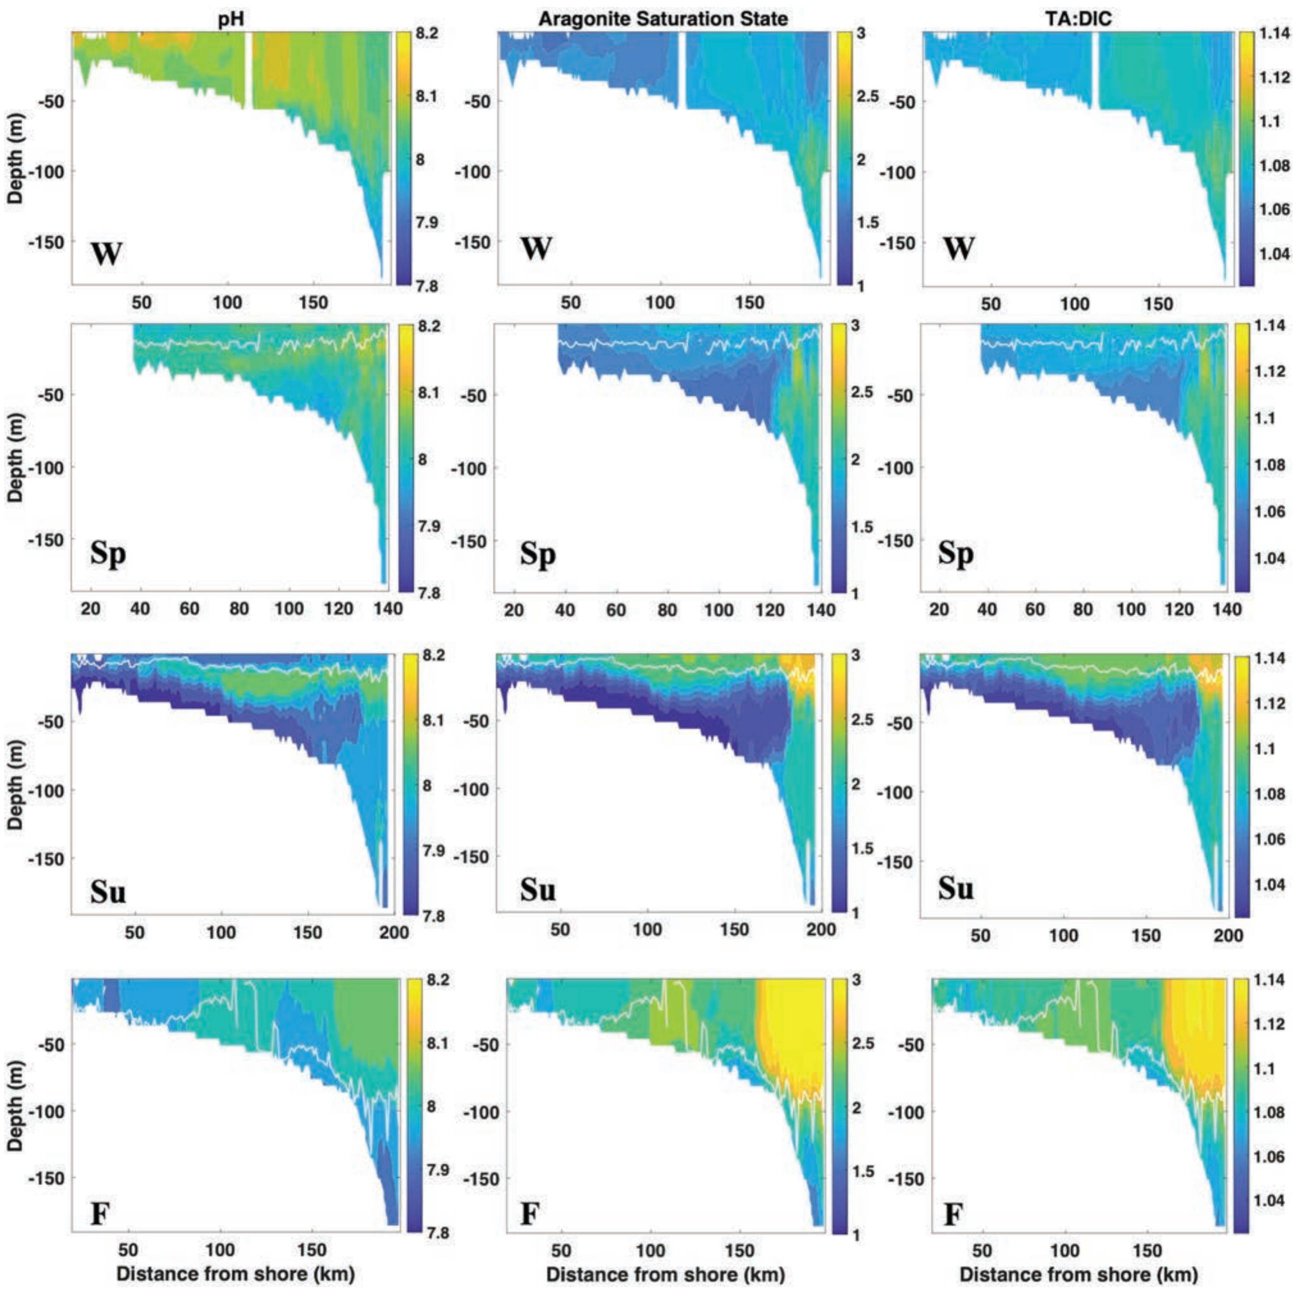

Figure 6. Contour plots of in situ pH, Ω_{arag}, and TA:DIC from four seasonal glider deployments in the MAB (W = winter, Sp = spring, Su = summer, and F = fall). Data shown are from the first cross-shelf transect of each deployment. Mixed layer depth (MLD) for each binned profile is plotted in white. Winter had no significant mixed layer. The nearshore region was defined as 1–40 km offshore, midshelf was 40–160 km offshore (40–120 km in spring), and the shelf break was >160 km offshore (>120 km offshore in spring).

4.1. Drivers of MAB Seasonality

Seasonal glider deployments recorded physical water column changes caused by intense MAB seasonality. Observations aligned with established MAB physical climatology (Castelao et al., 2010, 2008). Warming of surface waters in the spring and summer, combined with freshening of surface waters, increased the strength of stratification and trapped a Cold Pool water mass below the mixed layer. Cold Pool bottom water generally contains relatively fresh (<34 PSU) and cold (<10°C) water, with source water likely originating from the Labrador Sea (Z. Chen et al., 2018). Wind- and storm-driven seasonal overturn in the fall caused surface and Cold Pool bottom waters to mix, resulting in a cool, well-mixed water column that persisted through winter.

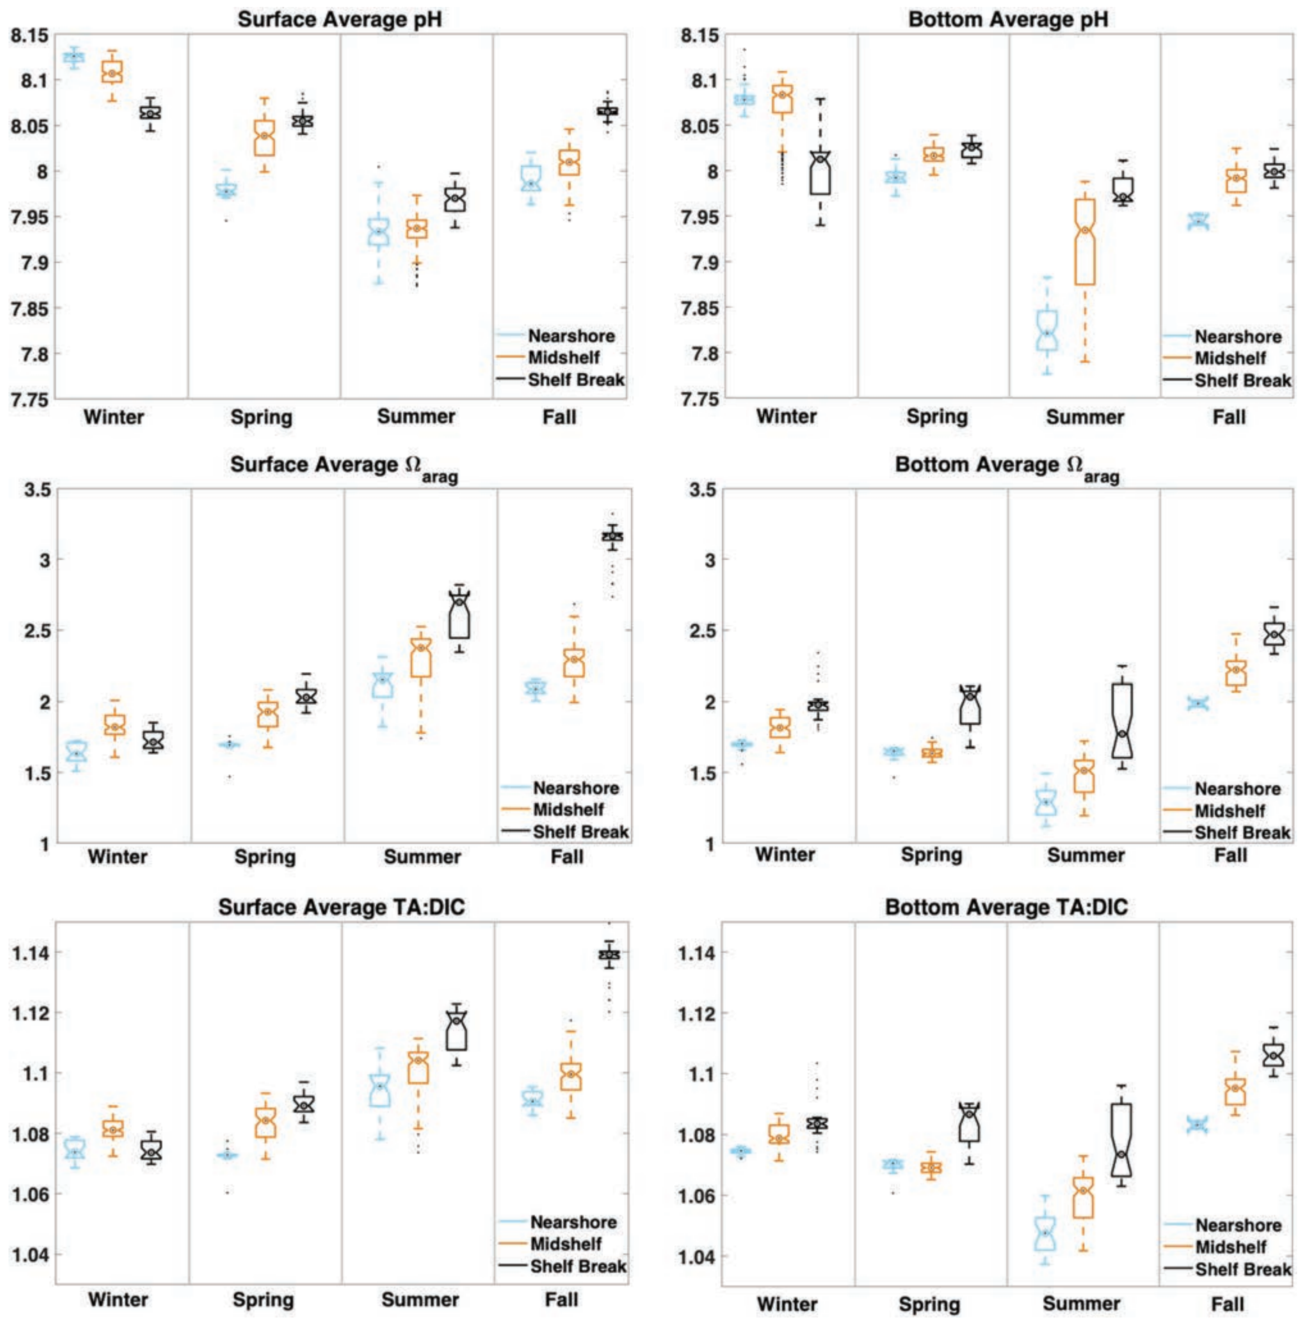

Figure 7. Comparisons of carbonate system parameters measured during and derived from seasonal glider deployments. Targets indicate median values, box limits indicate the 25th to 75th percentiles, and whiskers represent the full range of data. Data points beyond 1.5 times the interquartile range away from the top or bottom of the box were identified as outliers and are shown as black dots extending from the whiskers. Notches depict the 95% confidence interval around the median. If notches do not overlap, there is 95% confidence that the medians are different ($p < 0.05$).

The occurrence of low surface water Ω_{arag} and TA:DIC in winter and high Ω_{arag} and TA:DIC in summer surface waters supports the findings of Cai et al. (2020) who concluded that surface water Ω_{arag} and DIC are controlled additively by thermodynamic equilibrium and air-sea gas exchange in the MAB. Unlike Ω_{arag} and TA:DIC, shelf surface water pH during glider deployments exhibited a decoupling from the effect of gas exchange, with the highest pH recorded in winter and lowest pH values in summer. This indicated a more complicated system of seasonal surface pH drivers, including freshwater input (summer) and biological removal of CO_2 (winter), which acted on a time scale faster than gas equilibrium (Cai et al., 2020).

In areas and periods of dense chlorophyll biomass, primary producers remove CO_2 from the water, increasing DO and pH (Kemp et al., 1994). Fall and spring glider missions captured the highest seasonal integrated chlorophyll levels, due to high phytoplankton biomass. High fall integrated chlorophyll supports the findings of Y. Xu et al. (2011), who identified a bimodal cycle of biological production in the MAB, in which a dominant fall-winter phytoplankton bloom between the 20- and 60-m isobaths accounts for almost 60% of the region's annual chlorophyll production. This bloom forms when fall overturn injects nutrient-rich bottom water into the surface, promoting phytoplankton production. High productivity captured in the fall deployment led to high integrated DO and increased surface pH in the nearshore and midshelf. The second mode of MAB phytoplankton production described by Y. Xu et al. (2011) indicates a less dominant spring-summer bloom triggered by stratification, which allows phytoplankton to overcome light limitation caused by deep mixing during the winter. Spring and summer glider deployments captured the development of strong seasonal stratification, isolating a chlorophyll maximum just below the mixed layer predominantly in the midshelf region that was colocated with high pH (Figure 6).

High depth-integrated chlorophyll and DO in the fall and spring were followed by periods of lower integrated chlorophyll and DO in the winter and summer. In summer, this was likely influenced by Cold Pool bottom water, where respiration of surface-derived particulate carbon produces CO_2 and reduces DO. Once seasonal stratification is set up, the Cold Pool has little ventilation to seawater above the thermocline, and accumulation of respired CO_2 reduces pH, Ω_{arag}, and buffering capacity for CO_2 (Cai et al., 2011, 2017; Waldbusser & Salisbury, 2014; Wootton et al., 2008). Our summer mission captured the full extent of low bottom water pH, Ω_{arag}, and TA:DIC associated with stratification and the Cold Pool (Figures 6 and 7).

In summer nearshore surface and bottom waters, high-low-high cycles in pH, Ω_{arag}, and TA:DIC appeared in ~20-km increments (Figure 8). Cycles observed there align with the glider's average horizontal movement of 20 km day^{-1}, indicating potential diel variability in pH, Ω_{arag}, and TA:DIC. Daily swings in surface water pH were as large as 0.145 pH units, corresponding to swings in surface Ω_{arag} of 0.52 and TA:DIC of 0.033. These pH swings were about half the amplitude of those observed previously in nearby Mid-Atlantic estuaries, which can exhibit swings of up to 0.26 pH units day^{-1}, attributed to high productivity and shallow waters (Baumann & Smith, 2017). The pattern of daily variability was not always consistent (day vs. night), suggesting that these complex carbonate chemistry dynamics are likely driven by a combination of biological productivity, temperature swings, fluctuations in salinity, and mixing. For example, pH and Ω_{arag} in nearshore bottom water exhibited strong positive correlations with temperature and chlorophyll (Spearman's $r > 0.75$, $p < 0.001$) and strong negative correlations with salinity (Spearman's $r < -0.67$, $p < 0.001$). In nearshore surface water, these correlations were weaker and, in one case, the direction of the correlation flipped (Spearman's r between Ω_{arag} and chlorophyll $= -0.50$, $p < 0.001$). Therefore, trends in pH and Ω_{arag} cannot be explained by any one driver. Additional observations are needed in order to thoroughly analyze and establish the relative importance of these drivers to diel variability.

4.2. Year-Round Water Column Features

In every season, nearshore waters experienced the lowest surface salinities, highlighting the influence of freshwater inputs to the coastal system (Castelao et al., 2010). During the summer, freshening extended into the midshelf due to heavy rainfall and typical seasonal freshening due to peak seasonal runoff from the Hudson River (Castelao et al., 2010; Richaud et al., 2016). Freshwater inputs from rivers and storms introduce low TA water into the coastal system, decreasing CO_2 buffering capacity (Siedlecki et al., 2017; Waldbusser & Salisbury, 2014). Spring, summer, and fall exhibited their lowest respective pH, Ω_{arag}, and TA:DIC in nearshore waters compared to the midshelf and shelf break regions. Summer nearshore and midshelf surface waters had the lowest seasonal pH, pointing to freshwater input as a major driver of pH there. However, as discussed in section 4.1, summer nearshore and midshelf surface waters had the highest seasonal Ω_{arag} and TA:DIC, indicating that thermodynamic control was a stronger influence on Ω_{arag} and TA:DIC than salinity. These complex carbonate system dynamics indicate that freshwater influence is a complicated but important driver of the carbonate system on the shelf.

Throughout all seasonal deployments, a warm (>12°C), salty (>35 PSU) water mass persisted at the continental shelf break. This slope water mass signified that the glider traveled through a shelf-break front, formally called the MAB shelf-break jet, which is influenced by warm, saline Gulf Stream waters entrained into

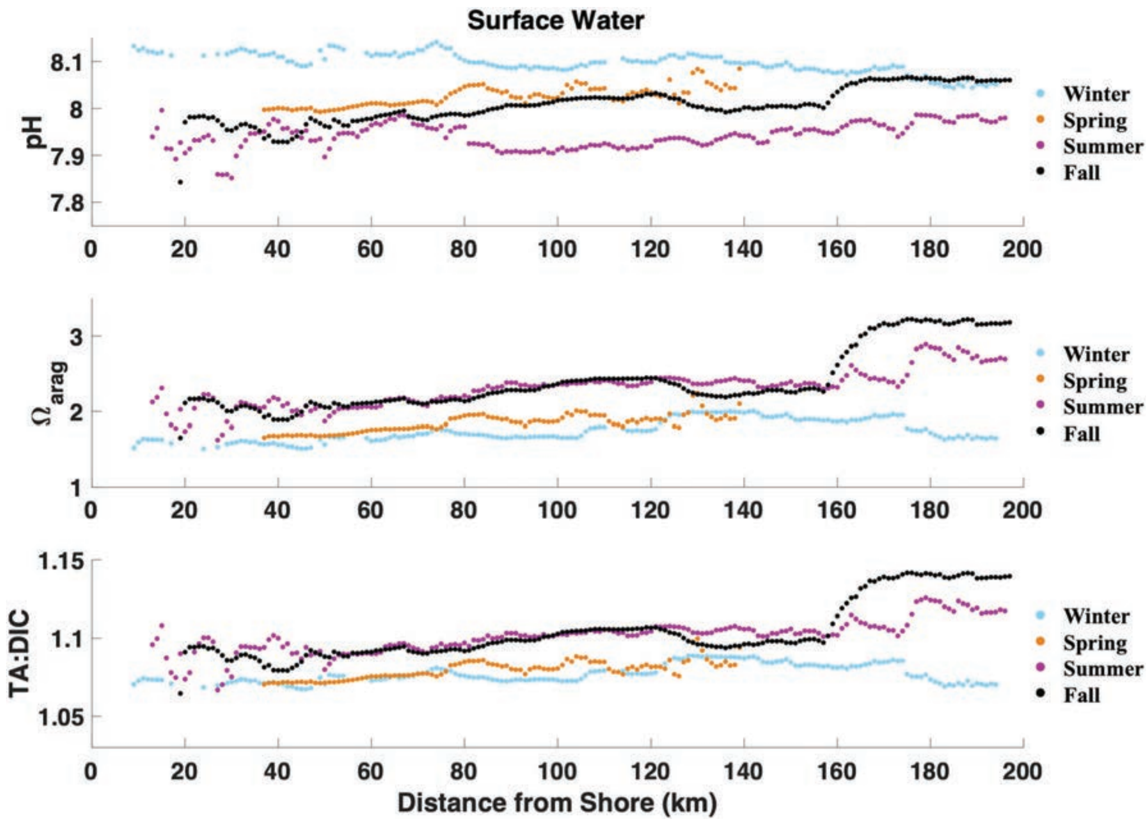

Figure 8. Seasonal differences in surface water pH (top), Ω_{arag} (middle), and TA:DIC (bottom) expressed as a function of distance from shore. Surface water is defined as above MLD in spring, summer, and fall, and as the top 5 m in winter. Data presented are from the entire deployment and are 1 m depth and 1 km distance binned.

the MAB by eddies (K. Chen & He, 2010; Fratantoni et al., 2001; Linder & Gawarkiewicz, 1998; Wanninkhof et al., 2015). The front was pushed progressively farther off-shelf with the onset and persistence of seasonal stratification and infiltrated back onto the shelf during fall overturn, following MAB shelf-break jet climatology described by Linder and Gawarkiewicz (1998). The deepest water sampled at the shelf break (>150 m) exhibited the lowest depth-averaged oxygen levels in each deployment, suggesting that this water mass is not well ventilated to the atmosphere, and ongoing respiration there depletes oxygen and adds CO_2. Despite ongoing respiration, shelf break jet deep water had high Ω_{arag} and TA:DIC, reflecting its Gulf Stream source and consistently high salinity levels. High TA:DIC indicated that this water mass had a high buffering capacity for CO_2 and therefore had high pH in spring, summer, and fall, regardless of high net respiration.

The intrusion of the highly buffered shelf break jet onto the shelf during fall overturn, along with the high fall phytoplankton biomass and a decrease in freshwater input, resulted in a well-mixed water column with high pH, Ω_{arag}, and TA:DIC. High pH persisted through winter, while thermodynamic interactions led to low winter Ω_{arag} and TA:DIC after the fall bloom. This suggests that seasonal intrusion of the shelf break jet could be an important mitigator of acidification on the MAB shelf during fall.

4.3. Potential Ecological Implications

It is important to consider natural seasonal, spatial, and depth variability when investigating MAB habitat suitability. Surface water pH, Ω_{arag}, and TA:DIC exhibited seasonal differences across the MAB shelf, with Ω_{arag} and TA:DIC diverging to a greater extent at the shelf break (Figure 8). Bottom water pH exhibited seasonal swings on the MAB shelf, but values converged at the continental shelf break, while bottom water Ω_{arag} and TA:DIC saw seasonal divergence at the shelf break (Figure 9). Seasonality in pH, Ω_{arag}, and TA:DIC across the shelf and shelf break demonstrated seasonal and spatial fluctuations in carbonate system drivers in the MAB.

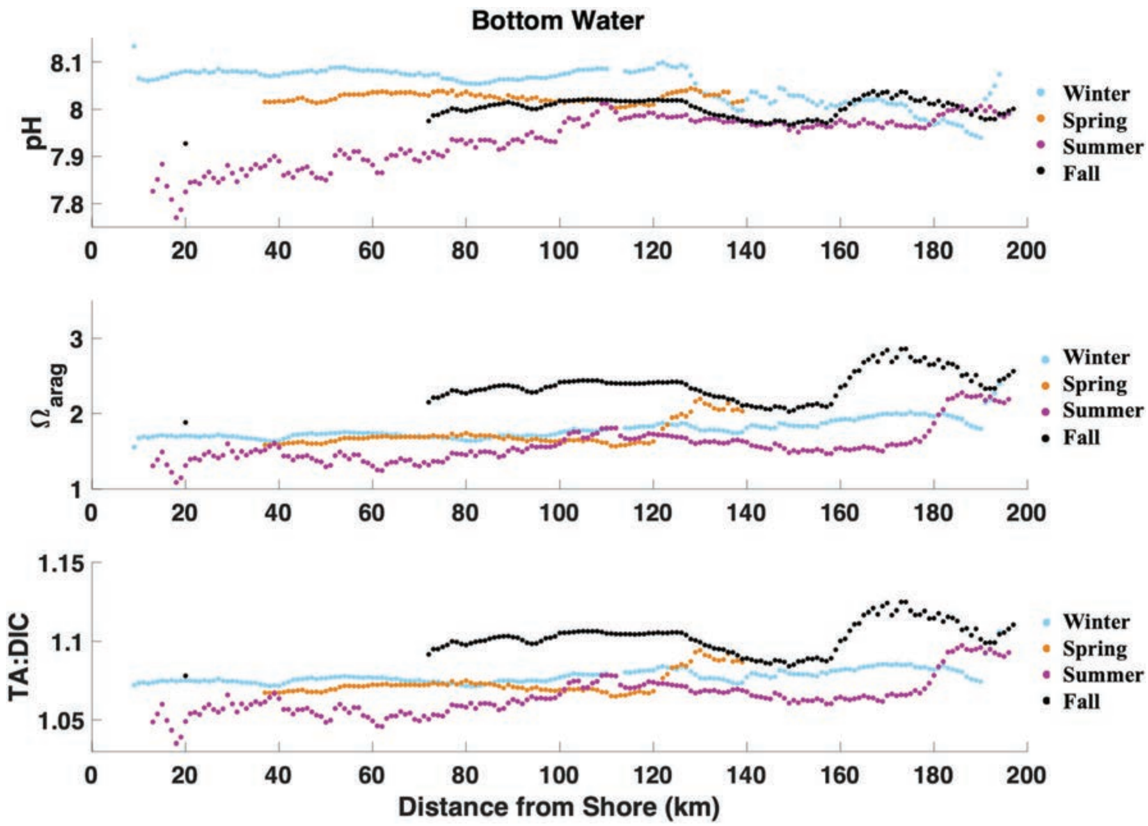

Figure 9. Seasonal differences in bottom water pH (top), Ω_{arag} (middle), and TA:DIC (bottom) expressed as a function of distance from shore. Bottom water is defined as below MLD in spring, summer, and fall, and as the bottom 5 m in winter. Data presented are from the entire deployment and are 1 m depth and 1 km distance binned.

Shelf water masses, specifically the MAB Cold Pool, have been linked to the distribution and recruitment of economically important fish species, including the calcifying shellfish Atlantic sea scallop (*Placopecten magellanicus*) and Atlantic surfclam (*Spisula solidissima*), which are vulnerable to acidification (Colvocoresses & Musick, 1984; Cooley et al., 2015; Steves et al., 2000; Sullivan et al., 2000; Weinberg, 2005). These organisms are able to survive and reproduce through observed seasonal swings in carbonate chemistry on the MAB shelf, but the extent to which survival and reproduction may be negatively impacted by current levels of pH and Ω_{arag} is unknown. Potential vulnerability of these organisms during late summer/early fall spawning events on the MAB shelf should be a consideration for future fishery management.

4.4. Limitations and Benefits

While the pH glider has undergone significant field testing for robustness, it is not exempt from limitations common to autonomous underwater vehicles (AUVs) and other sensors used in oceanographic field work. Gliders deployed in areas of high productivity are subject to biofouling over time, which can increase offsets between glider and discrete pH measurements (Saba, Wright-Fairbanks, et al., 2019). Increased offsets from deployment to recovery in winter, summer, and fall might indicate biofouling throughout deployment. Primary production associated with algal biofouling near the sensor intake would remove CO_2 from water in close vicinity to the glider, thereby increasing pH. Additionally, biofouling from barnacles or juvenile bivalves can occur on gliders. Saba, Wright-Fairbanks, et al. (2019) reported an instance of biofouling by a juvenile clam which settled onto the glider pH sensor intake valve. In that case, respiration would decrease pH around the sensor. Increases in offsets over time can also occur due to pH sensor drift. Sensor drift generally arises due to a lack of full conditioning to Br^- anion in seawater and is a common issue for autonomous pH monitoring platforms (Johnson et al., 2016).

Seasonal TA-salinity relationships derived from discrete samples perform generally well when compared to the CANYON-B algorithm and discrete sample TA values. Large offsets between discrete and regression-based TA corresponded to a break in the TA-salinity relationship at approximately 30–31 PSU (Figure S1). These offsets were particularly large in summer and fall, with discrete and calculated TA differing by up to 51.1 and 87.6 μmol kg^{-1} respectively (Table S5). Uncertainty in Ω_{arag} and TA:DIC due to TA uncertainty was as extreme as −0.08 and 0.0013 (fall; Table S4). However, the difference between CANYON-B-estimated TA and salinity-derived TA was quite small, averaging ~0.1%. Because of this, we are confident that seasonal TA-salinity regressions are applicable to full glider deployments.

While none of the seasonal deployment pH offsets described here exceeded manufacturer specifications for the sensor, changes in offsets over time underscore the importance of taking discrete samples at each glider deployment and recovery to ensure continued accuracy and data quality. These missions therefore require a vessel with water sampling capabilities, but the data provided during the otherwise automated 30- to 60-day missions far outweigh the cost to collect data of this resolution during major research cruises (Schofield et al., 2010). Furthermore, gliders have proven their effectiveness for high-quality observations in a range of coastal and open ocean environments, including locations that are not conducive to vessel operation or human presence (e.g., polar environments and hurricane seas) (Testor et al., 2019).

5. Significance

The work presented here highlights the distinct capability of an autonomous Slocum glider equipped with a deep-ISFET based pH sensor to make highly accurate, high-resolution observations of the marine carbonate system. The use of pH glider technology can be scaled up to address regional, national, and global OA observing needs. Using this glider sensor suite, we have observed seasonal patterns in the carbonate system directly associated with changes in other physical, biological, and chemical properties. While it is beyond the scope of this paper to quantify the relative importance of different carbonate system drivers, these data make clear that several drivers impact the strength of acidification. These include air-sea CO_2 exchange, seasonal stratification, biological activity, and freshwater input, as well as physical mixing of the MAB shelf break front. Importantly, data presented here describe the typical seasonal patterns of carbonate system dynamics in the MAB, but absolute values will change from year-to-year due to differences in regional climate, temperature, precipitation, wind patterns, and storm activity. Continued seasonal glider observation efforts, together with other carbonate monitoring platforms, will assist in developing a mean carbonate chemistry climatology for the MAB. This will help to inform the design of laboratory experiments investigating the response of commercially important species to acidification using realized carbonate system values and variability (Goldsmith et al., 2019; Saba, Goldsmith, et al., 2019). Furthermore, ongoing monitoring efforts can be used to identify areas or time periods prone to acidification due to interaction with other potential stressors, and the derivation of synergistic relationships between these variables. Continued simultaneous collection of chemical, physical, and biological metrics will allow the development of algorithms linking carbonate chemistry to other ocean properties. These quantitative relationships are necessary to develop broader predictive forecast models for the coastal ecosystem, which will ultimately aid in fisheries management planning and mitigation of short-term acidification events in the MAB.

Acknowledgments
We thank Rutgers University Center for Ocean Observing Leadership (RU COOL) glider technicians: David Aragon, Nicole Waite, Chip Haldeman, Laura Nazzaro, and John Kerfoot for their efforts in glider preparation, deployment logistics, fieldwork, mission piloting, and data management. We also thank Rutgers undergraduate alumni Brandon Grosso and Laura Wiltsee for their dedicated work with gliders in the field and lab. We acknowledge RU COOL faculty Oscar Schofield, Scott Glen, Josh Kohut, and RU COOL manager Michael Crowley for facility support. We appreciate Yui Takeshita (Monterey Bay Aquarium Research Institute) for his support on data interpretation. Finally, we thank our colleagues at SeaBird Scientific including Dave Murphy, Cristina Orrico, Vlad Simontov, and Dave Walter, along with Clara Hulburt and Christopher DeCollibus at Teledyne Webb Research for their technical expertise and support. This project was funded by National Science Foundation's Ocean Technology and Interdisciplinary Coordination program (National Science Foundation [NSF] OCE1634520 and OCE1634582). E. W-F. received support from the Mid-Atlantic Sea Grant/NOAA OAP Graduate Research Fellowship (NA18OAR4170087) and the Rutgers University School of Environmental and Biological Sciences Excellence Fellowship.

Data Availability Statement

Data supporting the conclusions made in this paper can be obtained online (at http://slocum-data.marine.rutgers.edu/erddap/search/index.html?page=1&itemsPerPage=1000&searchFor=ru30).

Monitoring ocean biogeochemistry with autonomous platforms

Fei Chai, Kenneth S. Johnson, Hervé Claustre, Xiaogang Xing, Yuntao Wang, Emmanuel Boss, Stephen Riser, Katja Fennel, Oscar Schofield and Adrienne Sutton

Abstract | Human activities have altered the state of the ocean, leading to warming, acidification and deoxygenation. These changes impact ocean biogeochemistry and influence ecosystem functions and ocean health. The long-term global effects of these changes are difficult to predict using current satellite sensing and traditional in situ observation techniques. Autonomous platforms equipped with biogeochemical sensors allow for the observation of marine biogeochemical processes and ecosystem dynamics, covering a wide range of spatial and temporal scales. The international Biogeochemical-Argo (BGC-Argo) project is currently building a global, multidisciplinary ocean-observing network of autonomous Argo floats equipped with an extensive range of biogeochemical sensors. Other autonomous platforms, such as gliders and surface vehicles, have also incorporated such sensors, mainly operating on regional scales and near the ocean surface. Autonomous mobile assets, along with remotely sensed data, will provide the 4D information required to improve model simulations and forecasts of ocean conditions and ecosystem health.

Anthropogenic activities are rapidly changing the oceans, contributing to ocean warming, acidification, eutrophication, pollution, deoxygenation, nutrient flux reduction, vital habitat destruction, declining fishery resources and an increasing number of endangered marine species[1]. Recent observation-based estimates show that the ocean has been undergoing rapid warming over the past few decades, and that the rate of warming has increased[2]. Ocean warming has been linked to increases in rainfall intensity in tropical regions, declines in ice sheets, glaciers and ice caps in the polar regions, rising sea levels, enhancement of ocean stratification and a decrease in primary production[3]. Ocean-ecosystem health responds to anthropogenic activities in general through transforming the dynamics of marine organisms, altering the rate of the carbon cycle and changing marine-animal behaviour[4].

The upcoming United Nations (UN) Decade of Ocean Science for Sustainable Development marks a global push towards collecting comprehensive observational data for biogeochemical processes in order to encourage the sustainable development of the ocean. However, marine ecosystems and biogeochemical cycles are complex, involving a range of physical processes, such as wind-driven mixing, convective mixing, upwelling, downwelling, isopycnal mixing, diapycnal diffusion and horizontal advection, chemical processes, such as air–sea CO_2 exchange, ocean acidification and deoxygenation, and biological processes, such as primary production, phytoplankton growth and loss, and zooplankton grazing[5–8]. Many of these complex processes cannot be observed using only traditional observation platforms, such as ships and moorings.

To address the limitations of existing observation methods, new sensor technologies for conducting biological and biogeochemical measurements are being developed and equipped on novel observational platforms, such as autonomous mobile platforms[9]. Together with more traditional observation methods, these new platforms can collect data to assess the changes in biogeochemical and physical properties of the ocean on global and decadal scales[10,11].

In this Perspective, we explore the application of autonomous platforms in assessing ocean biogeochemistry and ecosystem health. We first review traditional methods used for observing ocean biogeochemistry. Then, we discuss the demand for conducting observations to resolve marine biogeochemical and ecosystem spatial and temporal variations. We present current examples of the use of multiple autonomous mobile platforms and how different platforms are used synergistically. Finally, we describe the approaches for applying 4D data to monitor and forecast ocean biogeochemistry and ecosystem health.

Traditional ocean observations and challenges

The use of observing platforms has evolved over the past century (FIG. 1). Early motivations for using such platforms were to investigate the productivity of the ocean, and fisheries in particular, to mitigate marine destructive events, such as typhoons and tsunamis, and to study geography[12]. Whereas ships and moorings were the platforms of choice to survey the ocean, recently, the application of remote sensing has greatly improved the spatial coverage of the entire ocean to near real-time. In this section, we describe existing ocean-observing platforms and their related applications and challenges.

Shipborne observations. Oceanographers historically collected data from the ocean and seafloor using ships during cruises of limited duration. This expeditionary research approach has resulted in major advances in our understanding of the global ocean. The *HMS Challenger* expedition in the 1870s pioneered the concept of a systematic global survey of the subsurface ocean, measuring the physics and chemistry of seawater and collecting biological samples at hundreds of sites. Later efforts, such as the Geochemical Ocean Sections Study (GEOSECS) in the 1970s, the World Ocean Circulation Experiment (WOCE) in the 1980s and 1990s, and the ongoing Global Ocean Ship-Based Hydrographic Investigations Program (GO-SHIP) (FIG. 1), have improved global coverage and included measurements of

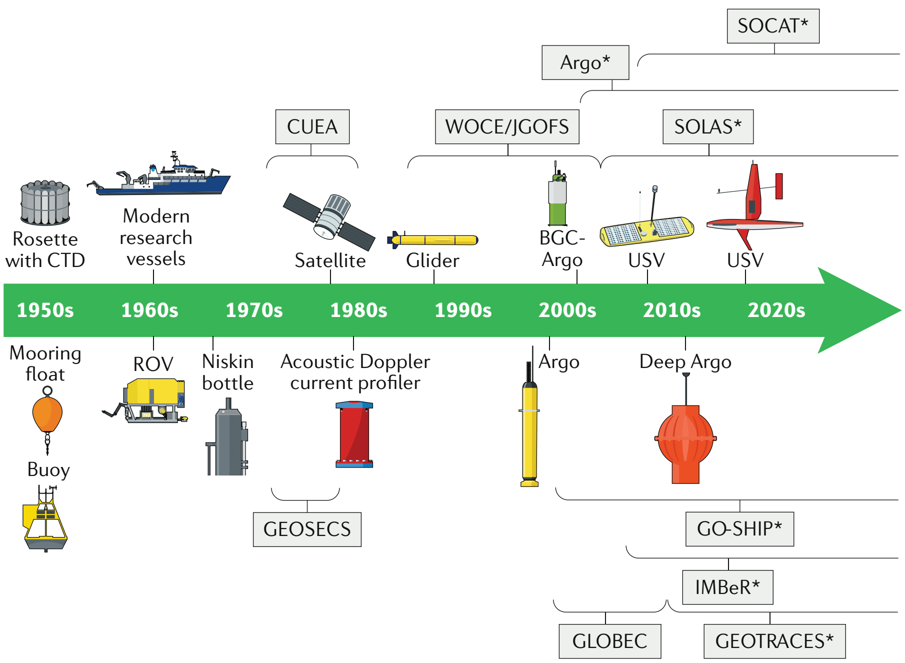

Fig. 1 | **Timeline of oceanographic observation platforms and international projects measuring marine biogeochemistry.** International project durations are indicated with brackets. Ongoing projects are denoted with an asterisk (*). biogeochemical variables, such as nutrient concentrations and the carbonate system[13]. Research and industry partnerships have also supported networks of autonomous physical and chemical measurements on ships of opportunity, such as in the Surface Ocean CO_2 Atlas (SOCAT) since 2007 (REF.[14]). Shipborne observations have allowed the discovery of large spatial variations in productivity through the identification of phenomenon such as high-nutrient, low-chlorophyll zones[15] and the oligotrophic gyres[16]. More recently, the GEOTRACES programme has identified processes and quantified fluxes that control the distributions of key trace elements and isotopes in the oceans[17], and the Tara Oceans project has shown the enormous taxonomic diversity of photosynthetic microorganisms in the surface ocean[18].

However, ship-based observations are limited by their spatial and temporal coverage, and can be prohibitively expensive, such that only a limited number of cruises can be conducted at any given time. Cruises can also be constrained by extreme weather conditions, particularly during winter; as a result, ship-based observations can be sparse and strongly biased towards summer-season sampling.

Sustained, fixed-location observations. Modern ocean moorings have evolved from the weather stations established in the 1940s (REF.[19]). By the 1980s, moorings had become critical platforms, enabling studies into ocean biogeochemistry and the role of the ocean in influencing climate and weather[20]. Data from historical stations such as Ocean Station Papa and ALOHA revealed ecosystem responses to the El Niño–Southern Oscillation events[21], global warming[22] and ocean acidification[5]. Moorings now provide the backbone of many of the global ocean networks used for studying ocean–atmosphere interactions[23,24] and for characterizing marine-ecosystem changes[25,26], particularly in coastal waters[27]. OceanSITES, a worldwide system of open-ocean reference stations, coordinates time series of global mooring observations and serves as a global long-term network[26].

Fixed-location moorings will continue to be a key element of ocean-observing infrastructure, providing high-frequency subsurface data to supplement data collected by ships, autonomous vehicles and satellite remote sensing. A disadvantage of these systems is their high maintenance cost, which severely limits the number of systems that can be deployed. Furthermore, sensors are often located at fixed depths, and instruments near the surface are subject to biofouling. Thus, despite being an ideal platform for collecting high-resolution times series, fixed-location moorings are ineffective at providing large-scale spatial coverage or tracing the movement of different water masses.

Remote sensing. Satellites are an important innovation in oceanographic technology[28]. A range of satellite observing systems is available, including active scatterometers, microwave spectrometers, radiometers, microwave imagers, altimeters and probes for advanced gravity missions. Ocean-colour satellite observation systems started with the launch of the Coastal Zone Color Scanner (CZCS) in the late 1970s, which provided the first global view of phytoplankton distribution[29]. Global ocean-colour data have been recorded continuously since the SeaWiFS project began in 1997, sustained by the MODIS-Aqua, MERIS, VIIRS and OLCI sensors[30]. In the past four decades, satellite observations have resulted in numerous advances in our fundamental understanding of the ocean through resolving global features associated with the mesoscale circulation of physical and biological properties[30,31].

Satellite observations can be used to estimate long-term trends in marine-ecosystem change at both basin and global scales. Satellite remote sensing has shown that global chlorophyll *a* is decreasing (REF.[32]), especially in the subtropical gyres[33], and that oligotrophic areas of all oceans are expanding[34]. The response of primary producers to climatic oscillations, ranging from intraseasonal[35] to multidecadal scales[36], has been clearly shown by satellite imaging, in particular, following El Niño–Southern Oscillation[37]. Unfortunately, satellites have limited capabilities for resolving features below the ocean surface. The presence of clouds can also interfere with some satellite sensors; this is especially problematic for cloudy regions, such as high-latitude oceans, which play a predominant role in driving global biogeochemistry[38]. At high latitudes, data from ocean-colour satellites often contain large gaps in winter, owing to low sun angle and increased cloudiness[39].

Needs in ocean observation

Due to the limitations of traditional observing systems, there is a need for new systems capable of resolving complex, multiscaled biogeochemical phenomena.

Observing the ocean requires large spatial coverage, high temporal sampling frequency and capability to conduct measurements at depth with high vertical resolution.

Spatial coverage. Compared with traditional in situ observations by ships and moorings, the greatest strength of autonomous-platform networks is their capacity to conduct multiscale and cross-disciplinary measurements. Such resolution is critical, as biogeochemical processes and associated dynamics can vary largely in scales; for example, basin-scale phytoplankton growth can be influenced by the atmospheric transport and deposition of Asian dust-associated iron tens of thousands of kilometres away[40].

In recent years, mesoscale and sub-mesoscale data have been increasingly acquired by Biogeochemical-Argo (BGC-Argo) project floats, gliders and unmanned surface vehicles (USVs)[41–47] (FIG. 2). Data from such autonomous platforms have rapidly improved our understanding of relationships between physical and biogeochemical processes. This is particularly true for observations from gliders, as they are capable of adaptive sampling through eddies and fronts. Based on glider data and model interpretations, Mahadevan et al.[47] showed that mixed-layer dynamics can be driven by sub-mesoscale processes and, conversely, patchy blooms can be triggered when the mixed-layer depth is abruptly shoaled due to eddy-driven restratification. Another study combining BGC-Argo and glider observations found that sub-mesoscale physical processes are also likely to affect algal-community composition, as more diatoms appeared in the patchy bloom areas than outside them[43]. BGC-Argo float and glider data have shown that sub-mesoscale subduction induced by eddy pumping can contribute to the biological carbon pump, transferring dissolved and particulate organic matter from the surface into the mesopelagic zone[45,48]. Integration of meteorological measurements with biogeochemical measurements by USVs can also help to determine how strong atmospheric forcing and mesoscale physical processes drive ocean biogeochemistry[49].

A global array of 1,000 BGC-Argo floats can capture a snapshot of the global upper-layer biogeochemical and ecosystem state every 10 days, which is higher in sampling frequency and much less costly than ship-based surveys[50]. For example, the Global Ocean Data Analysis Project Version 2 (GLODAPv2), a ship-based survey comprised of 724 cruises between 1972 and 2013, collected data from 52,317 stations globally[51]; a global BGC-Argo array would be able to surpass this total number of temperature, salinity, chlorophyll *a*, nitrate concentration, pH and oxygen profiles in only 2 years[11].

Some high-density networks capable of wide-ranging spatiotemporal coverage are already active on a regional scale. In the Southern Ocean, 35 BGC-Argo floats have revealed discrepancies in air–sea CO_2 fluxes in various sub-provinces and during different seasons[52]. In the Mediterranean Sea, data taken from 39 BGC-Argo floats between 2012 and 2017 have improved the performance of a pre-existing regional biogeochemical model[53]. On a global scale, more than 100 BGC-Argo floats produced the first global bio-optical data set (chlorophyll *a*, particulate backscatter and spectral radiometry) in order to address differences in regional distribution in bio-optical properties[54], regional discrepancies in photoacclimation effects on phytoplankton chlorophyll-to-carbon ratios[55] and global distribution of non-algal particles[56]. The large-scale observations made by the BGC-Argo array allowed characterization of biogeochemical provinces and biomes, and potentially provides data for improving biogeochemical model performance, as well as the calibration and validation of satellite measurement systems.

Vertical coverage. As ocean satellite measurements are limited to the surface ocean, there is a need to extend biogeochemical observations throughout the water column[57]. For example, the biological carbon pump has an important role in transferring atmospheric CO_2 from the sea surface, through the water column

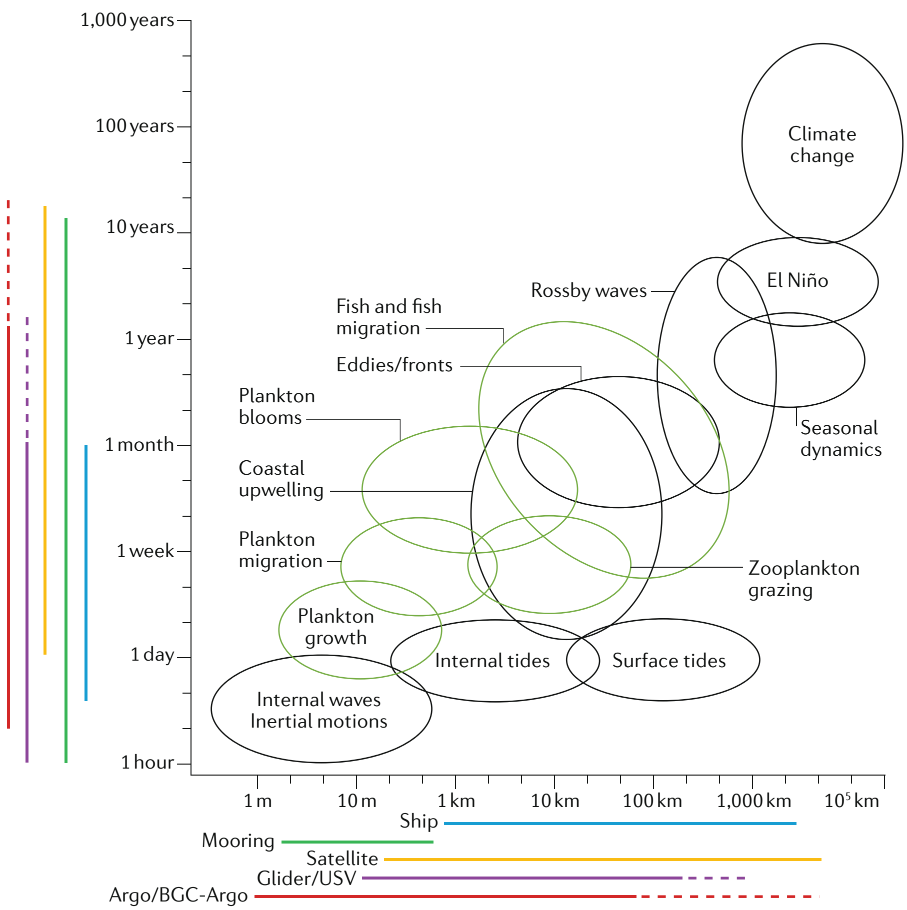

Fig. 2 | **Measuring across spatiotemporal scales in marine systems.** Spatial and temporal scales of marine dynamic and ecosystem processes, and the measurement capabilities of different observational platforms. Dynamic and/or physical processes are represented by black circles and biological and/or ecological processes by green circles. The presence of new autonomous platforms, such as Biogeochemical-Argo (BGC-Argo) floats (red line) and gliders and similar unmanned surface vehicles (USVs) (purple line), fill the cross-discipline and cross-scale observational gaps left by traditional observation methods such as remote sensing by satellite (yellow line), moorings (green line) or ship-based observations (blue line). Dashed lines indicate potential extension of an observational network. Data from REF.[179]. Adapted with permission from REF.[180], Elsevier.

and into the ocean interior, and, thus, is responsible for modulating climate change and supporting deep-ocean ecosystems. Studies on the efficiency of the pump, and related physical–biogeochemical coupling processes, now rely heavily on the observations from autonomous platforms[58–63]. BGC-Argo and gliders are excellent tools for resolving physical and biogeochemical variables in various oceanic conditions, as they are operational in both open and deep oceans (>1,000 m), and gliders can also operate in marginal seas (<1,000 m). Moreover, autonomous platforms equipped with transmissometers can operate in drifting mode as 'optical sediment traps' and can directly and accurately observe particle sedimentation on daily to weekly scales with higher frequency than traditional sediment traps that operate at monthly scales[64].

Temporal coverage. Autonomous platforms can fill some of the important temporal continuity gaps inherent with traditional platforms, improving observation frequency in the open ocean from monthly or seasonal to daily and weekly timescales. USVs such as saildrones and Wave Gliders can perform continuous observation of sea-surface biogeochemical properties, such as $p\mathrm{CO_2}$, dissolved oxygen, pH, chlorophyll *a* concentration and air–sea carbon flux[65,66]. As autonomous platforms can operate in harsh environments, even operating underneath sea ice[52,67,68], they are capable of recording continuous time series at high latitudes under all-weather conditions; these data can fill the temporal gaps seen during winter using satellite-based observations[52,69–71].

Rapid weather changes can lead to transient ecosystem responses not captured by ships or satellites. For example, a large number of BGC-Argo observations have revealed that rapid changes in mixed-layer depth could efficiently pump particles from the surface ocean into deep waters[59,60]. A BGC-Argo float in the Bay of Bengal recorded subsurface chlorophyll *a* enhancement after a tropical cyclone induced regional upwelling and turbulent mixing; the surface chlorophyll *a* bloom was attributed to the combined effect of subsurface chlorophyll *a* entrainment and nutrient injection[6].

Autonomous platforms

The presence of new autonomous platforms, such as Argo floats, gliders and USVs, fill the cross-disciplinary and cross-scale observational gaps described above, providing revolutionary insights into ocean biogeochemistry and marine ecosystems.

Argo floats. The profiling float, a modern instrument that is complementary to ship-based systems, was first used in prototype form, carrying only temperature and pressure sensors, during the WOCE[72]. Large-scale deployments with commercially prepared instruments commenced in 1999 (REF.[73]). The float uses an inflatable, oil-filled bladder to change its buoyancy, in order to vertically profile from the sea surface to depths of 1,000–2,000 m, a process that occurs over the course of ~10 days[72]. Data are reported in near real-time using a satellite link and recent versions are outfitted with conductivity, temperature and depth (CTD) instrumentation. Presently, ~4,000 profiling floats are collecting publicly available, real-time observations, providing a synoptic view of the ocean interior every few days as part of the international Argo programme[74]. Some profiling floats have also been adapted to extend observations to deeper oceans or shallower marginal seas, including deep Argo floats reaching 6,000 m (REF.[75]) and coastal Argo floats with fast observation time and anti-drift capabilities[76].

Modern versions of Argo floats (FIG. 3a) used in the BGC-Argo network are equipped with a variety of additional physical, chemical and bio-optical sensors, such as an optode for oxygen sensing, ultraviolet spectrophotometers for measuring nitrate concentrations, electrochemical sensors for pH measurements, chlorophyll *a* fluorometers, scatterometers and radiometers[77]. Throughout the ocean, including in ice-covered regions, floats can operate for between 2 and 7 years after launch, depending on battery usage[50,78]. Using a global network of sensors greatly enhances the probability of encountering transient phenomenon such as carbon export by mixed-layer pump processes during the late winter–spring transition[60,79], episodic responses of dissolved oxygen during tropical cyclones[8] and blooms induced by restratification[80]. Recently, the first observational evidence of a hydrothermal-vent-triggered bloom was captured by BGC-Argo floats in the Southern Ocean, revealing that iron from hydrothermal vents can play an important role in modulating surface primary production[7].

Profiling floats can also be used for long-term data collection. A recent study on nitrate measurements, using data collected from Ocean Station Papa in the North Pacific, demonstrated interannual changes in nitrate concentration, which lead to significant changes in ecosystem functions[81]. They enable predictions of ocean health, including fishery yields. However, Argo floats are limited by the available sensor technology[82] and by sensor offsets and drifts[77]. Moreover, unlike moorings, Argo floats drift passively and, therefore, cannot remain at a fixed location, making long-term observations of a single location difficult.

Gliders. Gliders (FIG. 3b) are similar to Argo floats and operate using similar buoyancy engines[83]. Some gliders are equipped with wings that can translate some vertical movement through the water column into horizontal movement; an adjustable weight inside the glider allows the platform to be steered automatically in order to fulfil spatial requirements for measurements. Gliders use the Iridium global telecommunications network to transmit data to shore-based servers and receive commands for future actions from shore-based personnel when at the surface[84]. Consequently, gliders can conduct uninterrupted missions for up to a year; however, most deployments are shorter in duration, as these systems generally operate continuously, whereas profiling floats sleep for up to 10 days between profiles.

With the ability to carry many diverse sensors (TABLE 1), gliders effectively collect and integrate information related to the physics, chemistry and biology of the ocean[85]. Unlike Argo networks, gliders mainly sample on continental shelves and reveal energetic features of the coastal oceans. Furthermore, their adaptive capabilities allow for sampling of subsurface ocean features that cannot be observed from satellites, such as thermoclines, nutriclines and the deep chlorophyll maximum[41]. Gliders can even collect and transmit ocean data from within hurricanes[86], making them well suited for storm research. Much of the uncertainty in storm forecasts is caused by storm-induced ocean mixing processes, which can alter the storm's intensity at landfall[86]. Given that gliders can adjust their positions dynamically, national agencies are now exploring how gliders might provide a network that can be adaptively positioned during a storm's approach to fill data gaps from traditional methods. Use of gliders in this way could allow more accurate forecasting of storm trajectory and intensity. However, operational time during deployment is limited by the glider's battery life[87].

Unmanned surface vehicles. USVs, including saildrones and Wave Gliders, are capable of basin-scale observations of meteorological variables and surface ocean conditions. A number of USVs are in various stages of development and use (FIG. 1), with the majority of testing done by the Tropical Pacific Observing System (TPOS) and Innovative Technology for Arctic Exploration (ITAE)[66].

A saildrone (FIG. 3c) is a 7-m-long USV with a 5-m-high wing, which uses wind for propulsion and solar energy for powering its sensors[44]. Meteorological sensors are mounted on the wing of the saildrone, and oceanographic sensors are present in the hull and keel. Saildrones are capable of measuring air temperature, barometric pressure, relative humidity, solar irradiance, wind speed and direction, sea-surface temperature and salinity, ocean colour, dissolved oxygen, pH, and atmospheric and seawater pCO_2, and can use active acoustics to measure currents, bathymetry and fish, and passive acoustics to measure ocean noise caused by marine mammals and subsea volcanoes. Adaptations can be made for extreme environments; the current fleet of ~70 saildrones, active since 2015, has been operating in the Arctic[49,88,89], Southern Ocean, western boundary currents and coastal waters.

New USV designs such as Wave Gliders (FIG. 3d) show promise for operating in extreme currents, wind and wave conditions in western boundary currents and high latitudes, where air–sea observations are currently undersampled[90,91]. The surface float of the Wave Gliders that hold the sensor package are 2–3 m long and are propelled by the conversion of ocean wave energy into forward thrust independent of wave direction through subsurface wings at 8 m depth tethered to the float. Wave Gliders have been utilized on several repeat observing missions[92], but, although subsurface measurements have been made on the Wave Glider's 8-m-depth wings, sampling of subsurface waters is a current limitation of surface vehicles.

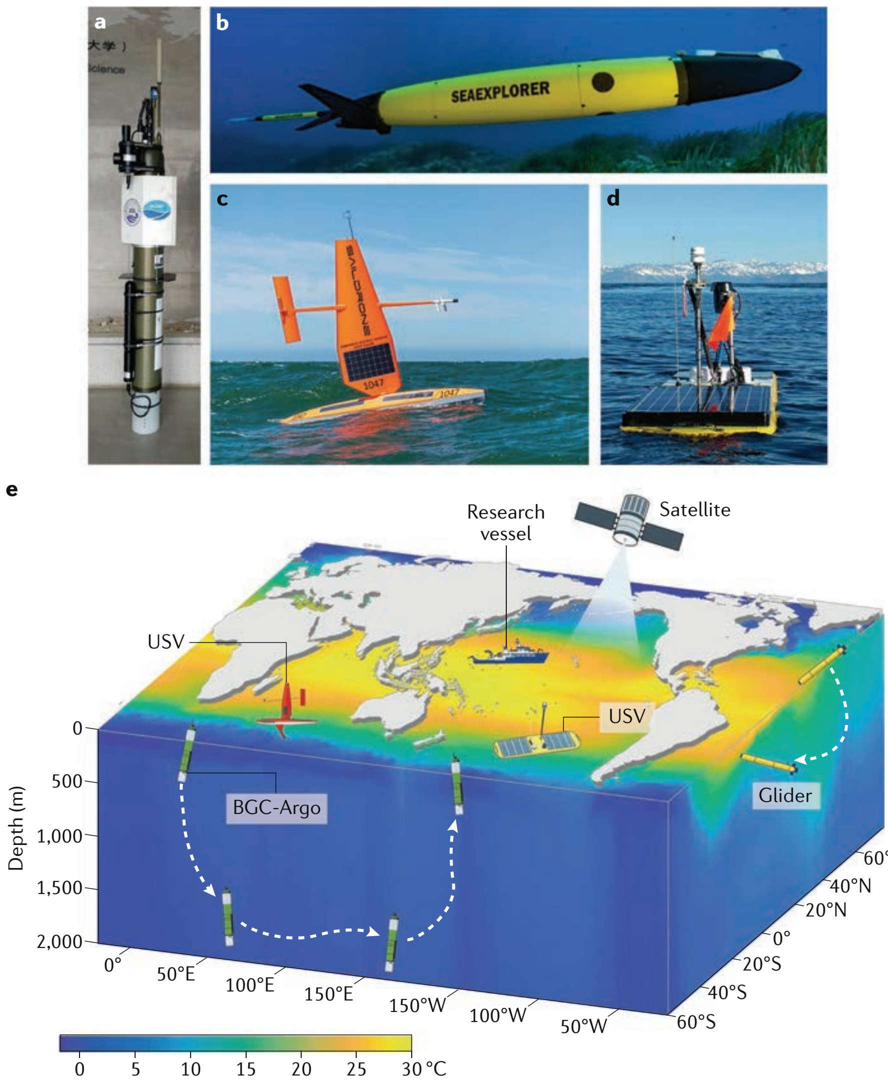

Fig. 3 | **Four available ocean-observation platforms and example areas of operation. a** | A typical Biogeochemical-Argo (BGC-Argo) float. **b** | A glider. **c** | A saildrone (a type of unmanned surface vehicle (USV)). **d** | A Wave Glider (a type of USV). **e** | A schematic diagram of ocean-observation-platform operations, along with research vessels and satellites. Traditional shipborne platforms provide fundamental reference data for many biogeochemical variables across all platforms, and satellite sensing provides the continuous spatiotemporal coverage of sea-surface variables. The Argo and BGC-Argo arrays measure ocean variables through the water column, with all floats reaching up to 2,000 m. Gliders are more suitable for observation at various depths in coastal and shallow oceans, whereas USVs provide air–sea flux data. Panel **b** reprinted with permission from ALSEAMAR. Biogeochemical sensors on autonomous platforms. A novel ensemble of biogeochemical sensors capable of operating on floats, gliders and USVs is now available (FIG. 3e) and has been used on hundreds of profiling floats[93,94] and regional and global networks of gliders[85,95]. Some other sensors have also been equipped on gliders[96,97] and USVs in specific cases[98]. Available sensors are listed in TABLE 1.

New sensors are currently in development; alkalinity sensors[99], for example, could complement already operational pH sensors to robotically estimate CO_2 flux with lower uncertainty than present statistical methods[100,101]. Imaging techniques, as well as active acoustic systems, are presently being developed and tested to better quantify organisms in higher trophic levels, such as zooplankton and mesopelagic fishes. Their applications in the near future could help investigate critically undersampled components of ecosystems and biogeochemical cycles, potentially representing neglected biomass and food resources[102,103]. Finally, passive acoustic sensors have the potential to measure meteorological properties[104,105], as well as anthropogenic noise and mammal presence[89,106–108]. A global integrated observational system, equipped with a large variety of sensors, is now capable of fulfilling the need for multifunctional and multidisciplinary sampling from marginal seas to open oceans and from the surface to the deep ocean.

Current mobile platform networks

The establishment and development of global and regional observation arrays of multiple autonomous platforms will aid

Table 1 | **Major observed biogeochemical properties on mobile platforms**

Observed property	Sensor	Platforms applied	Ref.

the development of 4D data sets to inform and constrain oceanographic models.

Global BGC-Argo array. The BGC-Argo programme is in charge of planning and managing global deployment of BGC-Argo floats, with the goal of conducting global measurements of biogeochemistry and ecosystems. The science and implementation plan identified from the Biogeochemical-Argo Planning Group[93] proposed that an initial step was to carry optical and chemical sensors to support the assessment of biogeochemistry and ecosystems in a changing ocean. At OceanObs'19, a multidisciplinary global ocean-observation-system conference, the specifics of BGC-Argo implementation were refined. The revised plan aims for better interaction and synergy with the global Argo programme, allowing the development of a long-term vision for Argo, defined as 'global, full-depth, and multidisciplinary'[11,50].

The initial target size for the BGC-Argo array is 1,000 floats[93], a goal based on modelling[109] and in situ data analysis[110,111]. The BGC-Argo array currently consists of over 350 floats reporting data regularly, fostering interdisciplinary studies that range from the tropics to high latitudes (FIG. 4). It is becoming an essential component of the global observing network proposed for the next decade and will transform our ability to systematically observe, document and understand changes of ocean environment and marine ecosystems. However, there are some drawbacks associated with the BGC-Argo array. As Argo floats move passively with currents, it is possible floats could drift into an exclusive economic zone (EEZ), which can cause legal issues that could delay data transfer. Moreover, operation of Argo floats is expensive; the average lifetime of a float is ~4 years, and the yearly global cost of a sustained BGC-Argo array is estimated to be ~US $30 million[93]. Improving Argo technology to extend its average working lifetime is an important target for the future and could proportionally reduce running costs[50].

Regional arrays of other autonomous platforms. Similar to BGC-Argo, gliders are being used by an international community through the Boundary Ocean Observing Network (BOON)[95], which is also in the initial phases of incorporating USVs into the network[112] (FIG. 4). In the northeast Pacific, two regular glider lines have operated since spring 2006 (REFS[113,114]), supported by the Ocean Observatories Initiative (OOI). These gliders measure major biogeochemical variables, such as oxygen, chlorophyll *a*, coloured dissolved organic matter (CDOM) fluorescence and particulate backscattering[115]. Sustained glider deployments also monitor upper-ocean conditions in areas frequently impacted by tropical cyclones[116–118], which have been an important part of the NOAA Hurricane Field Program[119]. The OOI also sustains a long-term glider line in the USA east coast, focusing on frontal processes[120,121]. Gliders have been deployed in high-latitude oceans and all over the Southern Ocean, including in the Antarctic Circumpolar Current (ACC)[122–124], continental shelves[125–129], near ice shelves[117,130,131] and in the Arctic Ocean[23]. Also, in the Mediterranean Sea, more than five glider endurance lines are currently in operation[132].

USVs are also filling a growing need for surface-based observations in the Southern Ocean (FIG. 4e), assessing physical air–sea fluxes[133,134] and gas air–sea fluxes, notably, CO_2 (REF.[92]). While existing USV missions are primarily regional, saildrones and other USVs are designed and have been used for basin-scale observations[46,66]. Given the ability to actively navigate USVs, they present an opportunity for sampling in regions where ships do frequent less. For example, USV-based seawater pCO_2 observations covering observing gaps of open-ocean missions from the tropical Pacific to the South Pacific Gyre are being incorporated into the 2020 version of the SOCAT.

Multiplatform synergy

Generally, ship-based measurements are of very high quality and include key variables that cannot presently be measured by floats or gliders, for example, levels of silicon, phosphorus, iron, ammonia, bacteria, total dissolved organic carbon (DOC) concentration and phytoplankton species[135]. Moreover, remote sensing offers a large-scale snapshot of the ocean surface, which cannot be covered by individual autonomous platforms. Therefore, autonomous platforms could complement these observation methods by extending observations into full seasonal cycles, or from open-ocean to coastal regions, and by providing the three-dimensional real-time data needed for operational models.

Synergy between autonomous and ship platforms. Although ship-based observations are infrequent and biased to summer months, well-calibrated shipborne data provide, by far, the most important reference for in situ validation of autonomous platforms[77]. For the delayed-mode quality control of autonomous platforms in particular, climatological data captured by ships can validate previously acquired oceanographic measurements. NO_3^- and pH measurements by autonomous platforms may be biased by sensor offsets and drifts[77]. The high-quality GLODAP data set, generated from ship-based measurements, includes deep (>1,000 m) NO_3^- and pH measurements that can be used as reference values to correct the sensor offsets and drifts. Methods for using GLODAPv2 to produce reference measurements at float geolocations are based on multiple linear-regression analyses[136] and neural networks[137,138]. These regressions and neural networks are driven with data from CTD and O_2 sensors on the floats. Similarly, observation of other platforms (ships, buoys and USVs) in the Surface Ocean CO_2 Network (SOCONET)[24] can provide the reference measurements for calculated pCO_2 based on BGC-Argo observations[139].

Synergy between autonomous and satellite platforms. Variables measured by autonomous platforms, for example, chlorophyll *a*, backscattering and photosynthetically available radiation (PAR), can be used to validate satellite platforms[140–142] and evaluate calibration of in situ sensors[143,144]. Several recent studies also present prototype floats that can be used as calibration platforms for ocean-colour satellites through acquiring high-quality radiometric measurements[145,146]. The combination of in situ BGC-Argo observations with ocean-colour remote sensing can be assisted by machine-learning techniques; this approach has been used to develop a 4D global map of the backscattering coefficient, a proxy for measuring particulate organic carbon[11,79].

The calibrated sensor data from floats and gliders can be used to evaluate satellite observation platforms. Recent studies using this approach showed that NASA's chlorophyll *a* and POC algorithms perform without significant mean bias in the Southern Ocean[77,141], despite several publications suggesting the opposite[147–149].

Multiplatform experiments. Comprehensive data sets can be collected by combining data from autonomous platforms, ship, buoy and satellite observations. Increasingly, oceanographic experiments and observation networks are being conducted across multiple platforms. The OOI not only supports two regular glider lines as mentioned above but also hosts several surface and profiler moorings[121]. Early-stage, multiplatform experiments included the in situ iron-enrichment experiment IronEx-I in 1993 (REF.[150]), the CLIVAR Mode Water Dynamics Experiment (CLIMODE) in 2006–2007, the North Atlantic Bloom experiment (NAB08) in 2008 (REF.[58]) and the coastal experiment in the eastern Alboran Sea, AlborEx, in 2014 (REF.[151]). These studies have greatly improved our understanding of phytoplankton physiology and impacts of mesoscale and sub-mesoscale dynamics on regulating primary production, among other biogeochemical phenomena[43,47].

In 2016 and 2017, the Salinity Processes in the Upper-Ocean Regional Study (SPURS-2)[152] and the Northern Arabian Sea Circulation-Autonomous Research (NASCar)[153] coordinated almost all autonomous platforms (including Argo floats, gliders and USVs) and moorings focused on targeted mesoscale eddy. These studies demonstrated the use of multiple platforms to resolve physical

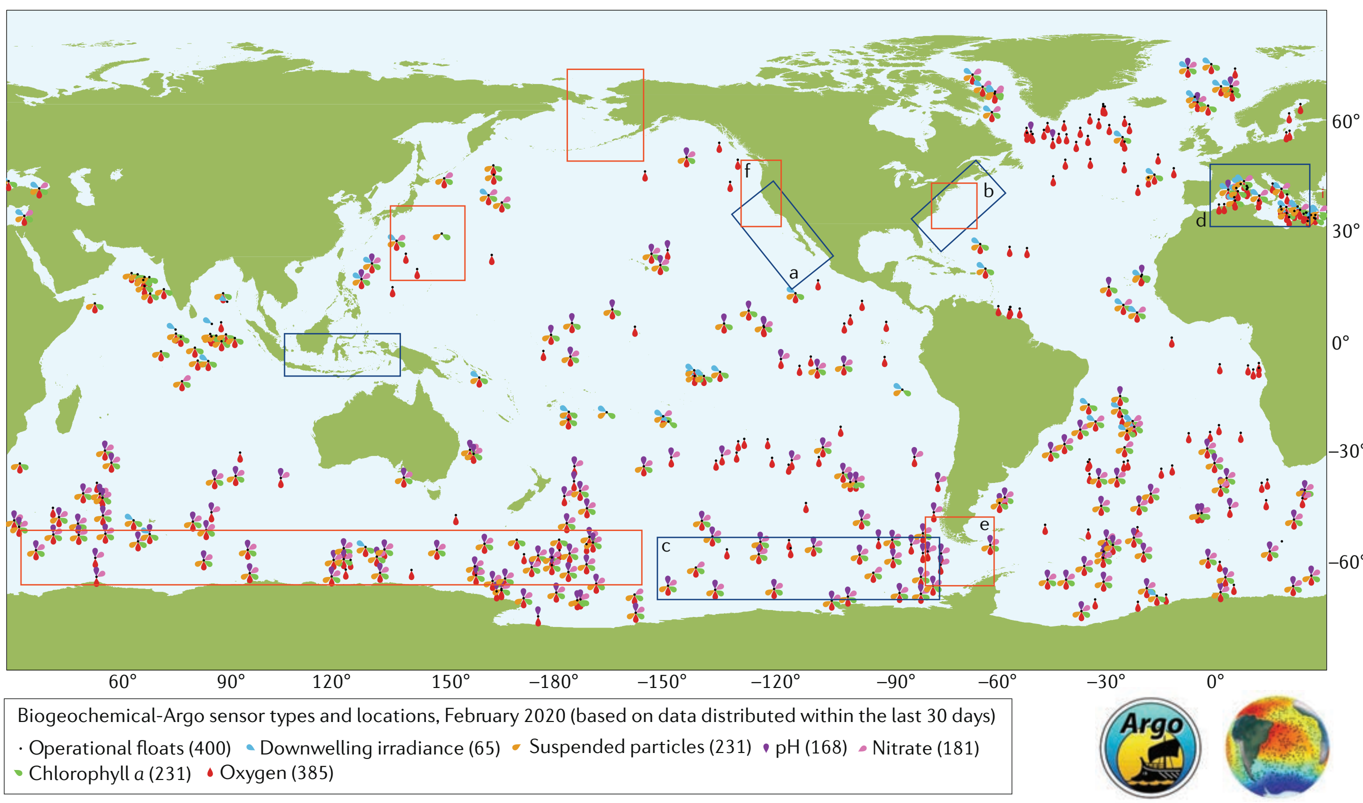

Fig. 4 | **Locations of recent autonomous ocean observations.** A map of the global array of Biogeochemical-Argo floats with various sensors in February 2020, with locations based on data distributions over 30 days. Boxes indicate areas that have been observed frequently by gliders (blue) or unmanned surface vehicles (red). Data in a obtained from REF.[115]; data in b from REF.[119]; data in c from REFS[124,130]; data in d from REF.[132]; data in e from REF.[133]; and data in f from REF.[112]. oceanography, and their approaches could be used for measuring biogeochemistry in the future. The EXport Processes in the Ocean from Remote Sensing (EXPORTS) project is currently developing a predictive understanding of the export and fate of global ocean net primary production and its implications for present and future climates, based on BGC-Argo floats, gliders and satellites[154]. These experiments and projects suggest a multiplatform future for marine biogeochemical research, in which synergic observations are capable of providing comprehensive 4D oceanographic information at a high spatiotemporal resolution.

The future of modelling and forecasting

Data from integrated observational platforms can be applied to evaluate and improve existing numerical models, ensuring model reliability for predicting marine biogeochemical processes (FIG. 5).

Reliable modelling for ocean biogeochemistry and ecosystem. Biogeochemical models can guide assessments of the current state of the ocean, elucidate ongoing trends and shifts, anticipate impacts of climate change and management policies, and maintain ocean ecosystem health (see a recent overview by Fennel et al.[155]). Such modelling capabilities can only be achieved in combination with comprehensive ocean biogeochemical observations, such as those provided by autonomous platforms.

Presently, biogeochemical modelling applications lag behind physical ocean modelling and prediction, mainly because traditional biogeochemical observation streams are too sparse for comprehensive validation, initialization and optimization of biogeochemical models[155]. Improved biogeochemical models can be used to estimate system properties that are not directly observable, such as lateral NO_3^- supply and air–sea exchange of CO_2 in the Southern Ocean[156]. They further offer spatial and temporal coverage not attainable by direct observations. The technological readiness for assimilating observations from BGC-Argo data into biogeochemical models has been demonstrated for state estimation[53,156,157], as well as parameter optimization[158].

Assimilation of physical observations in biogeochemical models can significantly reduce model biases[157]. BGC-Argo observations provide much better constraints than traditional observation streams on the dynamics and vertical structures of biogeochemical properties, as shown by a forecasting system for the Mediterranean Sea[53] and a biogeochemical-parameter-optimization study for the Gulf of Mexico[158]. New observations might also elucidate previously unrecognized shortcomings in biogeochemical models and satellite-based data products, and prompt modifications and refinements of model structures, parameterizations and algorithms for data products.

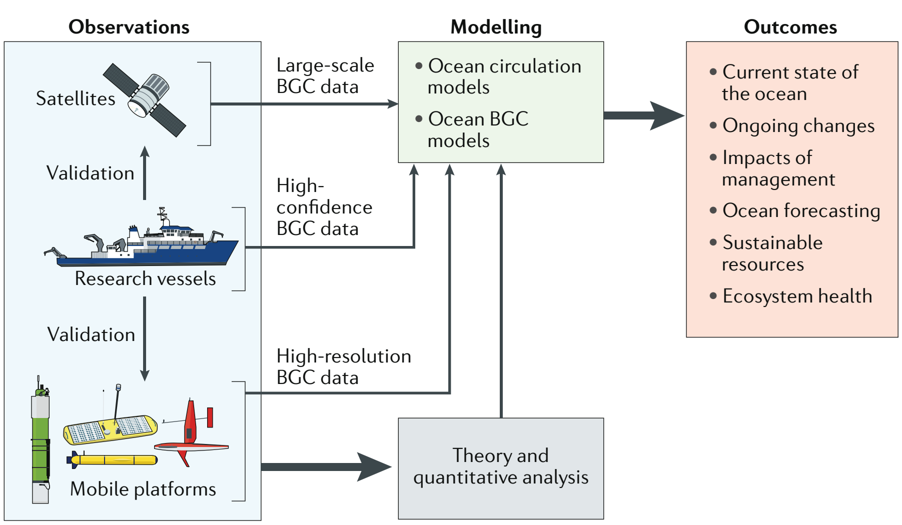

Fig. 5 | **Relationships between new observation technologies, biogeochemical models and ecosystem health management.** Mobile platforms, as an important component of global ocean-observing systems, provide high-resolution biogeochemical data. The data sets acquired by multiple platforms, including also ships and satellite sensors, are crucial to improving ocean biogeochemical models, and, in turn, to better evaluating the current state of ocean ecosystems and forecast its changes. BGC, biogeochemical.

Forecasting systems to support decision-making. A major focus in delivering the UN's sustainable development goals and aims set out in the Paris Agreement[2] is the construction of a reliable and comprehensive forecasting system. Forecasting systems are fundamental for facilitating the decision-making process, and there is great potential for BGC-Argo and other autonomous platforms to be at the forefront of these systems.

4D data sets can optimize forecasting system parameters[71,104]. Autonomous platforms have been used in marginal seas during spring blooms to measure nutrient content in high temporal frequency and vertical resolution, in order to resolve anomalous NO_3^- drawdown[159]. The implementation of high-spatiotemporal-resolution observational data into ocean models can fill observational gaps and help make reliable predictions for biogeochemical cycles, ocean primary production and fishery resource[160,161]. The behaviours of fishes, such as tuna in the tropical Pacific, can be better understood and simulated using accurate observational data to fit the likelihood of spawning, model migration patterns and improve stock assessment[162]. An ecosystem-based modelling procedure could also refine fishing policies adaptively, mitigating stressors induced by anthropogenic activities and guarding ecosystem health by informing sustainable resource use[163,164].

One of the major expectations from the UN Decade of Ocean Science for Sustainable Development is a well-predicted ocean, which relies on a sustainable ocean-observing system[165]. The major bottleneck for the development of biogeochemical models is the lack of observations; the use of in situ biochemical data from floats, gliders and USVs is, therefore, expected to be important for increasing the capability and credibility of ocean models[166]. Well-established models are anticipated to steer sustainable development of human society and can optimize approaches for assessing the responses of marine ecosystems to stress conditions, for example, algal blooms and storms, and help stakeholders make reasonable decisions[167].

Machine learning and artificial intelligence could be used to handle the autonomous-platform data sets[168]. These new approaches can extract spatial and temporal patterns from geospatial data to construct a hybrid model, systematically describing the multidisciplinary marine system[169]. A technique integrating a near real-time data-transmission system and data processing can enable the forecasting system to predict the ocean state in a comprehensive manner[170]. Improved forecasting models based on observational data streaming and cutting-edge data sciences are predicted to help explore the carbon cycle and underlying Earth systems[171]. An accurate forecasting system could, therefore, reduce the threats on climate and marine ecosystems through refining the decision-making process.

Conclusions

Many notable observations of ocean biogeochemistry and ecosystems have been made over the past century using traditional observation methods. However, these methods are now proving inadequate for capturing the varied temporal and spatial scales of biogeochemistry[11]. Autonomous platforms will play an important role in filling the observational gaps in monitoring and forecasting marine ecosystems. Argo floats and other autonomous platforms have also been considered as the most effective way to globally acquire vertical profiles of key environmental, biogeochemical and ecosystem variables[13,82]. They represent a new era of modern oceanographic observations, with great potential to provide new Essential Climate Variables and Essential Ocean Variables (ECVs and EOVs, respectively) related to ecosystem health and resource management[1]. There are ongoing developments in merging satellite and in situ robotic measurements for constructing a global three-dimensional view of biogeochemically relevant variables[79], and, in the near future, these three-dimensional fields will likely become essential parts of the data set for the initialization and/or validation of global biogeochemical models.

Currently, the implementation of integrated observation systems has primarily been addressed by the physical community[172,173]. It is now obvious that the scope of observational networks has to expand to include ocean biogeochemical and ecosystem components, and to integrate efforts across these scientific disciplines. The methodology for developing physical observational systems should serve as a guideline for the development of their biogeochemical and ecosystem counterparts[24]. The integration of biogeochemical and ecosystem components into an already existing physical observational system, however, is not just a matter of adding new sensors[77]. The implementation strategy of these new components will have to be discussed and organized by the physical, biogeochemical and ecosystem components[66].

BGC-Argo and other emerging autonomous platforms equipped with biogeochemical sensors are essential components for global observations of ocean conditions on multiple temporal and spatial scales. These global and regional networks of autonomous platforms, along with remotely sensed data, will provide the 4D information required to improve model simulations and forecasts of ocean conditions and ecosystem health. The success of any future ocean-observation system will strongly depend on the capability of the observing community to improve interactions between physical, chemical and biological oceanographic disciplines and integrate in situ, satellite and modelling components[174].

Abstract*—Hurricane Dorian devastated the Bahamas in August 2019 when it underwent rapid intensification and transitioned from a category 4 to a category 5 storm. The operational hurricane forecasting models consistently under predicted the intensity evolution of Dorian. It has been shown that an accurate representation of the upper ocean processes that affect air-sea heat fluxes in coupled atmospheric-ocean models is necessary for an accurate hurricane intensity forecast. In this work, we evaluate several ocean surface metrics that are relevant to air-sea heat fluxes in one of NOAA's operational hurricane forecasting systems during the 2019 hurricane season: HWRF2019-POM initialized from climatology, and two experimental hurricane forecasting models: HWRF2020-POM and HWRF2020-HYCOM, both initialized from the Real Time Ocean Forecasting System (RTOFS). For this, we use temperature and salinity data from a fleet of autonomous underwater gliders, dedicated to hurricane research and operations, during the passage of Hurricane Dorian through the Caribbean. We contrast our results with estimates from a data assimilative model, the Global Ocean Forecasting System (GOFS 3.1). We found that even though all the models have a good skill in predicting temperature and salinity over the full water column, the model's skill considerably deteriorates for the ocean surface metrics evaluated. We also found that of the three hurricane forecasting models, HWRF2020-HYCOM is the model with the highest skill for the ocean surface metrics. All the models also show a cold bias in the mixed layer temperature and a deficit in the ocean heat content with respect to the glider observations. These results demonstrate that the implementation of HYCOM as the ocean model underneath the hurricane forecasting models, will significantly improve the representation of key quantities that are important for the air-sea heat fluxes during tropical cyclones.

***Index Terms*—Hurricane Dorian, HWRF-POM, HWRF-HYCOM, Underwater Gliders**

I. Introduction

It has been demonstrated that the sea surface thermal structure plays a very important role in the intensification of storms [4], [9] and that an accurate representation of the upper ocean processes that affect air-sea heat fluxes in ocean-atmosphere coupled models is necessary for an accurate intensity forecast [6], [8], [18]. In the last three decades there has been significant progress reducing the error in the storm track in the operational hurricanes forecasting models, however the error reduction in the intensity has been marginal [15].

In August 2019, Hurricane Dorian developed from a tropical wave off the west coast of Africa and moved through the Caribbean gaining strength. Dorian continued its way into the Atlantic and made landfall in Great Abaco Island on September 1 as a category 5 hurricane, becoming the strongest hurricane in record to make landfall in the Bahamas. None of the hurricane forecasting models captured the intensity evolution five days prior to Dorian reaching its maximum strength [1].

We evaluated three upper ocean metrics that have been identified as having an effect on the intensification and/or weakening of storms in four different models: the HWRF2019-POM operational, the HWRF2020-POM experimental, the HWRF2020-HYCOM experimental and GOFS 3.1 during the passage of Hurricane Dorian through the Caribbean. The first metric evaluated is the surface mixed layer temperature. The surface mixed layer is the surface portion of the water column where turbulent processes, such as wind-driven mixing, make water density nearly uniform [3]. The second metric is the ocean heat content (OHC), defined as the amount of heat in the surface ocean above the 26 degrees isotherm. OHC is a Metric that has been shown to be correlated with the intensification of storms in the open ocean [11]–[13]. The last metric is the depth average temperature in the top 100 meters (T100). T100 was proposed as a metric that quantifies the resulting sea surface temperature (SST) after the passage of a hurricane that fully mixes the top 100 meters, somehow accounting for the effect of cold subsurface water and the strength of vertical stratification on storm weakening [17].

II. Methods

A. Observational Data Sources

A fleet of underwater gliders was deployed in the Caribbean Sea, Gulf of Mexico, the South and Middle Atlantic Bight during the 2019 hurricane season as part of the National Oceanic and Atmospheric Administration (NOAA) hurricane underwater glider project and operations [16]. During the passage of Hurricane Dorian through the Caribbean, there were six underwater gliders deployed in the region north and south of Puerto Rico. These gliders were deployed by the NOAA Atlantic Oceanographic and Meteorological Laboratory (AOML) and the Integrated Ocean Observing Systems (IOOS) from July 15 to November 15 2019 (Fig. 1) The gliders collected temperature and salinity with an approximate frequency of 2 hours and reaching a maximum depth of 900 meters. The glider data is publicly available through the IOOS glider data assembly center (DAC) (https://data.ioos.us/gliders/erddap)

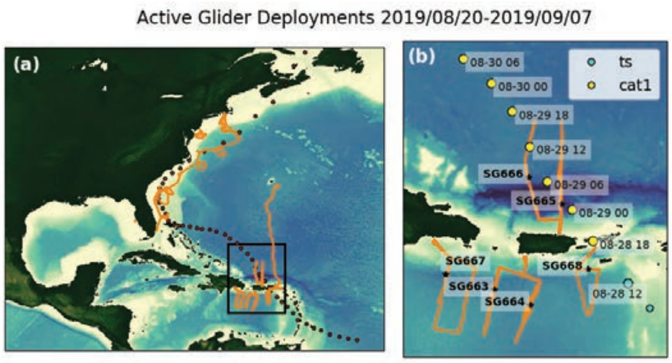

Fig. 1. (a) North Atlantic map showing the path of hurricane Dorian (red dots) and the glider trajectories between Aug 20 to Sept 7 2019 (yellow lines). (b) Detail of the Caribbean Sea around Puerto Rico showing the path and category (red symbols) and the glider trajectories (yellow lines).

B. Numerical Data Sources

The Hurricane Weather and Forecasting model (HWRF) coupled to the Message Passing Interface Princeton Ocean Model - Tropical Cyclone (MPIPOM-TC) is one of the hurricane forecasting systems run by NOAA National Centers for Environmental Prediction (NCEP) [2]. Hereon we will call this couple system HWRF2019-POM and it is one of the models that was used by the National Hurricane Center (NHC) to guide their official track and intensity hurricane forecast in the North Atlantic Basin during 2019. The ocean component of HWRF2019-POM was initialized from climatology and a feature-based model. In this study, we also accessed the output of an experimental version of the coupled system, HWRF2020-POM, with the ocean component initialized from the Real Time Ocean Forecasting system (RTOFS). In addition, we evaluated another experimental system, HWRF coupled to the Hybrid Coordinate Ocean Model, HWRF2020-HYCOM, with ocean initialization from RTOFS [10].

The Global Ocean Forecasting System, GOFS 3.1, is the US Navy operational ocean model. It is a global model based on the Hybrid Coordinate Ocean model (HYCOM). GOFS 3.1 implements a 3DVar data assimilation algorithm, called NCODA that uses satellite altimeter data, satellite and in-situ surface temperature, in-situ vertical temperature and salinity from Argo floats, buoys, gliders and XBTs (only temperature). More details about GOFS 3.1/NCODA system can be found in the GOFS 3.1 validation test report [14]. The hindcast output for GOFS 3.1 used here can be accessed at https://tds.hycom.org/thredds/dodsC/GLBv0.08/expt 93.0/ts3z.html.

C. Surface Ocean Metrics

The mixed layer was estimated as the surface portion of the water column that presents very small changes in vertical stratification. We used two different criteria, a density criteria (2) and a temperature criteria (1).

$$T - T_{10} \leq 0.2^o \tag{1}$$

$$\rho_{10} - \rho \leq 0.125 \frac{kg}{m^3} \tag{2}$$

where ρ_{10} is the water density at 10 meters depth and ρ is density at different depths.

The average Temperature and salinity within the mixed layer are calculated as the average temperature and salinity of every profile that is within the mixed layer.

Ocean heat content is defined as the depth integrated heat content between the depth of the 26 ^{o} isotherm to the surface (Eq. 3).

$$OHC = C_p \rho_0 \int_{Z_{26^o}}^{0} (T - 26) dz \tag{3}$$

Where C_p is the heat capacity of sea water, ρ_0, is the mean density of water column down to the 26^o isotherm and T is temperature at different depths in degrees Celsius.

The depth average temperature in the top 100 meters (T100) is a metric that estimates the resulting SST after the passage of a hurricane due to vertical mixing processes in the ocean interior [17].

D. Taylor Diagrams and Mean Bias

In order to quantify the model's skill, we estimated the normalized standard deviation and correlation between the observational data and the model's output. We used all the available temperature and salinity profiles from the fleet of gliders present north and south of Puerto Rico when Hurricane Dorian was transiting through that region (Fig. 1). We obtained the corresponding along-track temperature and salinity glider-transects in the ocean models by interpolating the glider position and time onto the model grid and output timestamp. The normalized standard deviation and correlation for all the different metrics can be visualized together by constructing a Taylor diagram [19], giving us a compact way to assess the model's skills.

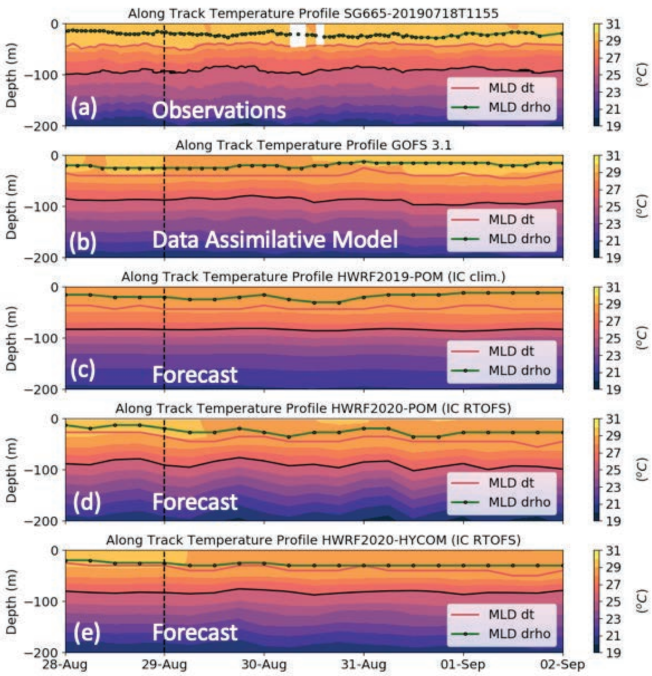

Fig. 2. (a) Temperature transects for glider SG665 from Aug 29 to Sep 2. (b), (c), (d), (e) The same along-track transect as for SG665 but interpolated onto the respective model grid and timestamp. MLD dt and MLD drho stands for mixed layer depth based on the temperature criteria and density criteria respectively. The dash vertical line in all figures shows the time when Hurricane Dorian was the closest glider SG665.

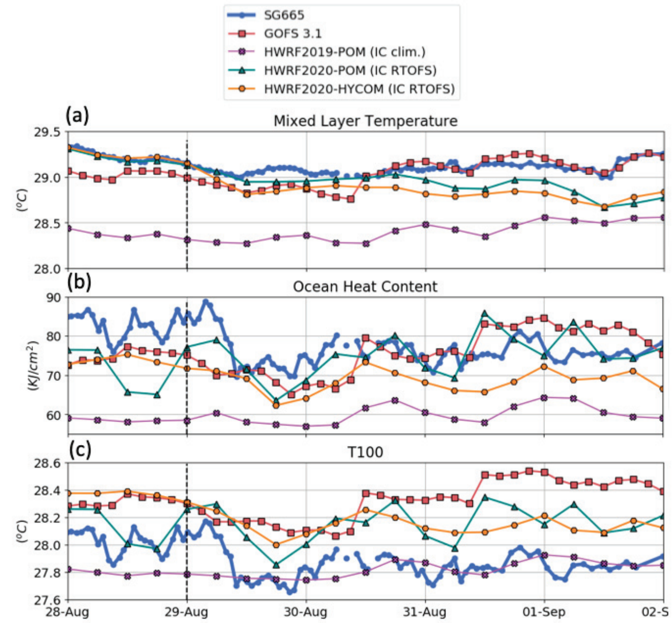

Fig. 3. Time series of (a) mixed layer temperature, (b) ocean heat content and (c) T100 for glider SG665 (blue), GOFS 3.1 (red), HWRF2019-POM (IC clim.) (purple), HWRF2020-POM (IC RTOFS) (green) and HWRF2020-HYCOM (IC RTOFS) (orange). The dash vertical line in all figures shows the time when Hurricane Dorian was the closest glider SG665.

Another statistical quantity that is not represented in a Taylor Diagram is the mean bias. We estimated the mean bias percentage of the different metrics as

$$Bias\% = \frac{\overline{X_{obs}} - \overline{X_{model}}}{\overline{X_{obs}}} \times 100\% \tag{4}$$

Where $\overline{X_{obs}}$ is the mean value of a specific metric from the observations and $\overline{X_{model}}$ is the mean value of the same metric from the different model's output.

III. Results

The temperature transects from the glider observations show that the surface temperature at the end of August north of Puerto Rico was close to $30^oC$and that the 26^oC isotherm is approximately at 100 meters depth (Fig. 2 (a)). The mixed layer depth (MLD) based on the temperature criteria (MLD dt) (Eq. 1) is consistently deeper than the mixed layer depth based on the density criteria (MLD drho) (Eq. 2). A qualitative comparison of the glider transect for the SG665 glider from Aug. 28 to Sep. 2 2019 shows that the temperature fields in the four ocean models agree well with the glider observations (Fig. 2 (b)-(e)). In all the models the MLD based on the density criteria is shallower than the MLD based on the temperature criteria and the 26^oC isothermal is approximately at the same depth or slightly shallower than the observations. The discrepancy in the MLD using the two different criteria is caused by the so called barrier layer, a fresh surface layer

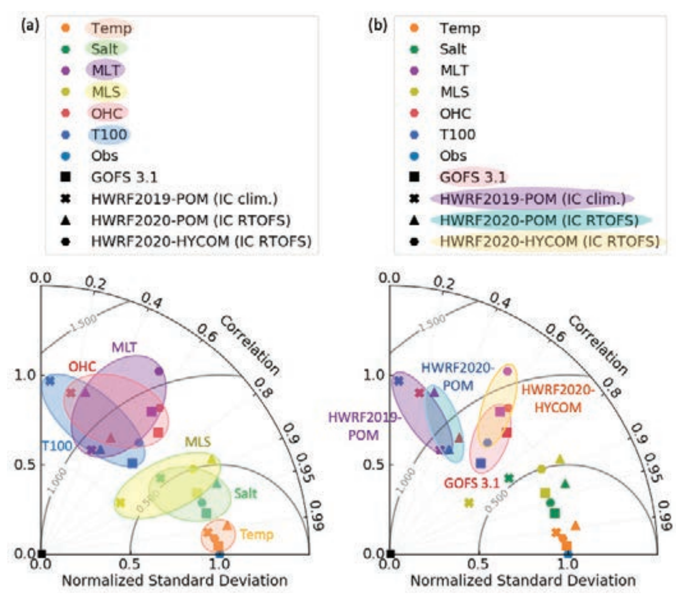

Fig. 4. Taylor diagram showing the model skill for the four models evaluated: GOFS 3.1, HWRF2019-POM (IC clim.), HWRF2020-POM (IC RTOFS) and HWRF2020-HYCOM (IC RTOFS). in (a) The ellipses group the skill by the different quantities and in (b) The ellipses group the skill according to the different models.

that characterizes the Caribbean Sea and is produced by the spreading of the Amazon and Orinoco river plumes [7]. As a consequence, salinity rather than temperature controls vertical stratification at the surface in the Caribbean Sea. For this reason, we will use the estimate of the mixed layer based on the density criteria from now on in our analysis.

Despite the general agreement in the temperature fields, there are obvious differences between the observed mixed layer temperature based on the density criteria and the one estimated from the models (Fig. 3 (a)). HWRF2019-POM, initialized by climatology, is about 1^oC colder than observations. HWRF2020-POM and HWRF2020-HYCOM, both initialized from RTOFS, have almost the same temperature as the observations during the first 24 hours of the forecast, but beyond this point the mixed layer temperature gets progressively colder. GOFS 3.1, the data assimilative model, starts colder than the glider temperature but it approaches it on Aug. 30 12Z, after a jump in temperature that could have been caused by the data assimilation algorithm. The measured ocean heat content (OHC) is well above $60Kj/cm^2$ (Fig. 3 (b)), the OHC level that is considered minimum to favor storm intensification [13]. The OHC in HWRF2019-POM is well below the observed value but the other models match better the measured OHC, although HWRF2020-HYCOM is consistently lower than the glider estimate. In contrast, T100 from HWRF2019-POM is the closest to the observational value, while the other models exhibit higher values (Fig. 3 (c)).

The previous qualitative assessments are quantified estimating the normalized Taylor diagrams and mean bias between the glider observations and the different models. (Fig. 4 (a)). The normalized Taylor diagram shows that all the models have a good skill in the temperature (Temp) and salinity (Salt) of the entire water column. However the three metrics relevant for the air-sea heat fluxes: temperature in the surface mixed layer (MLT) based on the density criteria, ocean heat content (OHC) and depth average temperature in the top 100 m (T100), are poorly represented in all models. In particular, HYCOM2019-POM, initialized from climatology, and HYCOM2020-POM, initialized from RTOFS, have very low skill for the surface metrics (Fig. 4 (b)). But these metrics are fairly represented in HWRF2020-HYCOM, initialized from RTOFS, and GOFS 3.1. The fact that HWRF2020-HYCOM, is close in skill to the data assimilative model GOFS 3.1, gives us confidence that of the three air-sea coupled hurricane forecasting models evaluated, HWRF2020-HYCOM is the one that better represents the ocean surface conditions.

The mean percentage bias (Table I) for the MLT shows that all the models are colder than observations within the ocean surface mixed layer, with HWRF2019-POM initialized from climatology being the coldest. We see a similar pattern for the OHC. HWRF2019-POM presents a 22% deficit with respect to the observations in the OHC while GOFS 3.1 has only a deficit of 3.6%. From the hurricane coupled models, HWRF2020-HYCOM has the lowest OHC bias.

TABLE I
MEAN BIAS PERCENTAGE BETWEEN THE OBSERVATIONS AND THE DIFFERENT MODELS FOR THE MIXED LAYER TEMPERATURE (MLT), OCEAN HEAT CONTENT (OHC) AND DEPTH AVERAGE TEMPERATURE IN THE TOP 100 METERS (T100).

	GOFS 3.1	HWRF19-POM (IC Clim.)	HWRF20-POM (IC RTOFS)	HWRF20-HYCOM (IC RTOFS)
MLT	-0.40 %	-3.0 %	-0.94 %	-0.62%
OHC	-3.6 $	-22 %	-17 %	-8.7 %
T100	1.4 %	-0.46 %	0.49 %	1.2 %

IV. Conclusion

The ocean-atmosphere coupled hurricane models HWRF2019-POM, HWRF2020-POM and HWRF2020-HYCOM, have a good skill in the temperature and salinity over the full water column when Hurricane Dorian was transitioning from tropical storm to category 1 hurricane. However, their skill is significantly reduced for the upper ocean metrics that are relevant to the air-sea heat fluxes such as temperature in the mixed layer, ocean heat content and average temperature in the top 100 meters. However the skill of HRWR2020-HYCOM was the best of the three coupled models and comparable to the data assimilative model GOFS 3.1. This shows that HRWR2020-HYCOM is the coupled model that best represents the ocean surface metrics that are important for the air-sea heat fluxes during storms.

ABSTRACT: The future Surface Water and Ocean Topography (SWOT) mission aims to map sea surface height (SSH) in wide swaths with an unprecedented spatial resolution and subcentimeter accuracy. The instrument performance needs to be verified using independent measurements in a process known as calibration and validation (Cal/Val). The SWOT Cal/Val needs in situ measurements that can make synoptic observations of SSH field over an $O(100)$ km distance with an accuracy matching the SWOT requirements specified in terms of the along-track wavenumber spectrum of SSH error. No existing in situ observing system has been demonstrated to meet this challenge. A field campaign was conducted during September 2019–January 2020 to assess the potential of various instruments and platforms to meet the SWOT Cal/Val requirement. These instruments include two GPS buoys, two bottom pressure recorders (BPR), three moorings with fixed conductivity–temperature–depth (CTD) and CTD profilers, and a glider. The observations demonstrated that 1) the SSH (hydrostatic) equation can be closed with 1–3 cm RMS residual using BPR, CTD mooring and GPS SSH, and 2) using the upper-ocean steric height derived from CTD moorings enable subcentimeter accuracy in the California Current region during the 2019/20 winter. Given that the three moorings are separated at 10–20–30 km distance, the observations provide valuable information about the small-scale SSH variability associated with the ocean circulation at frequencies ranging from hourly to monthly in the region. The combined analysis sheds light on the design of the SWOT mission postlaunch Cal/Val field campaign.

1. Introduction

The Surface Water and Ocean Topography (SWOT) mission is a pathfinder mission that will demonstrate the next-generation satellite altimeter based on a Ka-band radar interferometer (KaRIn) (Durand et al. 2010; Fu and Ubelmann 2014). The major thrusts of the mission are the low noise and wide-swath sea surface height (SSH) measurements of the KaRIn instrument. After its launch in 2022, understanding the performance of the KaRIn instrument against a ground truth of dynamical SSH is crucial for subsequent scientific applications. This emphasizes the importance of the mission's ocean topography calibration and validation (Cal/Val), which focuses on the wavenumber spectrum of SWOT SSH measurement errors.

In the past, the ground truth for satellite altimeters was typically produced using point measurements from ground stations such as tide gauges, a method that has been used successfully for all previous nadir-altimeter missions, such as the Jason-series altimeters (e.g., Haines et al. 2021; Bonnefond et al. 2019; Quartly et al. 2021). However, the SWOT mission requires a new approach for calibration and validation because the SWOT science requirement is specified in terms of the wavenumber spectrum over 15–1000 km wavelengths (Fig. 1; Desai et al. 2018). As such, validation of the sensor requires capturing a synoptic SSH field along a line covering 15–1000 km wavelengths. Validation of wavelengths ranging from ~120 to 1000 km will be accomplished by the onboard Jason-class altimeter (Wang and Fu 2019), whose performance in wavenumber space is known (e.g., Dufau et al. 2016). The ground truth over the short wavelength (15–150 km) may be achieved by airborne instruments such as lidar (Melville et al. 2016) for geodetic validation and in situ oceanographic measurements (Wang et al. 2018) for oceanographic validation. For the latter, we need an observing approach designed specifically for SSH wavenumber spectrum validation at scales between 15 and 150 km with subcentimeter accuracy.

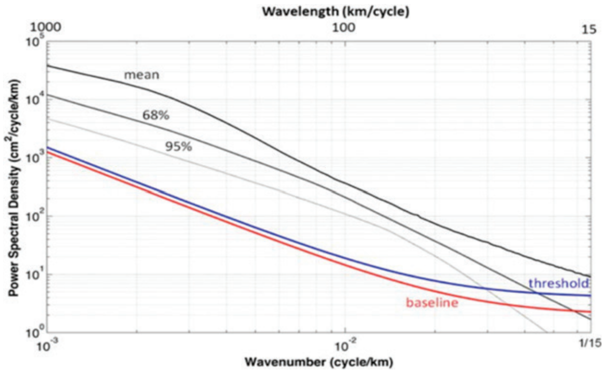

FIG. 1. The SSH baseline requirement spectrum (red line) as a function of wavenumber (Desai et al. 2018). The thick black line is the mean spectrum of the *Jason-2* altimeter track 159, which extends from the Southern Ocean to North Pacific. The 68th and 95th percentiles are marked by the thin black line and the gray line; i.e., 68% and 95% of the spectra are above the corresponding curve. The red curve defines the baseline requirement represented by $E(k) = 2 + 0.001\,25k^{-2}(\mathrm{cm}^2\ \mathrm{cpkm}^{-1})$. The blue curve represents the threshold requirement $E(k) = 4 + 0.0015k^{-2}(\mathrm{cm}^2\ \mathrm{cpkm}^{-1})$.

An observing system simulation experiment (OSSE) was conducted as a first step to evaluate the feasibility of an array of moorings to meet the Cal/Val requirement (Wang et al. 2018). Based on the OSSE, the top challenges in reconstructing the small-scale synoptic SSH field over a 150 km distance come from the emerging dominance of superinertial high-frequency SSH variability at spatial scales <150 km, and the weak SSH signal itself at those scales. These challenges led to a series of field campaigns to identify the relevant ocean processes at the Cal/Val site (near 35.6°N, 125°W) and to evaluate the performance of different in situ platforms and instruments in meeting the SWOT requirement.

Here we report the results from a recent field campaign conducted between September 2019 and January 2020. The rest of the paper is organized as follows. Section 2 summarizes the past development of SWOT oceanographic Cal/Val and the in situ field campaigns. The summary provides the background and motivation of this study. Section 3 discusses the instrumentation of the 2019/20 field campaign. Results are shown in section 4. Uncertainties in the observations and quantifications exist and are discussed in section 5. Summaries are presented in section 6.

2. The development of SWOT SSH Cal/Val

This section reviews the previous work in developing an in situ observing array for the SWOT oceanographic Cal/Val. Section 2a introduces the nature of the SWOT SSH Cal/Val. Section 2b discusses the theoretical basis for conducting oceanographic Cal/Val through in situ mooring platforms. Section 2c reviews the previous OSSE results. Section 2d discusses the transformation of the measurement errors from wavenumber spectrum to time series measurement at a single point and provides accuracy requirements imposed on individual observing platforms used in the field campaign. Section 2e briefly reviews a pilot field campaign that took place prior to the recent 2019/20 field campaign.

a. SWOT SSH Cal/Val

After the SWOT satellite launch, the first 90 days will be dedicated to instrument hardware checkout. The second 90 days will be for the mission Cal/Val along a 1-day-repeat orbit (Desai et al. 2018). The 90-day Cal/Val orbit provides more frequent SSH measurements at certain locations for both the validation of the instrument and to develop an understanding of the SWOT measurements from an oceanographic perspective at a very early stage. The SWOT mission Cal/Val has two aspects: 1) characterizing the performance of the instrument KaRIn from a *geodetic* perspective and 2) characterizing the SWOT-observed variability from an *oceanographic* perspective.

Recent studies have shown that the superposition of eddies and internal gravity waves in SSH may make the interpretation of SWOT observations complicated (Rocha et al. 2016; Qiu et al. 2018; Torres et al. 2018; Morrow et al. 2019). When considering the exploratory nature of the SWOT mission as the next-generation altimeter, it is crucially important that we use this 1-day repeat fast-sampling period, in which the satellite will overfly ground-track crossover region twice a day. The results will shed light on the connection of the SWOT SSH to the dynamics of ocean circulation beneath the sea surface (e.g., d'Ovidio et al. 2019), which is the mission's ultimate science goal for oceanography.

b. Closing the SSH budget using in situ observations

The ocean dynamics governing the large and mesoscale SSH variability have been the subject of intensive research over the past few decades, stimulated in part by satellite altimetry (e.g., Fu and Cazenave 2001). The SSH signal that has spatial scales smaller than mesoscale, however, has not yet been fully explored, largely because of lack of observations. The first task is to understand the observability of SSH at scales of ~150 km and smaller. To what level of accuracy can we close the SSH budget (formulated below) using available in situ instruments and platforms?

Integrating the hydrostatic equation $dp/dz = \rho g$ from the ocean floor to the free surface, the SSH budget equation can be written as

$$p(-H) = \int_{-H}^{\eta} g\rho(z)\, dz + p_a,$$

in which $-H$ is the depth of the ocean floor, η is the free sea surface height, p_a is the atmospheric pressure. We are interested in the temporal variability. Decomposing each term into a temporal mean (overline) and an anomaly (prime) gives

$$\begin{aligned} \overline{p}(-H) &= \int_{-H}^{0} g\overline{\rho(z)}\, dz + g\rho_0\overline{\eta} + \overline{p_a}, \\ p'(-H) &= \int_{-H}^{0} g\rho'\, dz + g\rho_0\eta' + p'_a, \end{aligned} \tag{1}$$

where ρ_0 the reference density, ρ' the in situ density anomaly, η' the sea surface height anomaly referenced to $\overline{\eta}$, p'_a the atmospheric pressure anomaly. The term $g\eta'\rho'$ is second order and neglected. $\overline{\eta}\rho'$ is implicitly included in the first term on the right hand by taking $z = 0$ at $\overline{\eta}$. The four terms in Eq. (1) represent temporal anomalies of bottom pressure, dynamic height, sea surface pressure due to the free surface, and atmospheric pressure. These terms from left to right can be assessed by bottom pressure recorders (BPR), moorings with CTDs, GPS buoys, and barometers, respectively. We test the closure of Eq. (1) using GPS, BPR, and mooring CTDs in section 4b.

Note that the dominant variability in both the bottom pressure and the free sea surface elevation is nonsteric, such as the barotropic tides. The steric component is much weaker, typically only on the order of a few centimeters.

Denote the steric and nonsteric components of the sea surface height and bottom pressure as η', η'_{ns}, p'_{bs}, and p'_{bns}, respectively. We further expand Eq. (1) into

$$p'_{\text{bs}} + p'_{\text{bns}} = \int_{-H}^{0} g\rho'\,dz + g\rho_0 s'_\eta + g\rho_0\eta'_{\text{ns}} + p'_a. \tag{2}$$

The cancellation of the nonsteric components is written as $p'_{\text{bns}} = g\rho_0\eta'_{\text{ns}} + p'_a$. After removing the nonsteric components, Eq. (2) becomes

$$p'_{\text{bs}} - g\rho_0\eta'_s = \int_{-H}^{0} g\rho'\,dz. \tag{3}$$

Equation (3) means that the dynamic height due to the density change can be calculated directly from density profiles or indirectly calculated from bottom pressure and steric sea surface height (after the atmospheric pressure correction). In reality, the steric and nonsteric components are impossible to separate from bottom pressure or GPS free sea surface based on a single mooring as a result of an underdetermined problem. Equation (3) is only used to illustrate the meaning of the closure of the SSH equation. It is worth noting that deriving $O(1)$ cm steric height from $O(100)$ cm GPS SSH and BP-derived SSH requires extreme accuracy in both instruments. For this reason, one of the objectives of the SWOT prelaunch campaigns (sections 2e and 3) was to examine the closure of the hydrostatic equation [Eq. (1)] and to quantify the errors associated with different platforms and instruments.

c. An OSSE

An OSSE was first conducted to understand the SSH signal at SWOT scales and the performance of different instruments and platforms in meeting the SWOT requirement (Wang et al. 2018). We used a tide-resolving high-resolution global ocean simulation as a virtual ocean and simulated the performance of several instruments/platforms commonly used in modern observational physical oceanography, i.e., underway CTDs (UCTD), gliders, fixed-CTD moorings, pressure inverted echo sounders (PIES). The model simulation is the high-resolution global ocean simulation using MITgcm with 1/48° horizontal resolution, llc4320, used in several recent studies (e.g., Rocha et al. 2016; Torres et al. 2018; Su et al. 2018; Yu et al. 2019). One conclusion was that in the Cal/Val region (near 35.7°N, 124.7°W) the total SSH over the 15–150 km wavelength range (SWOT scale) can be represented by the upper-ocean steric height after the large-scale barotropic signal and inverted barometer (IB) influence are removed through a high-pass filter. The residual is well below the mission error requirement shown in the error wavenumber spectrum in the OSSE study.

The OSSE study also found that internal gravity waves and internal tides (IGW) might be strong enough to mask the eddy field SSH signal over the small spatial scales and impose an observational challenge (Wang et al. 2018). This dominance of IGWs over small scales is simply because the SSH wavenumber spectrum of eddies (balanced motions) is steeper than that of IGWs (Qiu et al. 2018; Chereskin et al. 2019; Callies and Wu 2019). The presence of internal gravity wave motions on these scales poses a challenge for designing an in situ observational network. For example, through the OSSE we found that slow platforms such as ship-towed UCTD are unable to meet the Cal/Val requirement. An array of station-keeping gliders can marginally meet the requirements, but the errors are mostly over small spatial scales (~50 km) due to the high-frequency motions. PIES can empirically convert the travel time of an acoustic signal to steric height but have about 5 cm uncertainty (D. R. Watts 2016, personal communication; Wang et al. 2018), which is larger than SWOT's subcentimeter requirement. The OSSE study concluded that an array of CTD-equipped moorings could produce a steric height field that is sufficiently accurate to meet the requirement.

The numerical ocean simulation used in the OSSE, however, has excessive tidal energy (C. Wunsch 2017, personal communication; Savage et al. 2017; Yu et al. 2019), which introduces large uncertainties in the OSSE results. It is also not clear how well the deep-ocean variability is reproduced. Field experiments are necessary to test the performance of different platforms and instruments. In addition, while the OSSE focused on oceanographic Cal/Val, the geodetic SSH such as measured by GPS buoys needs to be evaluated to synthesize the oceanographic and geodetic objectives. It led to two objectives of the field campaigns: 1) quantify the performance of oceanographic in situ platforms and 2) test the GPS measurements and their relationship with those derived from hydrographic measurements.

d. SWOT measurement error requirement

In the two field campaigns described in the next section, we do not have a full-scale mooring array that enables a wavenumber spectrum calculation. To evaluate the performance of an in situ instrument, the SWOT error requirement in wavenumber space needs to be integrated over a range of wavenumbers $\int E(k)$ to assess time series in situ measurement. The mission requirement is specified between 15 and 1000 km wavelengths. The baseline error[1] is

[1] The "baseline error" is the error the mission currently plans to achieve. The "threshold error" is the error level that the mission must achieve to address the minimum science goals.

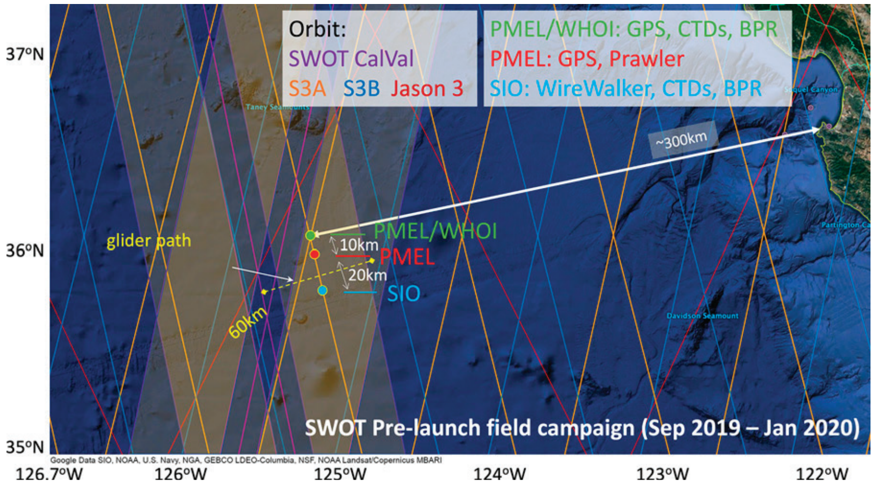

FIG. 2. Map of the field campaign instrumentation. The three moorings are marked by the three colored dots. From north to south, they are the PMEL/WHOI mooring, the PMEL Prawler mooring with GPS on the buoy, and the SIO full-depth mooring. The separation distance is 10 and 20 km. The dashed yellow line is the glider target path of 60 km wide. Two bottom pressure recorders were deployed near the PMEL/WHOI and SIO moorings.

$E(k) = 4\ \text{cm}^2\ \text{cpkm}^{-1} + 0.00125k^{-2}$, where k is the wavenumber with a unit of cycle km^{-1} (cpkm) and 2 cm^2 cpkm^{-1} is the KaRIn instrument noise averaged across a swath over 7.5 km distance for significant wave height (SWH) of 2 m (Fig. 1, red line). The threshold error requirement is similar: $E(k) = 4\ \text{cm}^2\ \text{cpkm}^{-1} + 0.0015k^{-2}$ (Fig. 1, blue line).

For the spatial range between 15 and 1000 km, an integration of the error based on the requirement is $\int_{1\times10^{-3}}^{1/15} E(k)\,dk = 1.36\ \text{cm}^2$, i.e., 1.17 cm RMS. If only the 15–150 km range is considered, the total integrated error has 0.29 cm^2 variance (0.54 cm RMS), the integrated random KaRIn noise is 0.12 cm^2 (0.35 cm RMS), and the integrated correlated error (cpkm) is 0.17 cm^2 (0.41 cm RMS). The 0.54 cm number represents a target accuracy needed for validating SSH measurements in the presence of oceanographic "noise," i.e., an upper limit for errors in observing ocean processes including those which are correlated on the scales of interest. These are the signals analyzed in this study. The 0.35 cm value is a requirement for inherent sensor/platform/sampling error at a single location that is uncorrelated from platform to platform.

The postlaunch Cal/Val approach involves calculating the wavenumber spectrum of the difference between the SWOT SSH measurement and the mooring-derived SSH during the SWOT overflight of the mooring array. A spatial linear trend over the length of the mooring array will be removed before calculating the wavenumber spectrum. This detrending operation minimizes the effects of the scales longer than those of the in situ Cal/Val. Such a difference spectrum is considered a snapshot of the measurement error spectrum, which will be averaged over the 90-day Cal/Val period to achieve statistical assessment of the SWOT performance.

Ideally, we would like to test the mooring capability using an array of moorings covering ~150 km. However, owing to the limited budget, we deployed three moorings spanning 30 km (Fig. 2). The evaluation of the mooring capability discussed in the following sections will be unavoidably influenced by the large-scale signals that are irrelevant to SWOT short-wavelength Cal/Val. It is thus difficult to rigorously define measurement requirement for a single mooring. However, from analysis of ocean model simulations (Torres et al. 2018), the temporal scales corresponding to 15–150 km wavelengths are roughly 2–14 days. We therefore impose the following for the requirement for the in situ SSH observations: Integrated over periods of 2–14 days, the RMS error shall not exceed 0.54 cm. A caveat is that this criterion is not rigorously derived due to insufficient mooring measurements and is only used as a guideline. The spatial–temporal separation can be directly calculated during the postlaunch Cal/Val where an order of 10 moorings will be deployed along a line under a SWOT swath (section 5).

e. The 2017 pilot field campaign

The first field campaign was conducted in Monterey Bay, California, during June/July 2017. Two gliders, one BPR, and a GPS buoy (Haines et al. 2017) were deployed near the Monterey Bay Aquarium Research Institute (MBARI) M_1 mooring. The two gliders sampled the upper 500 m near the mooring at 36.75°N, 122.03°W. The first objective was to quantify the capability of station-keeping gliders in constructing the high-resolution steric height derived from a fixed instrumented mooring. The second objective was to examine the connection between GPS-observed SSH that resembles spaceborne measurements and steric height that represents the ocean circulation.

The 2017 pilot campaign successfully tested the first objective, but not the second one. In particular, the results have not yet yielded satisfying closure between the GPS-derived SSH and upper-ocean steric height. The campaign took place 20 km from the shore, with the GPS buoy situated over the steep walls of the Monterey submarine canyon. One of the challenges was the large mean sea surface (geoid) gradient, which contributes to the time variation in GPS-derived SSH as the buoy meandered over the canyon wall and within the watch circle. This nearshore location was also dominated by nonsteric processes, making the site less representative of the open-ocean conditions expected near the SWOT Cal/Val crossover location. The campaign, however, shed new light on the challenges of reconciling SSH (from surface GPS or satellites such as SWOT) with steric height (from gliders and moorings), and the outcomes helped to inform the architecture of the subsequent 2019/20 prelaunch campaign reported in this paper. The next section provides the general information about this campaign.

3. The 2019/20 prelaunch field campaign

The 2019/20 prelaunch field campaign was conducted near the SWOT Cal/Val crossover location, about 300 km west of Monterey, California (Fig. 2), between September 2019 and January 2020. It was designed to mainly 1) test the closure of the SSH equation, which was not satisfactorily addressed in the 2017 field campaign, and 2) quantify the error in steric height using different platforms. There are six specific objectives: 1) test the SSH budget closure with GPS buoy, CTD mooring, and BPR following Eq. (1); 2) evaluate the vertical scale of SSH at the SWOT scales for different frequency bands; 3) evaluate the role of bottom pressure in SWOT SSH signals; 4) evaluate the small-scale steric height information; 5) evaluate the reconstruction of the upper-ocean circulation; and 6) provide information for the design of the postlaunch in situ observing system. We will mainly focus on 1–4 in this paper. The outcome will aid the design of the postlaunch in situ field campaign for SWOT Cal/Val.

Six institutions participated in the campaign: Jet Propulsion Laboratory, NOAA Pacific Marine Environmental Laboratory, Wood Hole Oceanographic Institution, Scripps Institution of Oceanography, Rutgers, and Remote Sensing Solutions. Three moorings and two BPRs were deployed between 1 and 7 September 2019, and recovered between 16 and 21 January 2020. One Slocum glider was deployed from Monterey Bay and piloted to the mooring locations around mid-September 2019.

The three moorings are 1) the PMEL/WHOI (*northern mooring*) configured with a GPS buoy and 18 fixed CTDs from surface to the bottom, 2) the PMEL GPS mooring (*middle mooring*) with a Prawler (Osse et al. 2015) sampling the upper-500-m temperature and salinity (*T*/*S*), and 3) the Scripps Institution of Oceanography (SIO) mooring (*southern mooring*) with a Wirewalker (Pinkel et al. 2011) sampling the top 500 m and fixed, real-time telemetered CTDs between 500 m and ocean floor. The mooring array was placed along a *Sentinel-3A* ground track, which fortuitously was in the middle of a SWOT swath along the Cal/Val orbit. The separation distances are 10 and 20 km for the northern and southern pairings, respectively, to support testing of small-scale SSH variability not resolved by conventional satellite altimeters. During the first phase of the campaign, the glider sampled a 60-km-long section perpendicular to the mooring line (Fig. 2) with a 1000 m dive depth, which was chosen to minimize the travel time for the 60 km section. During the second phase, the glider performed station keeping near the three moorings for cross calibration. The glider stayed at each mooring for about 5 days. The PMEL BPR is near the northern mooring and a PIES was deployed at the southern mooring location.

a. GPS measurements of SSH

A modular, low-power, high-accuracy GNSS measurement system was designed for long-term, continuous, and autonomous measurements of SSH on ocean- and cryosphere-observing platforms (Haines et al. 2017; Guthrie et al. 2020). It results from a joint project between NASA JPL, NOAA PMEL, and the University of Washington. The project aims to probe the limit of new kinematic precise-point positioning (PPP) techniques for accurately determining sea surface height and recovering neutral and charged atmosphere characteristics; and explore the potential scientific benefits—in the fields of physical oceanography, weather, and space weather—of accurate GNSS observations from a global ocean network of floating platforms. It integrates a Septentrio dual-frequency GPS receiver and a PMEL buoy. The receiver is low power (~1 W) and is accompanied by a miniaturized digital compass (for attitude information) and a load cell (to measure force on the mooring line). The buoy communicates using Iridium, and the payload is adaptable to multiple floating platforms such as surface buoys, wave gliders. When coupled with advanced precise point positioning techniques (Bertiger et al. 2010), the observations collected by the GPS buoy enable geodetic-quality solutions in remote locations without nearby reference stations.

The GPS level-2 data have 1-Hz temporal frequency, processed to accurate 3D positions using the GipsyX software (Bertiger et al. 2020) with units of meters for the height component. These high-frequency data were binned to hourly average to remove the surface gravity waves (Fig. 3). The hourly data were then corrected for an apparent systematic sea-state bias (estimated empirically), solid tides, line tension, mean sea surface (MSS), and IB effect. The MSS correction is important for comparing GPS-SSH with steric height because the horizontal displacement of the GPS buoy within its watch circle can project geoid variations into the GPS time series. This spatial-to-temporal projection is especially significant over steep bathymetry, which was the case during the 2017 field campaign, where the GPS buoy was placed near the Monterey submarine canyon and the spatial geoid variations were as large as 10 cm within the mooring watch circle of 2 km radius, but less significant over the prelaunch campaign region where ocean bathymetry is rather flat. The IB correction (Wunsch and Stammer 1997) follows IB (mm) = $-9.948p'$, where p' is the sea level pressure anomaly. The final derived SSH after the MSS and IB corrections was then detrended over the 4-month period (mid-September 2019 to mid-January 2020).

The GPS buoy system has developed from campaigns undertaken in progressively more challenging conditions.

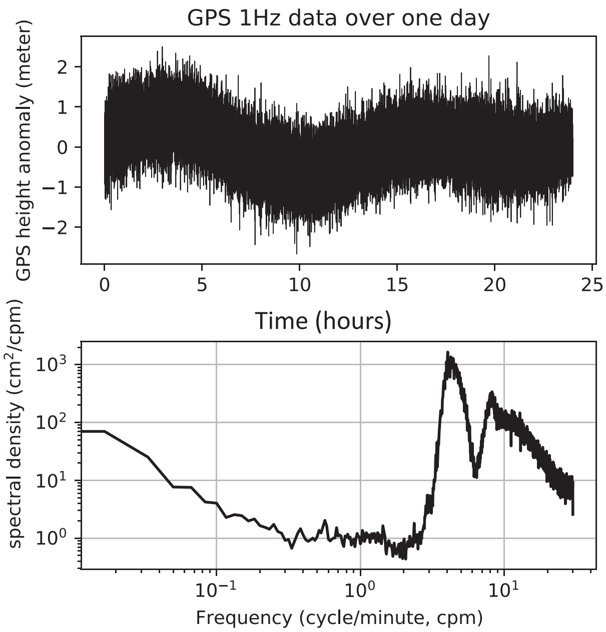

FIG. 3. (top) The 1-Hz GPS measurement of SSH. (bottom) The frequency spectrum of the 1-Hz GPS SSH.

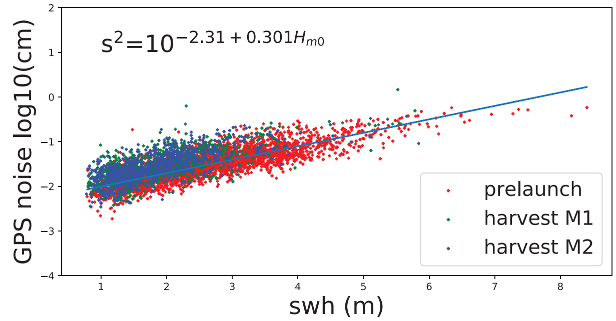

FIG. 4. The GPS error as a function of SWH derived from two SWOT prelaunch field campaigns described in section 2. The red dots are from the 2019 prelaunch field campaign and the green and blue dots are from the two GPS buoys of the 2017 pilot field campaign.

Nearly 1000 buoy days of data have been successfully collected since 2015, over SWH ranging from calm to 9 m. The GPS buoys have been an integral part of the SWOT pilot experiment in 2017 (Monterey Bay) and the prelaunch field campaign (2019/20). An example of the processed 1-Hz data is shown in Fig. 3. The 1-Hz sampling frequency is high enough to reveal detailed expressions of surface waves. The amplitude of the high-rate (1-Hz) height estimates reach 5 m for this day. The frequency spectrum illustrates the wind wave and swells by the two spectral peaks. SWH can also be derived from this 1-Hz data following SWH = 4 × RMS(SSH), where SSH is high-pass filtered with a cutoff frequency of 1 cycle min^{-1}.

We tried to estimate the GPS measurement errors in the context of the SWOT requirements. Without a true reference, we need to make assumptions in order to derive the error from the GPS measurement itself. We assume the minimum in the spectrum near 1 cycle min^{-1} reflects random instrument noise. As we are interested in ocean signals that are of periods longer than 1 h, the GPS error can be estimated by integrating the random noise spectrum, assumed constant taken as the value of the spectrum minimum near 1 cycle min^{-1}, over the frequency range (0–1 cycle h^{-1}). The SWH can be derived from the surface wave spectrum. We can split a long time series into 1-h-long segments, then derive an empirical relationship between GPS error and SWH. Based on the two SWOT prelaunch field tests, there is a clear relationship between SWH and GPS errors following a logarithmic function as shown in Fig. 4. The relationship is $S^2 = 10^{-2.31+0.3H_{m0}}$, where H_{m0} represents the SWH, and S^2 is the noise variance. Under these assumptions, the GPS error from a single buoy meets the SWOT mission geodetic requirement, i.e., 0.13 cm^2 for SWH < 4.1 m, which corresponds to 2 cm^2 cpkm^{-1} instrument noise in the wavenumber space (Fig. 1).

Other errors exist in addition to those induced by the surface waves. Those errors are correlated but difficult to unravel with a single GPS buoy. They will contribute to the total error presented in section 4. Residual atmospheric refraction delays are one of the dominant correlated error sources. As the ionospheric refraction is corrected to first order using the two GPS frequencies, the primary concern here is refraction from the troposphere. Taking advantage of mapping functions, the wet troposphere delay in the zenith direction is estimated along with the buoy position. Despite the relatively small magnitude, the wet component of the troposphere delay is highly variable and sometimes difficult to capture, especially during intense weather fronts with large atmospheric gradients. Other important systematic errors for the buoy technique are related to the platform altitude and to the force on the mooring line, both of which impact accurate modeling of the buoy's waterline and thus the SSH (Zhou et al. 2020). Here we use, respectively, the digital compass and load cell data from our payload package to mitigate these errors.

b. Hydrographic measurements

1) MOORINGS WITH FIXED-DEPTH CTD INSTRUMENTATION

The fixed-depth CTD mooring is one of the most conventional in situ platforms for observational oceanography. The CTDs used in the campaign are the Sea-Bird Electronics, model SBE-37. The SBE-37 can be configured with and without a pressure sensor. The pressures for those instruments without the corresponding sensors (from the northern mooring) were determined through interpolating from the next instruments above or below, using the known wire lengths between the instruments. For these fixed-depth CTDs, the distances between instruments along the mooring line are fixed, but the actual depths of the CTD instruments change over time. The amount of vertical excursion depends on the currents and winds as well as the mooring design: the northern mooring was a "slack mooring" (i.e., mooring line much longer than water depth) of an inverse catenary design with vertical sensor excursions up to about 300 m, while the southern mooring had a taut lower section that limited vertical excursions to about 60 m. The nominal depths of the fixed CTDs are (505, 618, 810, 1182, 1690, 2365, 3202, 4384) m on the southern mooring and (20, 30, 59, 107, 174, 261, 367, 492, 609, 805, 1180, 1408, 1692, 1909, 2189, 2488, 2750, 4545) m on the northern mooring.

A climatological mean in situ density profile is removed before the density anomalies are interpolated onto a uniform vertical grid to avoid interpolation error in calculating steric height. We have also used the mean profile constructed from all the measurements in the campaign instead of the climatological mean. No quantitative difference is observed. This procedure removes the spurious deep-ocean variability introduced by the vertical-to-temporal projection due to the vertical movement of the CTD sensors. The bottom CTD on the northern mooring was corrupted so the full-depth steric height was calculated with the assumption that the ocean below 3000 m has no temperature and salinity variability.

2) MOORINGS WITH PROFILERS

Two moorings had profilers with CTD instruments. The middle mooring had a Prawler that covered the upper 500 m with a Sea-Bird Electronics (SBE-PRAWLER) CTD, and the southern mooring had a Wirewalker in the upper 500 m with an RBR Concerto CTD. Profiling methods are not subject to errors due to vertical resolution, but the temporal resolution is less favorable. The Prawler was set to 8 profiles per day on average during the 2019/20 campaign. The number of profiles per day can be higher, but was chosen to test the endurance of the Prawler mooring. The Wirewalker on the southern mooring yielded about 80 up- and downcast profiles per day (i.e., ~7000 profiles, or 3500 vertical kilometers profiled over 86 days of deployment). The profiler CTDs pass through vertical gradients of temperature and conductivity in the upper ocean, which requires data processing to remove spikes in salinity, and to adjust for lagged sensor responses. After this alignment, vertical profiles of density with 1 and 0.25 m vertical resolution over the upper 500 m are produced for the Prawler and Wirewalker, respectively.

Below the profiler, the southern mooring featured additional, vertical fixed instrumentation. It used a taut mooring between the seafloor and 600 m, connected to the surface buoy via a reverse catenary inductive connection and the Wirewalker profiling wire. The taut mooring has a very small watch circle (<250 m) and so the fixed instruments stay within a narrow depth range. The inductive connection allowed real-time data from the fixed instruments all the way to the seafloor. This experimental mooring design is less tested, and the catenary wire parted after 86 days of the intended 90-day deployment.

3) UNDERWATER GLIDERS

The hydrography data collected by the gliders are similar to the moored profilers. Vertical resolution is high and requires no additional interpolation steps, although the same precautions against mismatched sensor response times and resulting spikes in salinity data need to be taken. Gliders have the advantage of mobility, but they may experience large horizontal deviation from target locations due to strong currents. A station-keeping glider can act as a virtual mooring. A glider that performs station keeping at different mooring locations can also be used for cross-mooring calibration and validation. The Slocum glider used in this campaign has a vertical speed of about 18–20 cm s^{-1} yielding ~30 profiles per day for 500 m dives.

4) APPROACH TO CALIBRATION AND VALIDATION OF CTD DATA

An effort was made to cross calibrate all CTD data to a common reference. For the fixed-depth, moored CTD instruments, this was done by attaching the mooring instruments to a recently calibrated, ship-based CTD and Rosette system, and then collecting vertical profiles with 10 min stops at several depths. At these dwell depths, water samples were taken for laboratory salinity measurements to provide an absolute salinity reference. This approach was carried out for mooring instruments both before mooring deployment and after mooring recovery. The method is described by Kanzow et al. (2006), and has the key advantage that all three sensors (conductivity, temperature, pressure) are adjusted independently of one another. Over the course of the mooring deployment, the corrections applied to the mooring data are shifted linearly from the predeployment to the postrecovery values. For temperature data, the adjustments are offsets added to the raw data. For conductivity data, the adjustments are gain factors multiplied by the raw data. For pressure data, the adjustments are a combination of a gain factor and an additive offset (Kanzow et al. 2006).

The glider was flown to the vicinity of each mooring on several occasions. A comparison of the glider data against the fixed-depth, cross-calibrated moored CTDs was used to adjust the glider conductivity with a gain factor, such that the temperature–salinity curves derived from the glider would best match those from the nearby mooring. This assumes that the glider temperature and pressure sensors are correct.

For the two moored profilers, two different approaches were done: The Prawler conductivity data were adjusted against the (adjusted) glider data, based on nudging the conductivity such that the temperature–salinity curves would be matched. For the Wirewalker on the southern mooring, a spare fixed-depth instrument that had the ship-based corrections was attached to the profiling body. The profiler conductivity was nudged against the data from this collocated instrument, again to best match the temperature–salinity relationship, but the comparison was restricted to deeper depths because the fixed-depth instrument does not have a sensor response time suitable for the upper-ocean profiles. For both moored profilers, the result is that the conductivity data are adjusted, while the temperature and pressure data are assumed correct, as for the gliders.

c. *Ocean bottom pressure*

There were two ocean bottom pressure instruments: the northern one was a system based on the DART tsunami detection technology (Meinig et al. 2005), and the southern one a PIES (pressure-sensing inverted echo sounder) (Watts and Rossby 1977). The actual pressure sensors are identical in the two systems (Paroscientific Digiquartz) that are operated at about 15-s acquisition times. The DART-based systems operate nearly continuously, while the PIES have a 10-min sampling interval. When subsampling a near-continuous DART-like record at 10-min resolution, hourly averages can be reproduced to about 0.5 mm accuracy. Availability of the data in near–real time depends on the available underwater communication systems, which typically operate acoustically at low bandwidth. For PIES, hourly data were telemetered on an irregular schedule during the 2017 field campaign, typically with several days' latency. The data transfer uses the nearby glider as a communication device. The northern ocean bottom pressure data were telemetered four times per day during the 2019/20 field campaign using an acoustic modem.

The absolute magnitudes of the pressure data are not particularly useful in the context of SWOT Cal/Val, for two reasons: first, calibration uncertainties typically result in offsets to the data, which are not constant but drift with time; second, the exact depths where the sensors are on the seafloor are not known, i.e., one cannot assign a known vertical coordinate to the data. Therefore, a time mean that includes sensor drift is subtracted from the record. Following Eble and Gonzalez (1991), the preferred trend removal involves the sum of an exponentially decaying function and a linear trend. The variability in the residuals is then dominated by tidal signals. From comparing different tide removal algorithms, such as harmonic fits with different tidal constituents as well as low-pass filters of the data, coherent tidal signals can be removed.

d. *Auxiliary datasets*

GPS measures total SSH, so it is the closest equivalence of SWOT SSH. GPS SSH and SWOT SSH will share the same MSS and IB corrections. For the MSS correction, we used an MSS height model (MSSCNESCLS19), which is based on all available radar altimeter data (Schaeffer et al. 2018) with 16–20 km spatial resolution. The hourly ERA5 atmospheric pressure (Copernicus Climate Change Service 2017; Hersbach et al., 2020) used for IB correction and the gridded DUACS-DT2018 L4 SSH product (Pujol et al. 2016; Taburet et al. 2019) and *Sentinel-3A* L2P data are provided by Copernicus Climate Change Service (2017).

4. Results

a. *Large and mesoscale background during the campaign*

The campaign was conducted in the California Current system, a typical eastern boundary current system that comprises a wind-driven coastal upwelling and equatorward surface current. It is one of the best-studied and longest-observed regions in the world oceans (e.g., Hickey 1979; Flament et al. 1985; Ikeda and Emery 1984; Capet et al. 2008a,b; Collins et al. 2013; Rudnick et al. 2017; and many others). The coastal upwelling driven by the equatorward alongshore wind during summer brings cold waters to the surface (Fig. 5d), which introduces strong thermal fronts next to the warmer open ocean to form a southward California Current. This upwelled water also contains abundant nutrients to support the dynamic ecosystem indicated by the high chlorophyll concentration (Fig. 5e).

Mesoscale and submesoscale eddies are ubiquitous in the California Current System (CCS). The cold coastal water often pinches off from the coastal current and drifts westward into the open ocean supporting the coastal–open-ocean exchange of water masses (e.g., Strub and James 2000, among numerous others). Meanwhile, this offshore transport of mass and heat is balanced by the onshore transport of the deep open-ocean water that feeds the upwelling and the horizontal onshore transport by mesoscale and submesoscale eddies.

During the period of the 2019/20 prelaunch field campaign, the mooring array observed the formation of a warm-core anticyclonic mesoscale eddy. The process started from a southward flow meander at the beginning of the campaign around early September 2019 (Fig. 5a). The meander started to stretch and fold, a typical evolution of baroclinic instability, during October 2019 (Fig. 5b), which eventually detached from the initial meander to form a coherent mesoscale eddy near the end of the campaign (Fig. 5c). The mature mesoscale eddy trapped the warm, nutrient-scarce open-ocean water and drifted shoreward to resupply and mix with coastal water. During this evolution, the three moorings were within the meander at the start of the deployment and on the edge of the formed eddy by the end of the deployment. From the mesoscale perspective, then, the observations during the campaign were skewed toward ocean dynamics of a meander and the edge of a mesoscale eddy in CCS. Detailed in-depth analyses of the underlying mesoscale dynamics are not a focus of this paper and will be reported elsewhere.

b. *SSH closure*

As discussed in section 2b, one can derive an equivalent full-depth steric height from GPS, BPR, and atmospheric pressure through the hydrostatic equation. The derived full-depth steric height is then compared with the steric height derived from hydrographic measurements through mooring CTDs. Their differences contain the errors in both GPS-derived and CTD-derived steric heights.

Figure 6 shows the hourly steric height derived from GPS/BPR (red) and 6-min-resolution steric height from hydrographic measurements (blue). The top panel shows the full-time series for four months. The bottom panel shows the details of the time series over a 10-day period. The two independently derived steric height time series agree over low frequencies (top panel) and over major tidal frequencies (bottom panel). Note that the barotropic tides are eliminated by the difference between the GPS SSH and BPR-derived SSH, leaving the residuals at tidal frequencies, the baroclinic internal tides.

The total RMSE between the two derived steric heights is 2 cm, but they also depend on the sea state as shown by the single GPS analyses (Fig. 4). To our knowledge, this is the first demonstration that the GPS-/BPR-derived sea surface height is equivalent to the steric height measured concurrently in

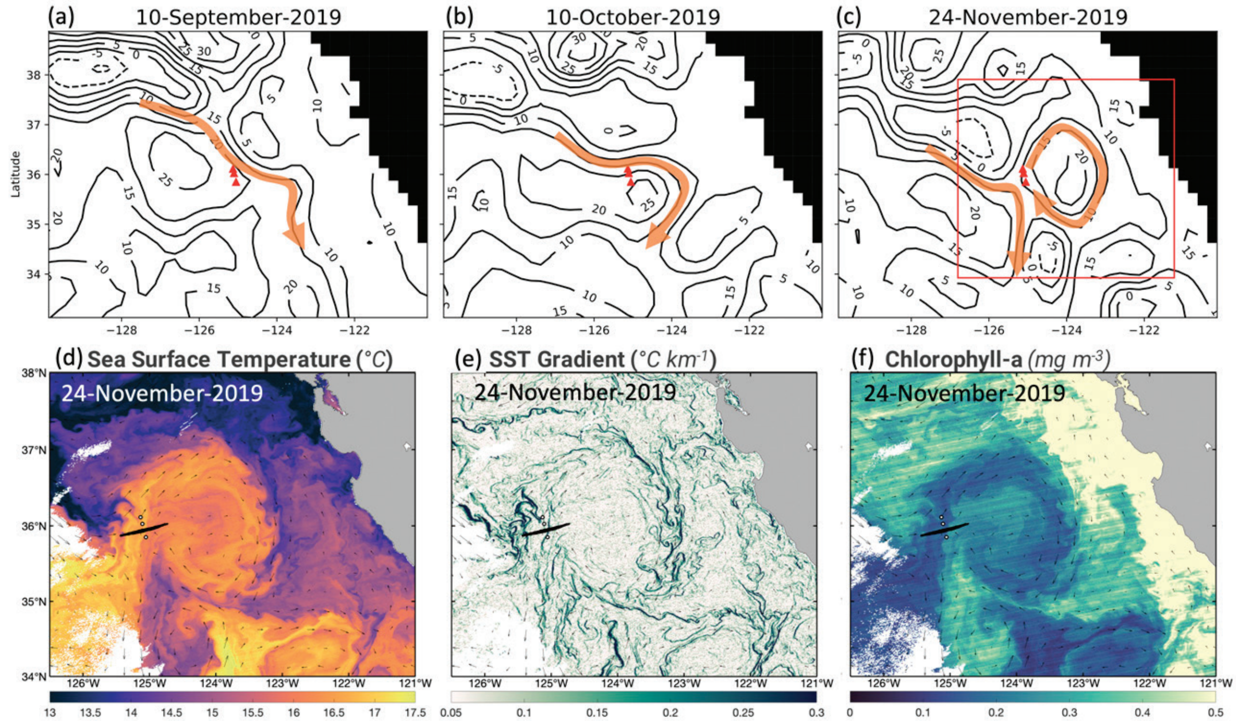

FIG. 5. (a)–(c) The altimetric sea level anomaly (SLA) on 10 Sep, 10 Oct, and 24 Nov 2019 corresponding to the beginning, middle, and end of the campaign, respectively. The thick orange arrows show the pinch-off of mesoscale eddy from the meander of the California current. The three red triangles mark the three mooring locations. The red box in (c) marks the domain boundary for (d)–(f) he SST and surface chlorophyll-a after the eddy formed approximately on 24 Nov (an ascending 750 m resolution swath from VIIRS *Suomi NPP* L2 taken at 2100 UTC). The black lines (60 km long) in (d)–(f) mark the glider flight path.

situ, indicating that the GNSS GPS system is accurate enough to measure the oceanic baroclinic signals.

The difference between the two steric height time series is further binned into different sea states characterized by SWH. As expected, the RMS difference between the two is a function of sea state (Fig. 7). The RMS difference is about 1 cm for calm seas with SWH < 1 m, 1.7 cm for SWH = 2 m, and 3 cm for SWH > 6 m. These GPS errors may be of large scale and not contribute to 15–150-km-scale errors that are of primary interest here. Detailed discussions are given in section 5.

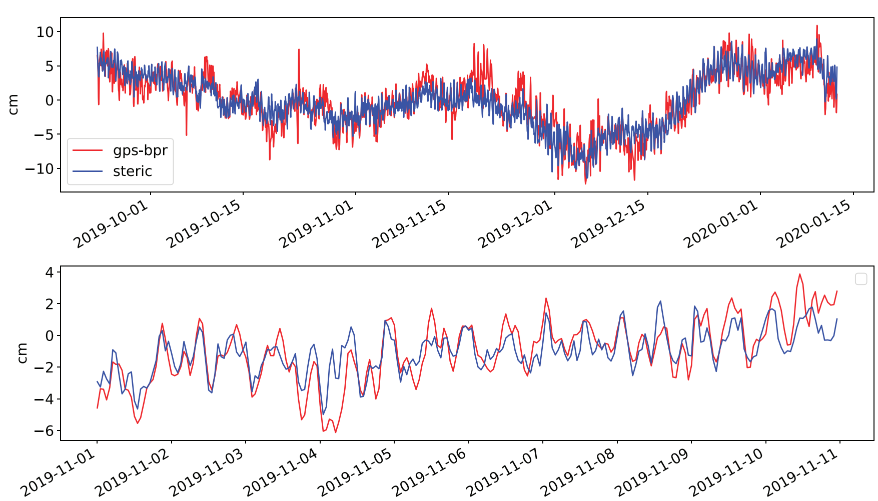

FIG. 6. (top) The steric height from the hydrographic measurements (blue) and the GPS-BPR-derived dynamic SSH. (bottom) As in the top panel, but for a short period (10 days).

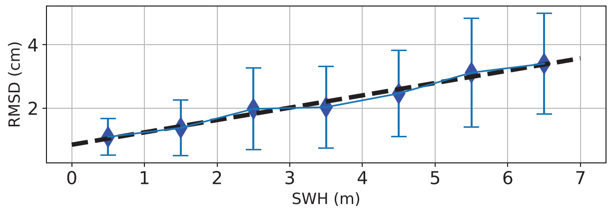

FIG. 7. The RMS difference (RMSD) between the steric heights derived from GPS/BPR and mooring CTDs as a function of significant wave height (SWH). The diamond symbols represent the mean RMSD binned to SWH values with a 1 m bin width. The error bars show the standard deviation of the absolute difference as an uncertainty measure. The line is the linear fit to the mean following RMSD=0.84 + 0.4SWH (cm).

The difference between GPS-derived and CTD-derived steric height can be scrutinized in frequency space, where we may identify the error sources. The GPS-based and CTD-based steric heights match at low frequencies with equal power spectral density within the 95% uncertainty bounds (Fig. 8). The major difference starts to show for periods less than 10 days, except for several major tidal periods such as M_2 and M_4 where the spectral peaks and coherence are significant. This is visible from the time series in Fig. 6. It is interesting to note that the coherence is high at 7.6-h period, which corresponding to the frequency of nonlinear interaction between inertial motions and semidiurnal tide denoted fM_2 (Mihaly et al. 1998).

The amplification of the differences over short periods less than 10 days is not fully understood, but could be related to the cadence of weather systems. The largest dispersions are sporadic in time (Fig. 6) and have a linear relationship with sea state (Fig. 7), and could also reflect refraction errors for the GPS systems. Errors in CTD-derived steric height exist but should not be a function of sea state and are less likely to be the dominant error source. The major difference between red and blue lines in Fig. 6 probably arises from the GPS-derived steric heights, which reflect not only GPS errors but also the errors in the IB correction through ERA5 and errors from MSS uncertainties. However, these errors may well be of large spatial scales that are less relevant to the SWOT in situ Cal/Val focus in this region (<150 km; Wang et al. 2018). If the GPS and IB related uncertainty/errors have large spatial scales, they can be removed through a spatial high-pass filter or simply by removing a linear trend along a 150 km distance as done in Wang et al. (2018).

c. *The vertical scale*

To minimize the cost of the postlaunch in situ Cal/Val, we may need to tolerate some uncertainties due to missing direct

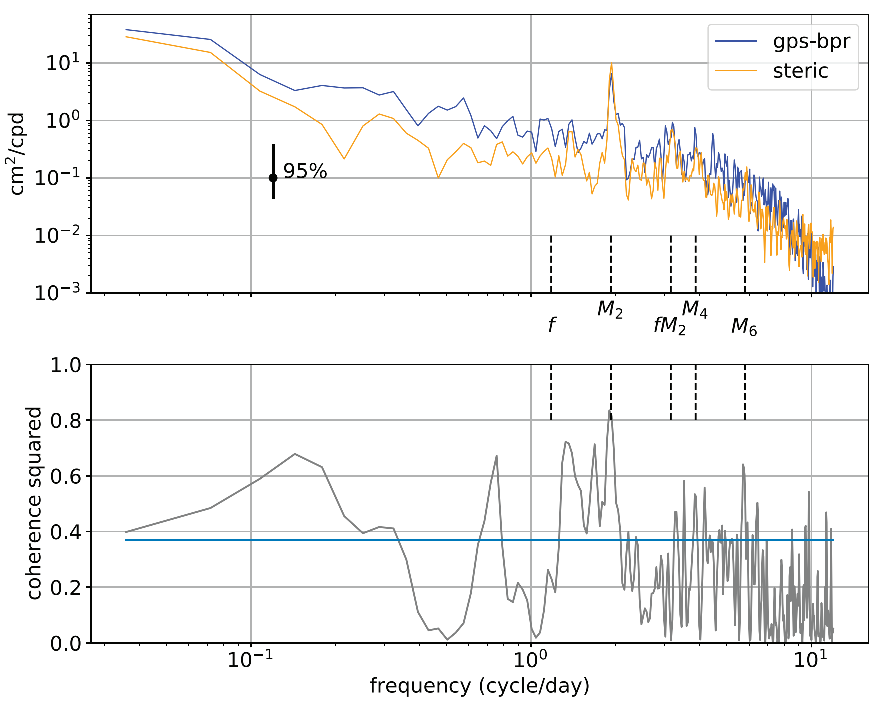

FIG. 8. (top) The frequency spectrum of the full-depth steric height (orange) [right-hand side of Eq. (3)] and the GPS-derived dynamic SSH (blue) [left-hand side of Eq. (3)]. The spectra are calculated using the Welch method with four nonoverlapped segments giving a degree of freedom (DOF) of 8. A Hanning windowing and linear-detrend operation were applied. The 95% significance level with DOF = 8 is shown by the black vertical bar. (bottom) The magnitude-squared coherence between the two time series using the Welch method with the same number of segments and DOF. The blue horizontal line marks the 95% significant level with DOF = 8.

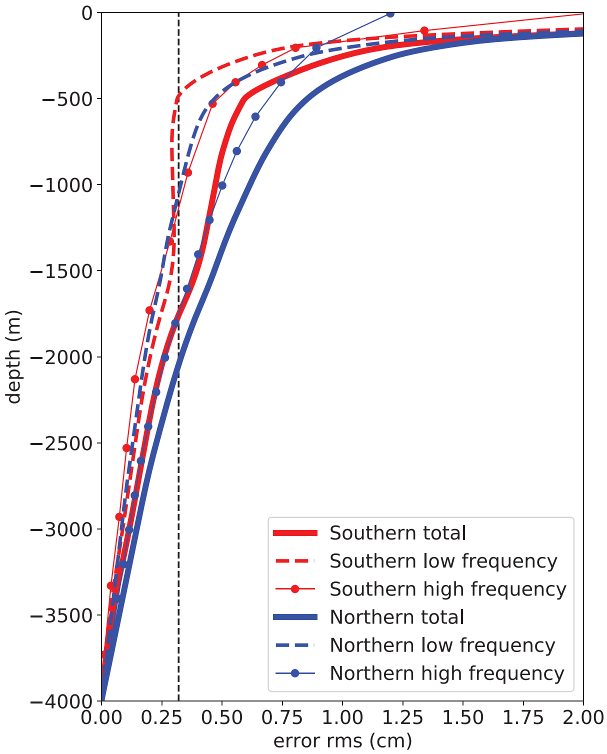

FIG. 9. The RMSE $\epsilon(z)$ of the upper-ocean steric height relative to full-depth steric height as a function of integration depth. Because the bottom CTD on the northern mooring was corrupted, we chose 4000 m as the deep-ocean reference for both moorings. By definition, the error decreases when the integration depth gets deeper and reaches zero at the bottom (4000 m in this case). The southern mooring is shown in red and the northern mooring in blue. The thick solid lines are for the total signals, the dashed lines for low frequency (>48 h), and the thin solid–dot lines for high frequencies (<48 h). The black dashed vertical line marks the 0.32 cm RMS level, which is derived from 2 cm^2 $cpkm^{-1}$ wavenumber spectrum noise level for stations separated by 10 km.

measurements of the deep ocean. How deep do we have to measure the ocean to generate a steric height accurate enough for SWOT Cal/Val?

The uncertainty introduced by missing deep-ocean measurement below a depth z is defined as the steric height integrated between ocean bottom and z:

$$\eta_{\mathrm{deep}}(z) = -\int_{-H}^{z} \frac{\rho'(z')}{\rho_{\mathrm{ref}}} \, dz',$$

where ρ' is the in situ density anomaly deviation from a time-mean density profile $\overline{\rho}(z)$, and ρ_{ref} is the mean in situ density (set to 1035 kg m^{-3} here). We quantify the uncertainty using the standard deviation of this deep-ocean steric height $\epsilon(z) = \mathrm{std}[(\eta_{\mathrm{deep}}(z))]$.

The results based on the northern and southern mooring are shown in Fig. 9. The $\epsilon(z)$ decreases toward the deeper ocean as defined but with a larger rate in the southern mooring (thick red) than the northern mooring (thick blue). The different vertical scales between the northern and the southern moorings may be caused by different dynamic regimes experienced by the two moorings. The 500 m depth is of particular interest because that is roughly the bottom depth of the Prawler and Wirewalker platform. Table 1 lists some relevant numbers about the errors $\epsilon(500)$. The total error $\epsilon(500)$, i.e., the error of missing the deep ocean below 500 m, is 0.61 ± 0.1 and 0.84 ± 0.17 cm for the southern and northern mooring, respectively. The errors represent the mean RMS and the standard deviation in a time series of $\epsilon(500)$ calculated based on segments of a 10-day duration subsampled from either the original or the filtered time series. The error amplitude changes over time. Most of these errors come from high-frequency processes with periods less than 2 days (we will use the format $T < 2$ d hereafter). They are 0.51 ± 0.06 and 0.67 ± 0.14 cm for the southern and northern moorings, respectively. The low-frequency (2–14 d) component on the other hand has errors less than 0.15 ± 0.1 cm for both moorings, accounting for less than 4% of total variance (Table 1). The deep-ocean (<−500 m) steric height has a 0.5–0.7 cm RMS values and accounts for 5% of the full-depth steric height for high frequencies with periods less than 2 days at the southern mooring. This ratio becomes 30% at the northern mooring. The northern mooring particularly presents a higher deep-ocean high-frequency variability. The causality cannot be confirmed without more independent observations. It may be caused by the topographically generated deep-ocean internal tide/wave signal that is strong for the northern mooring, or simply because of the errors in determining the depths of the deep CTDs, which have large vertical excursions.

The spectrum of the upper-500-m steric height and the full-depth steric height and their coherence are shown in Fig. 10. We used the Welch method with a Hanning window. The full time series is split into nonoverlapping segments. The steric heights of the upper 500 m (blue) and of the full depth (orange) agree well over subinertial frequencies with similar spectra density and high coherence for both moorings. The major difference comes from the superinertial frequencies, especially around the tidal frequencies at M_2 (and M_4 for the southern mooring). The errors are relatively high (green lines) but the coherence (red lines) is still large and significant

TABLE 1. Deep-ocean contribution to steric height ϵ(500 m) for the two moorings at different frequency bands. This represents the error by only measuring the upper 500 m.

	Total RMSE (cm)	2–14-day band (cm)	Variance percentage (2–14 days) (%)	High frequency (<2 days) (cm)	Variance percentage (<2 days) (%)
Southern	0.61 ± 0.1	0.14 ± 0.1	1	0.51 ± 0.06	5
Northern	0.83 ± 0.17	0.15 ± 0.07	3.4	0.67 ± 0.14	31

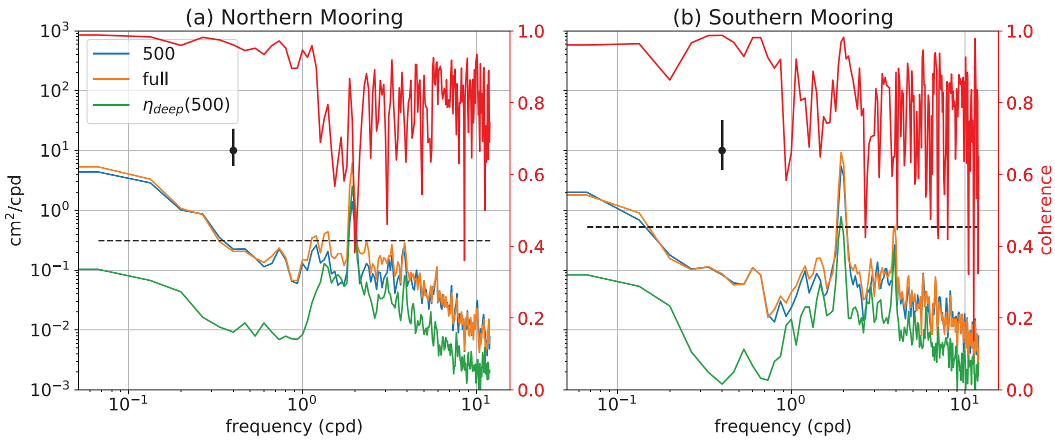

FIG. 10. The frequency spectra of 500 m (blue) and full-depth (orange) steric height and their difference (green) and the magnitude-squared coherence (red). The difference (green) is $\eta_{\text{deep}}(500)$. The spectra were calculated using Welch with nonoverlapping segments, each of which is of 15-day duration. The black error bar represents the 95% confidence interval. The degrees of freedom are 10 for the southern mooring and 18 for the northern mooring (due to its longer duration). The 95% significance level of the magnitude-squared coherence is shown by the dashed line: 0.31 and 0.53 for the northern and southern moorings, respectively.

(above 95% confidence level) for both moorings. This reflects that the superinertial motions, especially the semidiurnal internal tides, are of low baroclinic mode and reach deeper in depth than the subinertial submesoscale and mesoscale motions. [see also Lapeyre and Klein (2006) and LaCasce and Mahadevan (2006)].

The errors presented in this section include all spatial and temporal scales. Because of the SWOT focus on scales smaller than the mesoscale, correlated mesoscale scale error among the moorings can be removed, yielding a much smaller residual error budget. The high-frequency deep-ocean steric height with periods less than 2 days has 0.5–0.7 cm RMS and mostly from baroclinic tides (Fig. 10). If only the subinertial motions (2–14-day period) are considered, missing deep ocean introduce less than 2 mm error (Table 1), which is well below the KaRIn measurement error (0.54 cm RMS). These deep-ocean high-frequency signals require deep-reaching mooring CTDs.

d. Station-keeping glider as a virtual mooring

Gliders, unlike moorings, are mobile and add more flexibility to the campaign. We had one Slocum glider in the 2019/20 campaign for 1) testing the performance of a data assimilation system (Archer et al. 2022) and 2) testing the glider as a virtual mooring for the contingency of a failed mooring.

The glider vertical trajectories generally straight lines underwater, proceeding in a single direction fixed to a magnetic heading. This heading can be chosen to correct for ocean currents if one wishes to hold sampling lines. The downside of a single trajectory underwater means larger errors in station keeping and thus the ability to remain close to a single location. This is because of large distances traversed horizontally underwater, especially while diving deep.

To compensate for this and maintain a fixed position, the glider must have the ability to change heading underwater. It achieves this by maintaining a course of waypoints underwater which can be in any shape, for instance, a square, triangle, or even back and forth with two waypoints. Built into the underwater positioning is an algorithm to correct for estimated depth averaged current. This allows the underwater vehicle to continuously correct for current and maintain the same positions on Earth underwater for periods of several hours or more.

The Slocum glider's dive speed is about 18–20 cm s^{-1} yielding ~45 min per profile for a diving depth of 500 m. This will produce about 30 profiles a day. The capability of a station-keeping glider has been tested in our OSSE study (Wang et al. 2018) and the 2017 field campaign (Clark et al. 2018), where we confirmed that the glider-derived steric height matches the upper-ocean steric height from a nearby mooring for periods longer than 6 h with error-to-signal ratio smaller than 0.5 (figure not shown).

We tested the glider's station keeping again in the 2019/20 campaign and also used the glider as a conduit to connect and test the three moorings. The Slocum glider performed station keeping near the three moorings for three weeks between 27 November and 17 December 2019. The relative location of the glider flight path to three moorings are shown in Fig. 11. The glider stayed for about 3, 5.5, and 6.5 days around the southern, middle, and northern moorings, respectively. The associated mean glider–mooring distances are 1.2 ± 0.2 km, 0.8 ± 0.4 km, and 0.9 ± 0.2 km from south to north. The clusters of the glider surface locations have smaller circles referenced to its own center. The circles have a radius of 233, 350, and 520 m from north to south, respectively. The horizontal spread of the glider surface locations has a comparable size to the watch circle of the southern mooring during this period. A larger spread of the glider paths is expected for a longer duration and/or in a stronger flow field.

The Slocum glider's capability of being a virtual mooring was validated again in this campaign. The RMS difference

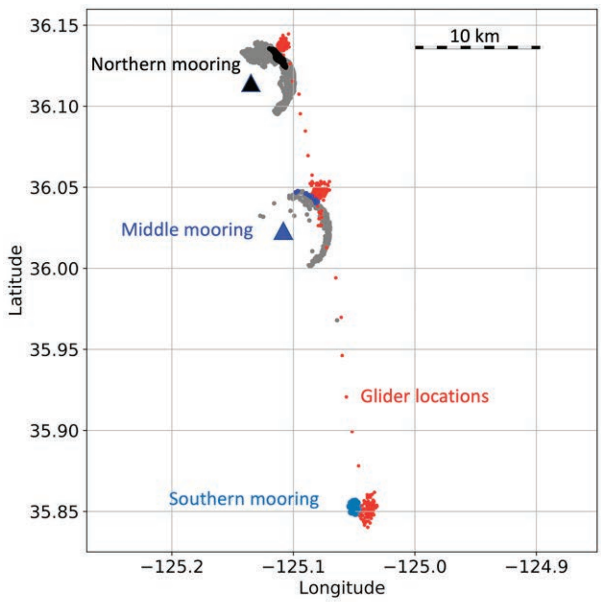

FIG. 11. The locations of the glider (red) and the northern mooring (black), the middle mooring (blue), and the southern mooring (navy blue) during the glider station-keeping phase, 27 Nov–17 Dec 2019. The mean separation distances during station keeping phase are 0.9 ± 0.2, 0.8 ± 0.4, and 1.2 ± 0.2 km for the northern, middle, and southern mooring, respectively. The two triangles show the anchor locations of the middle and northern moorings. The mooring watch circle shown by the gray dots has a radius of 4.5 km.

between glider and mooring upper-ocean (500 m) steric height is about 0.4–0.5 cm. Figure 12 (top panel) shows the time series of the upper-500 m steric height calculated from the glider (blue lines) and the moorings (orange lines). To avoid temporal interpolation errors, we used individual profiles to calculate the steric height without temporal interpolation between the subsurface temperature and salinity profiles. The time associated with the steric height of each profile was taken from the time at 250 m depth.

Figure 12 shows that the upper-500-m steric heights from glider and moorings are closely matched. The RMS differences are 0.4, 0.48, and 0.45 cm for the northern, middle, and southern mooring. The northern mooring has fixed CTDs binned to a 6-min grid close mooring–glider match confirms the capability of gliders to reproduce the upper-500-m steric height to time scales of several cycles per day.

The comparison of the glider to the northern mooring has the least RMS difference. The middle mooring was equipped with a Prawler, similar to a Wirewalker on the southern mooring, but was configured to sample about 8 profiles per day to test the endurance of the mooring. The larger RMS difference is mostly caused by the low temporal resolution (8 profiles per day) in mooring steric height (orange line/symbol in the top-center panel of Fig. 12). Because of the low temporal resolution, the middle mooring undersampled the internal tides especially the peaks that were captured by the glider. For example, the internal tidal variance at the beginning of 12 May 2019 is captured by the glider but not by the mooring (Fig. 12, top-center panel). This indicates the insufficiency of 8 profiles per day sampling frequency.

For the southern mooring comparison (top-right panel), there are superinertial variabilities in the mooring steric height largely captured by the glider except for the tidal peaks on 29 November. The glider dived to 1000 m at this location, so the temporal resolution is half that of the 500 m dives. The resulting lower temporal resolution in the glider steric height introduces an RMS difference 0.45 cm, which is larger than the 0.4 cm at the northern mooring. The time series comparison indicates that mapping the SSH variability due to the internal wave displacement of the density structure of the upper 500 m requires around 24 profiles per day. The spectral and coherence analyses shown in the bottom panel of Fig. 12 confirm the direct visual examination of the steric height time series discussed above. The glider steric height matches the northern mooring steric height in spectral density (bottom left, blue and orange lines) with high coherence (>0.6) down to approximately 5–6-h period (bottom left, purple line). For the middle mooring, because of the low temporal resolution in the mooring steric height, the glider–mooring only matches up to the M_2 tidal frequency, so ~8 profiles per day can resolve M_2 tides but not supertidal variabilities. For the southern mooring location (bottom-right panel), the mooring and glider match with high coherence (>0.6) down to a 6-h period.

In summary, the steric height derived from the glider matched the mooring upper-500-m steric height with 0.4–0.5 cm RMS difference. This largely validated the capability of gliders as a virtual mooring in the Cal/Val region with one caveat that the glider's error is referenced to the mooring's upper-ocean steric height, which itself carries about 0.6 cm uncertainty. Even though this uncertainty can be reduced by nearby deep-reaching CTD moorings with instruments in the deep ocean, the added uncertainty should be emphasized in a contingency scenario that a glider is needed to substitute a failed mooring.

e. *Spatial and temporal variability*

Each mooring produces a steric height time series. We can examine the temporal and frequency content of the signal. The spatial–temporal variabilities can be examined by combining the three moorings separated at 10 and 20 km even though a full wavenumber spectrum cannot be calculated across so few mooring separations.

1) TEMPORAL VARIABILITY

In the time domain, the mooring upper-500-m steric height closely follows the gridded SSH over long periods. Figure 13 shows the direct comparison between AVISO and the steric height of the northern and southern moorings (black solid and dashed lines). At the beginning of the campaign in early September 2019, the mooring steric heights and altimetric SSH are all at about approximately 76 cm level. This is associated with a south–north meandering current, whose SSH gradient is largest east–west perpendicular to the mooring array (Fig. 5a). When the meander curved toward the coast to form

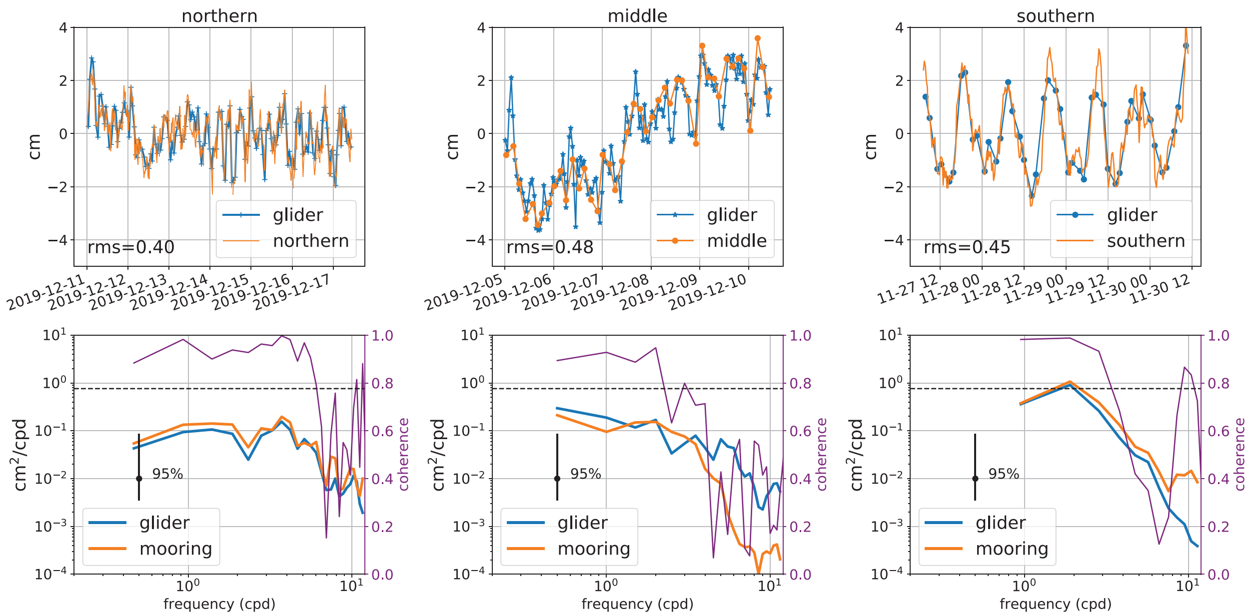

FIG. 12. (top) The upper-500-m steric height reconstructed from the glider (blue lines) and moorings (orange lines). (bottom) The frequency power spectral density for the glider (blue) and moorings (orange). The black vertical lines show the 95% confidence interval with 4 degrees of freedom (three nonoverlapping segments). The magnitude-squared coherence is shown in purple with the y axis on the right and the associated 95% confidence level marked by the dashed lines(left to right) The northern, middle, and southern moorings. The duration of the station-keeping phase was longest at the northern mooring (6.5 days) and shortest at the southern mooring (3.5 days).

an isolated mesoscale eddy during the eddy formation, the flow turned zonal (Fig. 5b) and the SSH differences between the three moorings can be as large as 10 cm between the southern and northern moorings, for example, at the end of October 2019 (Fig. 13, top panel). Near the end of November 2019, when the eddy was finally formed and detached (Fig. 5c), the meander regained its original north–south orientation with isolines oriented along the direction of the mooring array, resulting in a minimal SSH difference among the moorings. This eddy development can be seen from both altimetric SSH and mooring steric height, but the two-dimensional altimetric SSH field reveals more of the physical process than the one-dimensional array.

The gridded altimetry product and mooring have high coherence (>0.6) for periods longer than 20 days (figure not shown). The match between altimetric SSH and mooring upper-500-m steric height with less than 2 cm RMS error validates the upper-500-m steric height in representing satellite SSH over low frequencies. For periods shorter than ~20 days, the mooring steric height exhibits more variability than the gridded altimetric product, which is expected. From the example shown in the bottom panel of Fig. 13, the M_2 tide can be coherent and propagate from north to south shown by the gray arrow, but the coherency among the three moorings is intermittent. Over a 2-day period between 11 and 13 November, for example, the M_2 tidal peaks are less obvious at the northern mooring than at the southern mooring (Fig. 13, bottom panel).

The southern and northern mooring time series (Fig. 13, upper panel) reveal that the M_2 tide is stronger and more coherent at the southern mooring than the northern mooring. From a tidal analysis on the two steric height time series (figure not shown), the southern mooring has an M_2 steric height amplitude of 1.7 cm while the northern one has an amplitude of 0.7 cm. The M_2 baroclinic tide represented by the steric height is dominated by the first baroclinic mode that has a large wavelength longer than 100 km.

To address the question of why the M_2 tide is so different between two moorings separated by 30 km, we first eliminated the possibility that the difference comes from different mooring designs. The southern mooring uses a subsurface taut mooring connected to the profiler and surface buoy above by a reserve catenary. This design has a much smaller watch circle (250 m radius) than the northern slackline design mooring (~4 km radius). However, it is unlikely that this contributes to the difference in the M_2 signal at the different moorings, based on the glider results during its station-keeping phases shown in Fig. 12. The time variability at the M_2 tidal period is well characterized by the glider for both the southern and the northern moorings. During the 6-day period where the glider operated near the northern mooring, it confirmed the weak M_2 signal there. Likewise, at the southern mooring, the glider confirmed the elevated M_2 variability in steric height there. This mooring–glider comparison largely eliminates the influence of mooring design on the reconstruction of the coherent tides. As a result, the significantly different M_2 tide between the northern and the southern moorings appears to be real.

One possibility for the different tides between the northern and the southern moorings is that this small-scale difference is expected due to multiwave interference that has been

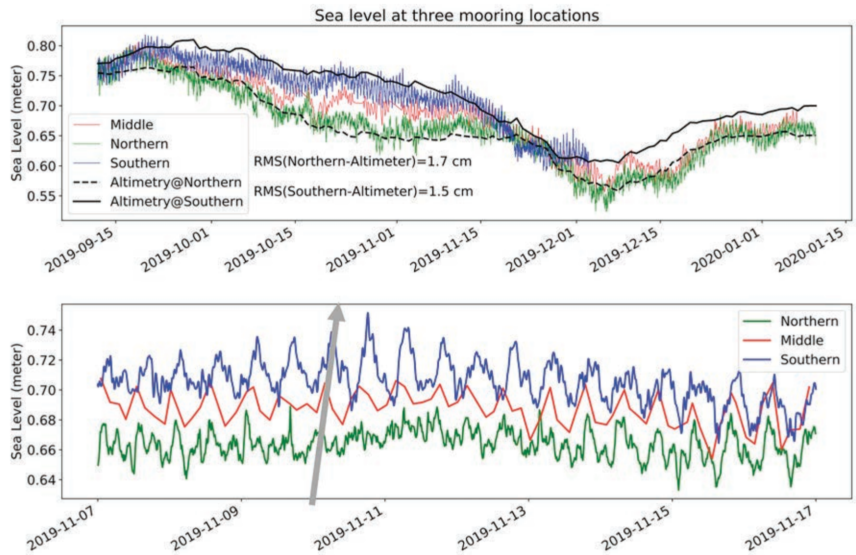

FIG. 13. (top) The time series of the upper-500-m steric height from three moorings (colored lines) offset by a constant 496.91 m, and the altimetric sea level anomaly interpolated at northern mooring (black solid) and southern mooring (black dashed). The RMS differences between WHOI mooring and SIO mooring steric height from their local altimetric sea level anomaly is 1.7 and 1.5 cm, respectively. (bottom) The same mooring steric height time series, but focusing on a 10-day window between 7 and 17 Nov 2019. The semitransparent gray arrow marked the propagation of the internal tides from the northern mooring through the middle mooring and to the southern mooring.

observed in the conventional altimetry (Zhao et al. 2019; Zaron 2019). An altimetry-based internal tide model that fits plane internal waves with multiple directions does also show similar amplitude variation of the mode-1 M_2 internal tide over the 30 km distance between the two moorings (Zaron 2019).

Another possibility is the modulation of coherent tides by balanced motions (e.g., Ponte and Klein 2015). The mesoscale and smaller mesoscale eddies are stronger at the northern mooring location than the southern mooring location, resulting in stronger eddy modulation of the tides and reduced tidal coherency. This can be seen from the frequency spectra of the steric height field of the three moorings (Fig. 14). The stronger M_2 tides at the southern mooring discussed above are illustrated in the frequency spectrum, i.e., the green line is much higher than the blue line at the M_2 frequency. The three moorings have matched energy on the low-frequency end with periods longer than 20 days. However, the spectral energy level at the southern mooring is drastically different from and one order of magnitude weaker than the other two moorings over 1–10-day periods. The gridded altimetry SSH maps (Fig. 5) show that the southern mooring is on the warm side of the meander and inside of the mature eddy at later stage, while the northern mooring spent more time on the further edge of the eddy where sharp horizontal fronts can be more prominent. This is confirmed by the horizontal gradient of SST, which is persistently stronger at the northern mooring location than at the southern mooring (figure not shown). This set of evidence points to the hypothesis that mesoscale eddies can modulate coherent low mode tides within a distance shorter than the tidal wavelength. The 2D SSH field to be observed by SWOT can be very useful to detect these small-scale eddy–wave interactions. Further proof of the hypothesis needs more observations or process-oriented numerical modeling studies and will be pursued elsewhere.

2) SPATIAL VARIABILITY

With two full-depth moorings at the northern and southern locations, we can start to examine the spatial variability from

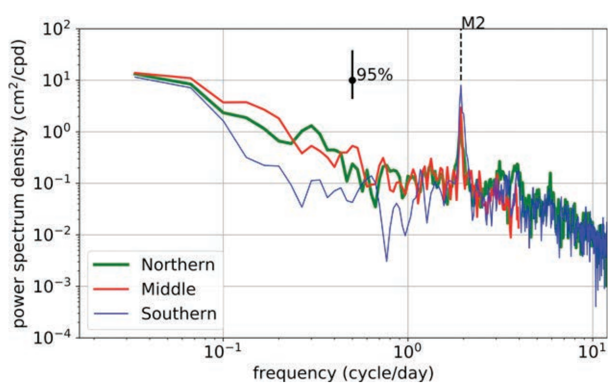

FIG. 14. The frequency spectra of the upper-500-m steric height from the northern (blue), middle (red), and the southern mooring (green). M_2 tidal frequency is marked by the dashed vertical line. The middle mooring spectrum (red) was cut at 4 cycles per day for its limited sampling frequency at 8 profiles per day.

TABLE 2. RMS differences between the northern and the southern moorings for the period 10 Sep–25 Nov 2019 when full-depth measurements are available at both sites. The temporal-scale separation is done in frequency space through Fourier analysis without windowing. The bottom row is done through a three-mooring scale separation described in the text representing a back-of-envelope calculation of the small-scale (<~30 km) variability. The unit for all values is cm.

	Full water column	0–500 m	500–4000 m
All frequencies	3.2	2.8	0.9
<14 days	1.6	1.4	0.8
2–14 days	0.7	0.7	0.2
<2 days	1.5	1.2	0.7
Anomalies to a linear function of the three moorings		0.2–0.7	

the mooring difference. Table 2 shows that the RMS difference over 30 km is 3.5 cm based on the full-depth steric height, among which 2.8 cm is due to the upper 500 m and 1 cm to the deeper ocean. These values include the influence of the wavelengths longer than 150 km, which is beyond the focus of the in situ Cal/Val. With only three moorings spanning 30 km, it is impossible to single out the signals with wavelength less than 150 km, but in general longer wavelengths are associated with longer periods. For example, these RMS differences are reduced for periods less than 14 days and significantly reduced for the 2–14-day band. The variability with periods less than 14 days is dominated by high frequencies (>1/2 cycle day^{-1}). This dependence of RMS difference on time scales is expected for a typical SSH frequency spectrum that is dominated by low-frequency (monthly and longer) variabilities and tidal peaks over high (superinertial) frequencies (e.g., Fig. 14).

The middle mooring does not have deep CTDs below the Prawler and samples only the upper 500 m. If we only focus on the upper-500-m steric height, the three moorings can be used to derive steric height difference for separation distances of 10 and 20 km. The standard deviations of the differences are 1.6 and 2.0 cm for 10 and 20 km, respectively.

These analyses with a single mooring (section 4c, Table 1) or two-mooring differences (Table 2) cannot distinguish different spatial scales, but we have used the above frequency filtering to isolate motions on SWOT spatial scales and thus could estimate the expected RMS differences due to these motions on the single spatial lag of 30 km. This is the size of SSH differences expected due to motions of interest to SWOT over such distances. In addition, with three moorings, we can begin to decipher the spatial–temporal variabilities due to the smallest-scale motions, even without the actual wavenumber spectrum. The main technique is discussed as follows.

Given three moorings with separation distances of 10 and 20 km, we have three points spanning 30 km distance. To examine small-scale signals, we removed the large-scale influence by removing a spatial linear trend through the three moorings for each hourly snapshot as shown in the schematic diagram in Fig. 15a. The middle mooring time series is linearly interpolated from 8 profiles per day to hourly, which inevitably introduces errors. The deviations from the fitted linear trend are considered the SSH anomaly at small scales.

The linear-trend removal is a crude spatial high-pass filter. The effectiveness of removing the local linear trend is evaluated using a Monte Carlo simulation to test a Hanning high-pass filter with different window sizes. We first generate 5000 128-km-long synthetic SSH profiles with certain wavenumber spectral slopes, then sample the profiles in the middle at three locations separated by 10 and 20 km, resembling the prelaunch campaign mooring placement. The synthetic mooring data are separated into large scale and small scale using the same method of fitting a three-point linear trend. The results are compared with results produced by a high-pass Hanning filter of different window widths. We find that for synthetic SSH profiles with k^{-4} wavenumber spectrum, the smallest difference between removing a local linear trend of the three moorings and a Hanning-window filtering occurs at 22 km Hanning-window width. For k^{-2} profiles, it is at 32 km. The SSH profile is "smoother" for steeper wavenumber spectrum, e.g., k^{-4}, so the local linear trend captures and removes large-scale signals more effectively. The anomalies after removing the local linear trend are mostly from spatial scales less than approximately 30 km. We denote these anomalies as "small scale" and the linear trend as "large scale" in the following paragraph. It is worth emphasizing again that this operation is a crude way of separating small and large scales, given the limitation of the spatial coverage of the data.

The derived small-scale variability is significantly weaker than the large-scale variability (Fig. 15b). The RMS values of the total upper-500-m steric height for the three moorings are 1.9, 1.3, and 1.9 cm from north to south. The corresponding large scales defined by the linear trend have RMS values of 1.7, 1.2, and 1.9 cm. The small-scale (<~30 km) steric height is 0.4, 0.7, 0.2 cm for the northern, middle, and southern moorings, respectively. These values for small scales are smaller or close to the SWOT KaRIn noise values around 0.54 cm (section 2d). It indicates that the SSH signal at the Cal/Val site can be weaker than the SWOT KaRIn noise for spatial scales 20–30 km and smaller. This result is consistent with Wang et al. (2019).

Note that the sum of small-scale and large-scale temporal variances is larger than the variance of the total signal. This provides evidence that this spatial filtering does not separate the signal in the temporal space. However, removing the local linear trend effectively removes most of the low-frequency variability that is visually obvious in the time series (Fig. 15b) and also clearly shown in the frequency spectra in Fig. 15c, where the power spectra of the total and large-scale signals converge over periods longer than 10 days (blue and orange lines). Removing the linear trend also effectively removes most of the M_2 baroclinic tides in the steric height, which means that the baroclinic tides have spatial scales larger than about 30 km. Even though the large-scale signal is more energetic than the smaller spatial signal over almost all

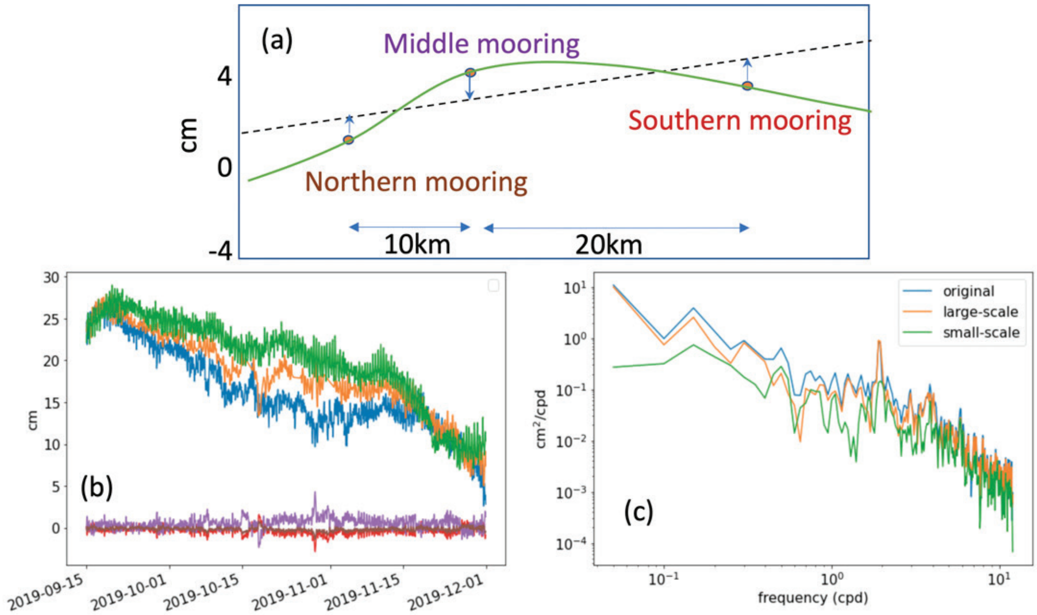

FIG. 15. (a) The schematic of deriving small-scale anomalies from three moorings. The linear trend (dashed line) was derived through the least squares method. The deviation of each mooring steric height from their linear trend is denoted as the small-scale component. Removing the linear trend over a 30 km segment is similar to high-pass filtering with a 20–30-km-wide Hanning window depending on the wavenumber slope of the signal. (b) The original steric height of each mooring (green, orange, and blue lines). The small-mesoscale signals defined in (a) are shown by purple, red, and brown lines for the three moorings. (c) The frequency spectra for the original steric height (blue), the linear trend representing the large-scale (orange), and the small-scale steric height (green) averaged over the spectra of the three moorings.

frequencies, the small-scale signal is particularly large over the period range of 2–5 days relative to the large scale. With a caveat of uncertain significance, we may tentatively associate <30 km spatial scales with 2–5-day temporal scales. This spatial–temporal-scale association may have a practical value for designing the optimal error covariance matrices in the data assimilation system with the multiscale approach, such as Li et al. (2019), D'Addezio et al. (2019), and Archer et al. (2022).

f. Comparison to Sentinel-3A *SSH*

The *Sentinel-3A* ground track was not a factor for the design of the SWOT Cal/Val orbit. It is rather fortunate that one of the *Sentinel-3A* (*S3A*) ground tracks is in the middle of a SWOT swath along the fast-repeating orbit. For this reason, the mooring array in the prelaunch field campaign was placed along the *S3A* ground track (Fig. 2). During the 2019/20 campaign period, *S3A* passed the mooring array five times (Fig. 16). The mooring steric heights (upper 500 m) match the *S3A* measurements within 2 cm RMS. There were two times when the steric heights and *S3A* values were different (the third and fifth rows). Despite the sizeable differences, the spatial structures in the mooring array steric heights resemble the spatial structures of the *S3A* SSH profiles. However, bias corrections of 2 and 6 cm were applied to 6 November 2019 and 2 January 2020 profiles, respectively. The nature of the bias is unknown at the time of writing and deferred to future investigations.

g. Bottom pressure

Bottom pressure recorders measure both the barotropic (due to additional water mass above the BPR) and baroclinic (due to interior temperature/salinity changes) signals on the ocean floor. The BPRs deployed in this campaign have enough precision to detect millimeter-level signals, but BPRs suffer from a large long-term drift that may be mistaken for a low-frequency signal in our ~90-day records. Ray (2013) analyzed a network of BPRs of this type, showing that the BPR-derived tide matches the altimetric tide model with about 5 mm RMS difference for the M_2 constituent. The BPRs used in the campaign should be accurate enough to detect deep baroclinic pressure signals even though separating them from much more energetic barotropic tides based on a single mooring is impossible (Ray 2013). The most prominent signal in the bottom pressure is the tide (Fig. 17a). We fit 53 tidal constituents to the measured bottom-pressure signal to produce a detided bottom pressure record (Fig. 17b) using the same tool from Ray (2013). The detided signals are relatively small (2.3–2.6 cm), but still potentially important. Unfortunately, we have little information about the spatial scale of the signals contributing to these residual bottom pressure signals. Taking the difference between the two detided bottom-pressure records can give us a vague sense of how small-scale signals

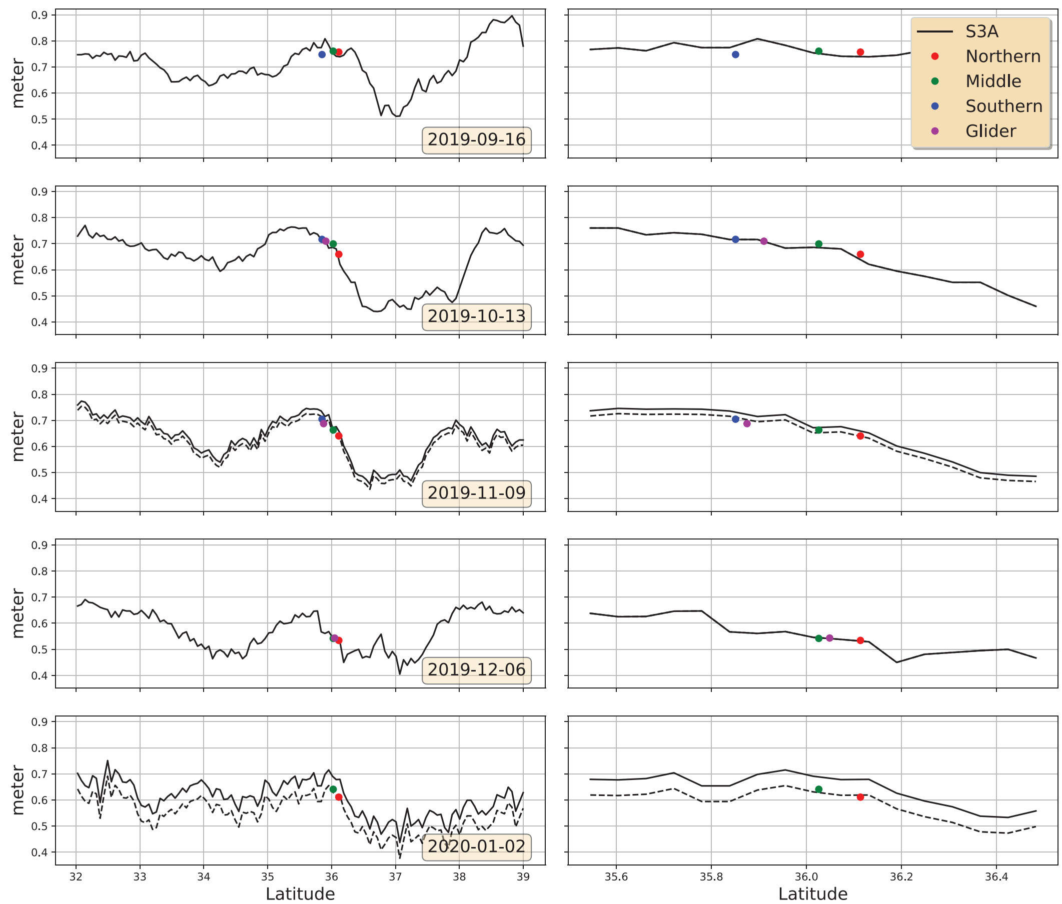

FIG. 16. The five *Sentinel-3A* SSH profiles during the 2019/20 campaign period that pass the mooring array (black lines). They are the L3 product with ocean (barotropic) tides, dynamic atmosphere correction (DAC), and long-wavelength-error (LWE) correction applied. The colored dots show the upper-500-m steric height from the northern (red), middle (green), and southern (blue) moorings and the glider (purple). (left) The 7° segment to show the large-scale context. (right) The same profile, but zooming in to focus on the mooring array within 100-km-wide segments. The dashed lines in the third and fifth rows are the black lines offset by 2 and 6 cm, respectively. The steric height is calculated from the original in situ density without removing the time mean, then offset by 496.385 m to match the *Sentinel-3A* profiles.

might contribute. This difference has an RMS amplitude of 0.6 cm based on the period of 1 October 2019–1 October 2020 when the bottom pressure drift becomes less obvious. It contains both barotropic and baroclinic signals, including several tidal frequencies and low-frequency variability, and the parabolic shape of the difference curve (Fig. 17b) suggests it may also be affected by differences in the low-frequency drift of the two bottom pressure recorders. Removing a quadratic fit to the difference between the two detided bottom-pressure records reduces the RMS difference to about 0.4 cm, which is below the SWOT KaRIn noise level derived in section 2d.

5. The design of a SWOT postlaunch campaign

The main purpose of the SWOT prelaunch campaign described in the paper is to provide information for the design of an effective yet affordable postlaunch SWOT ocean in situ observing system for the mission's calibration and validation. To validate the SWOT SSH, we need an array of observations for comparison with the nearly simultaneous measurement taken by the satellite in less than 23 s over 150 km. The resolution of SWOT in the California Cal/Val region is about 20 km in wavelength, below which the baroclinic SSH becomes less than KaRIn instrument noise (Wang et al. 2019). To meet the Nyquist wavelength requirement of 20 km, we need a measurement every 10 km. Although Wang and Fu (2019) indicated that the onboard nadir altimeter is able to validate SWOT at wavelengths longer than 120 km, we feel that, in order to reduce cost, it is acceptable to deploy an array of 11 moorings covering 100 km to meet the in situ Cal/Val objectives.

Based on the analysis presented in the paper, it is acceptable to sample only the upper 500 m for the low-frequency ocean variability. However, it is desirable to sample the ocean deeper than 500 m to capture the deep signals of internal tides and occasional deep eddies. Since the wavelengths of internal

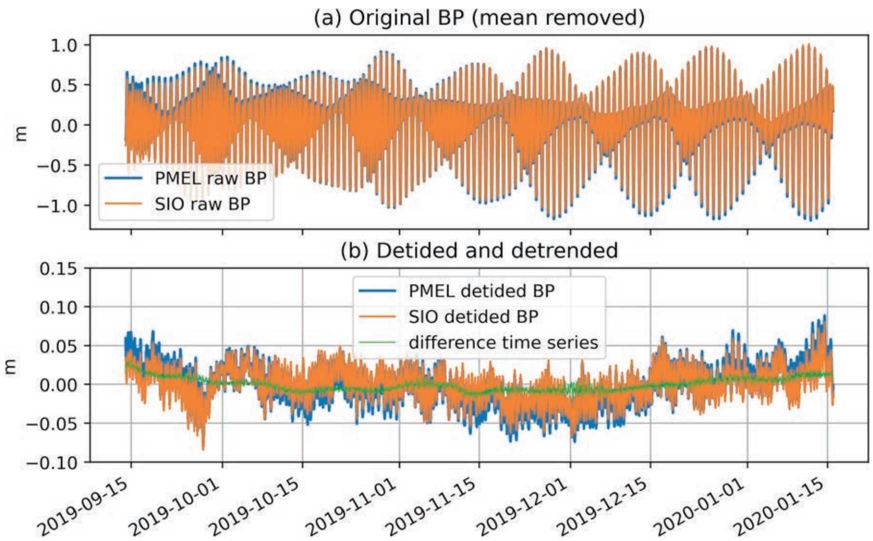

FIG. 17. (a) The original time series of the bottom pressure from the southern (orange) and the northern (blue) BPRs. (b) The residual after removing the fitted tides and linear trends. We fit 53 tidal constituents to the 4-month-long time series to reduce the residual. The remaining signal of each BPR still has 2.2–2.4 cm standard deviation.

tides are longer than 60 km (the two lowest modes of the M_2 tides; Zhao et al. 2019), the required Nyquist sampling interval for low-mode internal tides is 30 km. Shown in Fig. 18 is a baseline design of the postlaunch observing system. It contains 11 moorings with 4 of them (triangles) consisting of a Wirewalker and deep CTDs like the SIO system. The remaining 7 moorings are Prawler moorings like the PMEL system, sampling only the upper 500 m. These instruments will provide time series observations that allow the construction of the snapshots of steric height for comparison with the SWOT SSH measurement on a daily basis. The difference between the two observations will provide an assessment of the SWOT measurement errors for the small-wavelength range reconstructed by the in situ mooring array (20–100 km). Its wavenumber spectrum will be compared with the SWOT requirement (Fig. 1).

Based on the results from the prelaunch campaign, GPS buoys and BPRs are not critical for meeting the Cal/Val objectives. To make accurate IB correction for the SWOT SSH, one barometer at the center of the array is included in the design.

Two gliders are included to sample the cross-track ocean variability to aid the estimation of the two-dimensional state of the upper ocean for validating the science goals of the mission to determine the circulation of the upper ocean. If funding permits, more gliders would be highly desirable for achieving the science goals. As illustrated in the paper, the gliders, when operating in the station-keeping mode, will also serve as a contingency for any failed mooring.

Given the constraints of the mission's budget, this design presents a minimum system for meeting the mission's Cal/Val objectives. We look forward to opportunities of collaboration with other interested parties to expand this SWOT Cal/Val array into a larger-scope, submesoscale-focused experiment in this region.

6. Discussion and conclusions

It has been shown that observations from the moorings and the glider can be used to reconstruct a steric height field with accuracy at an RMS error below 1 cm at each location level. There are, however, remaining uncertainties in the accuracy of the horizontal wavenumber spectrum produced by an array of these moorings.

The moorings' large watch circles might be a source of uncertainty in making an SSH wavenumber calculation for the SWOT Cal/Val purpose. The watch circle can reach a 4 km radius. It may change the spacing between moorings and result in nonuniformly spaced mooring array. In addition, the deviation from the centerline of the mooring array (the middle of the SWOT swath) can also be as large as the watch circle radius. These along-track and cross-track drifts of the moorings will introduce errors and uncertainties, but we do not have a formal assessment of the error in this study. In any case, the size of the watch circle is less than the 15–20-km-wavelength resolution of SWOT in the Cal/Val region (Wang et al. 2019).

The deep-ocean steric height has variability and can contribute to the overall steric height signal. Based on the ~90 days of mooring observations collected during the 2019/20 campaign, the consequence of missing the deep-ocean steric height was about 0.6–0.8 cm standard deviation for each mooring, mostly arising from baroclinic tides (Fig. 10).

There is some evidence that eddies at and below 500 m occasionally occur in the Cal/Val region (Collins et al. 2013). Although Collins et al. (2013) do not report on the water

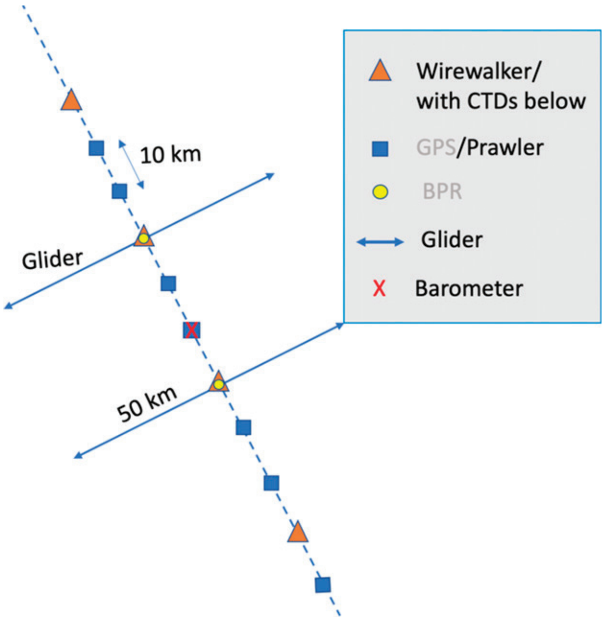

FIG. 18. A minimum baseline for the SWOT postlaunch ocean Cal/Val field campaign. The four hybrid moorings with full-depth *T*/*S* measurements can capture deep-reaching baroclinic tides with relatively longer wavelengths. The seven Prawlers will measure the upper-500-m steric height. Two gliders will sample the cross-swath direction and also serve as a contingency for failed moorings. The barometer will provide high-precision, high-frequency atmospheric pressure for IB correction. BPRs and GPS receivers are not part of the minimum baseline but will be a valuable upgrade.

column structure associated with the observed deep eddies, they could contribute to variability in steric height and to significant nonzero velocities at 500 m depth. For example, assuming a mode-1 structure, a 25-km-wide eddy at 1500 m with ~10 cm s^{-1} velocities as reported by Collins et al. (2013) would be associated with a ~1 cm change in steric height across its diameter. They also observed an eddy at 660 m depth with velocities that would correspond to 1.4 cm steric height signal across the eddy with a diameter of 54 km at that depth. However, deep eddies need not be associated with a mode-1 structure. For example, Gula et al. (2019) report on the presence of deep submesoscale coherent vortices (SCVs) in the Gulf Stream with diameters of 10–30 km. Those SCVs have a mode-2 like signature that would have little if any impact on steric height (e.g., Fig. 2d in Gula et al. 2019). Given the potential for deep eddies to contribute a small amount of steric height variability, a subset of moorings in the SWOT Cal/Val effort will monitor the deep ocean to account for these signals if they arise (Fig. 18).

Even though the error in GPS SSH from a single buoy (>1 cm RMS) is larger than SWOT mission requirements, much of this error is attributed to sea-state and water-line errors, and intrinsic GPS errors (e.g., from tropospheric refraction) that are spatially correlated over the campaign footprint. Significant cancellation of common mode errors can thus be expected from combined processing of observations of multiple buoys operating in the same campaign theater. This is supported by recent tandem buoy campaigns in the Bass Strait (Zhou et al. 2020) and near the Harvest platform (Haines et al. 2019), both of which suggest that errors (on ΔSSH between buoys in proximity) are reduced to less than 1 cm. Whether the accuracies achieved can approach the stringent requirements imposed by the validation of the SWOT wavenumber spectrum remains an open question (Zhou et al. 2020). Regardless, the GPS buoy technique has advanced significantly and already offers a powerful means of resolving discrepancies between steric height (as measured with hydrographic techniques) and geodetic SSH (as measured by SWOT).

We have shown that it is possible to measure the steric contribution to sea surface height to <1 cm RMS precision with several moorings and a glider. This allows confidence that an array of moorings and collocated glider lines (e.g., Fig. 18) will allow for a robust oceanographic calibration and validation of the KaRIn sensor on board the SWOT satellite during the planned 1-day fast-repeat period before the satellite is moved to its final orbit.

This is the first time when a combination of independent high-precision in situ instruments is used to analyze the SSH budget focusing on such small spatial scales (less than 30 km) and high frequencies (period less than monthly). The results shed light on the design of the SWOT postlaunch field campaign as well as the ocean physics over such small scales and high frequencies (periods ranging from hours to months).

We have shown that the ocean sea surface height measured by GPS, which is like altimeter/SWOT measurements, matches the steric height derived from the temperature and salinity measurements using CTDs after subtracting the bottom pressure and applying the inverted barometer correction. The consistency between the GPS-BPR and the mooring steric height validated the utility of the steric height as the ground truth for satellite calibration and validation. Even though the absolute RMS difference between GPS-BPR-derived steric height and CTD-derived steric height is larger than 1 cm, how much of the error is due to the large-scale common mode GPS error is unknown, but expected to be largely removable. The utility of GPS in the SWOT Cal/Val is still under investigation through the second GPS on the middle mooring. The major advantage of using steric height is the absence of the errors due to surface waves.

The variability in steric height is mostly due to the upper-ocean processes. For example, the deep-ocean ($z < -500$ m) steric height variability has a standard deviation of 0.6–0.8 cm, most of which comes from superinertial frequencies, especially around the semidiurnal M_2. If only subinertial variabilities with periods between 2 and 14 days are considered, missing deep ocean results in <2 mm uncertainty.

Small scales less than 30 km wavelength have very weak steric height variation, 0.2–0.7 cm standard deviation near the SWOT Cal/Val campaign region diagnosed from the 2019/20 campaign conducted in the wintertime. This small-scale variability is estimated based on the deviations of the three mooring steric heights from their spatial linear trend. This weak small-scale steric height signal underlines the challenge for

SWOT, but also highlights the opportunities provided by SWOT and the values of a full-scale array with a dozen CTD moorings in conducting the mission Cal/Val and studying the small-scale ocean circulation.

Acknowledgments. We are grateful to Anna Savage and R/V *Sally Ride* captain and crew for the unplanned recovery of the Wirewalker, and to Hong Zhang for providing ERA5 atmospheric pressure for the IB correction, Ed Zaron for the discussion on internal tides, and Marie Eble and George Mungov for the discussions on the tidal reconstruction from BP. The research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration (80NM0018D0004). All authors are supported by the SWOT project. J. T. Farrar was partially supported by NASA NNX16AH76G. The in-situ observations are available for download at https://podaac.jpl.nasa.gov/.

ABSTRACT: Suspended particle size and concentration are critical parameters that are necessary to understand water quality, sediment dynamics, carbon flux, and ecosystem dynamics, among other ocean processes. In this study we detail the integration of a Sequoia Scientific, Inc., Laser In Situ Scattering and Transmissometry (LISST) sensor into a Teledyne Webb Research Slocum autonomous underwater glider. These sensors are capable of measuring particle size, concentration, and beam attenuation by particles in size ranges from 1.00 to 500 μm at a resolution of 1 Hz. The combination of these two technologies provides the unique opportunity to measure particle characteristics persistently at specific locations or to survey regional domains from a single profiling sensor. In this study we present the sensor integration framework, detail quality assurance and control procedures, and provide a case study of storm-driven sediment resuspension and transport. Specifically, Rutgers glider RU28 was deployed with an integrated LISST-Glider for 18 days in September of 2017. During this period, it sampled the nearshore environment off coastal New Jersey, capturing full water column sediment resuspension during a coastal storm event. A novel method for in situ background corrections is demonstrated and used to mitigate long-term biofouling of the sensor windows. In addition, we present a method for removing schlieren-contaminated time periods utilizing coincident conductivity temperature and depth, fluorometer, and optical backscatter data. The combination of LISST sensors and autonomous platforms has the potential to revolutionize our ability to capture suspended particle characteristics throughout the world's oceans.

SIGNIFICANCE STATEMENT: This study details the integration and deployment of an optical particle size and concentration system on an autonomous underwater vehicle. The unique combination of this sensor and platform will enable broad sampling of suspended particle characteristics across the coastal and global oceans, within extreme storm events, in coastal river plumes, and throughout the deep oceans' "twilight zones." This will greatly enhance our ability to monitor water quality, sediment mobilization, ecosystem dynamics, pollutant fate and effects, and carbon export flux, among other important ocean-observing applications.

1. Introduction

In situ ocean observations of suspended particle size and concentration are important to monitor and study water quality, sediment dynamics, carbon export flux, fate and effects of pollutants, light propagation, ecosystem dynamics, water column visibility, and to ground truth remote sensing observations among other applications. Methods for measuring particle characteristics typically require labor intensive water sampling and sieving, or careful calibration of optical and acoustic backscatter sensors (Boss et al. 2018a; Agrawal and Pottsmith 2000; Bunt et al. 1999; Lynch et al. 1994; Thorne et al. 1991; Holdaway et al. 1999; Thorne et al. 2007). These approaches are not easily scalable beyond discrete sampling by ships or highly localized instrument deployment where calibration procedures remain valid. Laser In Situ Scattering and Transmissometry (LISST) particle analyzers have been used to reliably estimate particle size and concentration over the past two decades (Agrawal and Pottsmith 2000). These systems use laser diffraction as a composition insensitive method for sizing ensembles of particles in a sample volume. The near forward scattering of light onto concentric detector rings paired with inversion algorithms can be used to estimate particle size distributions (PSD) and volume concentration. Applications of LISST systems include storm-driven sediment resuspension (Dickey et al. 1998; Chang et al. 2001), sediment resuspension in estuaries and bays (Yuan et al. 2008; Wang et al. 2013), suspended sediment flocculates (Mikkelsen and Pejrup 2001), particle aggregation and disaggregation (Slade et al. 2011), phytoplankton size distributions (Karp-Boss et al. 2007), coastal water quality (Ahn et al. 2005), in flow-through systems across ocean basins (Boss et al. 2018b), bottom boundary layer studies (Agrawal and Traykovski 2001; Curran et al. 2007), monitoring the effect of dispersants during oil spill response (Bejarano et al. 2013), among many others. LISSTs along with other optical and acoustic sensors for monitoring suspended particles, are typically deployed on moorings, benthic landers, tripods, and other fixed point platforms (Trowbridge and Nowell 1994; Agrawal and Pottsmith 2000; Harris et al. 2003; Styles and Glenn 2005) or ship based profilers and underway

systems for regional surveys. In this study we demonstrate the use of a newly integrated LISST-Glider into a Teledyne Webb Research Slocum autonomous underwater glider. Pairing of these technologies enables new possibilities for sustained sampling of particle size and concentration at regional scales and in conditions and locations not readily accessible by ship-based surveys.

In nearshore regions autonomous underwater gliders are the ideal platforms for collecting physical and biological data persistently across local and regional scales (from tens to hundreds of kilometers). Gliders have proven to be uniquely suited for collection of persistent profiles of optical data during the initiation, transport, and clearance of suspended sediment during hurricanes, coastal storms, and discharge events (Glenn et al. 2008; Miles et al. 2013, 2015; Bourrin et al. 2015). One of the first studies using gliders to investigate storm-driven sediment resuspension and transport detailed the impact of stratification on sediment dynamics (Glenn et al. 2008). Specifically, this study found that even during hurricane events, stratification inhibits full water column resuspension in summer months on the U.S. Mid-Atlantic Bight (MAB) continental shelf. This strong stratification is formed seasonally on the MAB, driven by rapid surface warming isolating the summer cold pool near bottom (Houghton et al. 1982). Storms in the fall season that break down stratification or occur after it has eroded can resuspend sediment throughout the full water column. Similar results for fall conditions were found in a follow-on study (Miles et al. 2013). In that study a fleet of simultaneously deployed gliders highlighted how local variability in bottom type can influence shelf-scale sediment resuspension and transport. Glider studies focused on storm-driven sediment resuspension and the influence of river runoff on particle assemblages have also been carried out in the Mediterranean Sea (Bourrin et al. 2015; Many et al. 2016). While these studies have used multiple wavelength optical backscatter measurements, these sensors alone have limited capability in determining particle size in situ.

In an initial effort to broadly determine in situ particle size from gliders, Miles et al. (2015) measured acoustic backscatter from a Nortek Aquadopp deployed alongside a Wetlabs optical backscatter sensor. Differing particle size sensitivity for acoustic and optical sensors allows for partitioning of ''large'' and ''small'' particle concentrations (Lynch et al. 1997). This approach was used to observe resuspension during Hurricane Sandy and qualitatively evaluate patterns of resuspension in an application of the Regional Ocean Modeling System (ROMS) coupled to the Community Sediment Transport Model (CSTM). Quantitative suspended particle concentration estimates from optical backscatter sensors require calibration with local sediment samples to measure accurate water column sediment concentrations (Bunt et al. 1999) and cannot identify particle size distributions. Over the course of a glider mission this type of calibration has limited feasibility, as the glider may be sampling over a broad spatial area (10–100 km) with highly variable sediment characteristics.

To fill this gap, we have recently integrated the newly developed Sequoia Scientific, Inc., LISST-200X into a Teledyne Webb Research (TWR) Slocum glider. This approach combines two proven technologies to enable broad, quantitative, sampling of particle size and concentration across a diversity of environments and conditions. In this paper we detail the sensor integration approach, in situ calibration and correction procedures, and an example of storm-driven sediment resuspension in the nearshore region of the MAB.

2. Sensor integration and deployments

a. Sensor integration

Slocum gliders are robotic uncrewed underwater systems with a demonstrated operational maturity over the last 20 years (Schofield et al. 2016). These low-power buoyancy-driven systems can carry out sustained missions of weeks to more than a year in water depths of ~10–1000 m, allowing them to sample nearshore, coastal, and deep ocean environments. Their broad sampling range includes extreme environments such as beneath hurricanes (Glenn et al. 2016; Miles et al. 2017) in coastal riverine environments (Schofield et al. 2015), and in polar oceans (Kohut et al. 2015). Slocum gliders profile the water column in a sawtooth pattern with speeds in the vertical direction of 10–15 $\mathrm{cm\,s^{-1}}$ and in the horizontal plane of 20–25 $\mathrm{cm\,s^{-1}}$, resulting in high data density and full water column coverage. Gliders surface at preprogrammed intervals to obtain new GPS fixes, send data to shore, and receive new commands. Slocum gliders have modular payload bays located in the center section of the vehicle, which allow for customizable sensor loadouts and a flexible system for integrating new sensors.

Sequoia Scientific developed a LISST particle sizing instrument to fit within a Slocum second- (G2) and third-generation (G3) glider. The optical arrangement of the LISST-Glider is based on the Sequoia Scientific LISST-200X but mounted to fit within a Slocum glider hull section (Fig. 1). This system uses a ''monoblock'' optical head with the end cap machined as a solid component incorporating both receive and transmit windows for increased robustness of alignment under variations in temperature, pressure, and possible impacts. The basic measurement system is a sample volume exposed to ambient flow, flanked by a windowed pressure housing containing the laser source, and collimation optics, and the receive optics and detector array. The transmit optics consists of a fiber coupled 660-nm laser diode source with a beam splitter and reference photodetector and a lens providing a collimated source beam into the sample volume. The receive optics contains a focusing lens and a 36-element photodetector array placed at the focal plane of the lens. By the Fourier transform property of this lens, light scattered at a given angle at any point along the sample volume will be incident onto the ring detector plane at the same distance from the optical axis. A pinhole at the focal point allows transmitted light to be passed to a photodetector for measuring beam transmission. The LISST system is designed to measure the size distribution of particles from 1.00 to 500 μm in 36 size classes at 1 Hz (Agrawal and Pottsmith 2000; Agrawal et al. 2008).

The LISST-Glider was integrated into a Slocum glider short hull section, commonly referred to as a stack-on bay (Fig. 1). This configuration allows for the LISST to be rapidly installed or removed from an available glider with limited impact on other sensor loadouts. A tie-rod extension and wiring harness

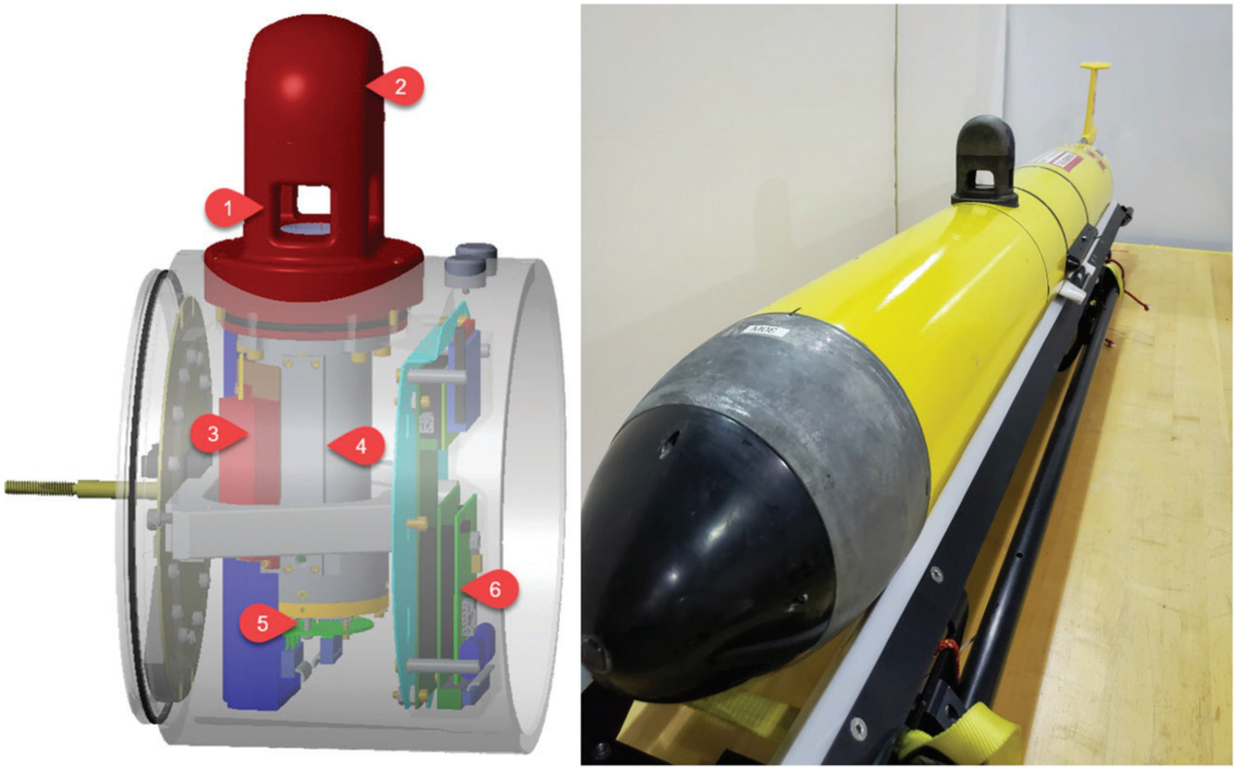

FIG. 1. (left) A schematic view of the LISST-Glider shows that the sample volume (label 1) is a 2.5-cm-pathlength scattering volume flanked with fused quartz windows for durability. The beam collimation optics and reference detector are also contained in the optical head (label 2), connected to a fiber coupled diode laser module (label 3). Scattered light is received through the lens tube (label 4), which also contains an extended detector array. The primary ring detectors and transmission sensor (label 5) are mounted on an XY stage that is used to adjust the instrument alignment, which can then be locked into place. An electronics section (label 6) digitizes the analog signals from the scattering detectors, controls the sampling process, logs the full scattering dataset, and calculates beam attenuation particle size metrics (i.e., mean size and total concentration). (right) A view of the LISST-Glider integrated into a G2 Slocum glider.

enable connection directly fore of the standard payload bay. During LISST-Glider production, quality control tests used bead standards to verify alignment and centration of the detector array. Factory clean water background measurements are stored on the instrument for use in data processing. These can be replaced by user-collected background measurements for both real-time onboard processing and with recovered datasets postdeployment following standard LISST-200X procedures. The resulting LISST-Glider payload bay underwent extensive pressure and thermal cycling at TWR. Currently, commercially available systems are rated to 600 m. Default sampling settings, and those used in this study, include 32 measurements averaged every second with full datasets saved on board.

New firmware was developed that allows the LISST-Glider to be controlled by the glider science controller. Raw laser scattering data are stored on board the instrument in binary files compatible with standard LISST-200X processing software. These raw files contain all ancillary data needed to process the raw scattering measurements to particle size distribution. In the default glider configuration, the LISST-Glider generates a separate binary file for each glider segment, the data collection period between each subsequent glider surfacing. As for the standard LISST-200X, the firmware also calculates beam attenuation from transmission measurements and estimates of particle volume concentration and Sauter mean diameter in real time (Agrawal and Mikkelsen 2009); these parameters are output to the glider and available for transfer to shore as standard real-time glider output variables in glider binary files. Stored full-resolution data can be downloaded upon glider recovery and processed using Sequoia Scientific software as in standalone LISST applications. Additionally, Sequoia Scientific provides Mathworks, Inc., MATLAB functions, which were used in this study to merge LISST recovered data with full-resolution Slocum glider data using Slocum Power Tools (https://github.com/kerfoot/spt/wiki).

b. *Glider configuration*

The LISST-Glider science bay used in this study was integrated into a TWR Slocum G2 glider, RU28. This glider was operated by the Rutgers University Center for Ocean Observing Leadership (RUCOOL) on behalf of the State of New Jersey Department of Environmental Protection (SNJ-DEP). These SNJ-DEP deployments are typically focused on mapping nearshore water quality, specifically nearshore hypoxic conditions that may impact critical fisheries and recreation in

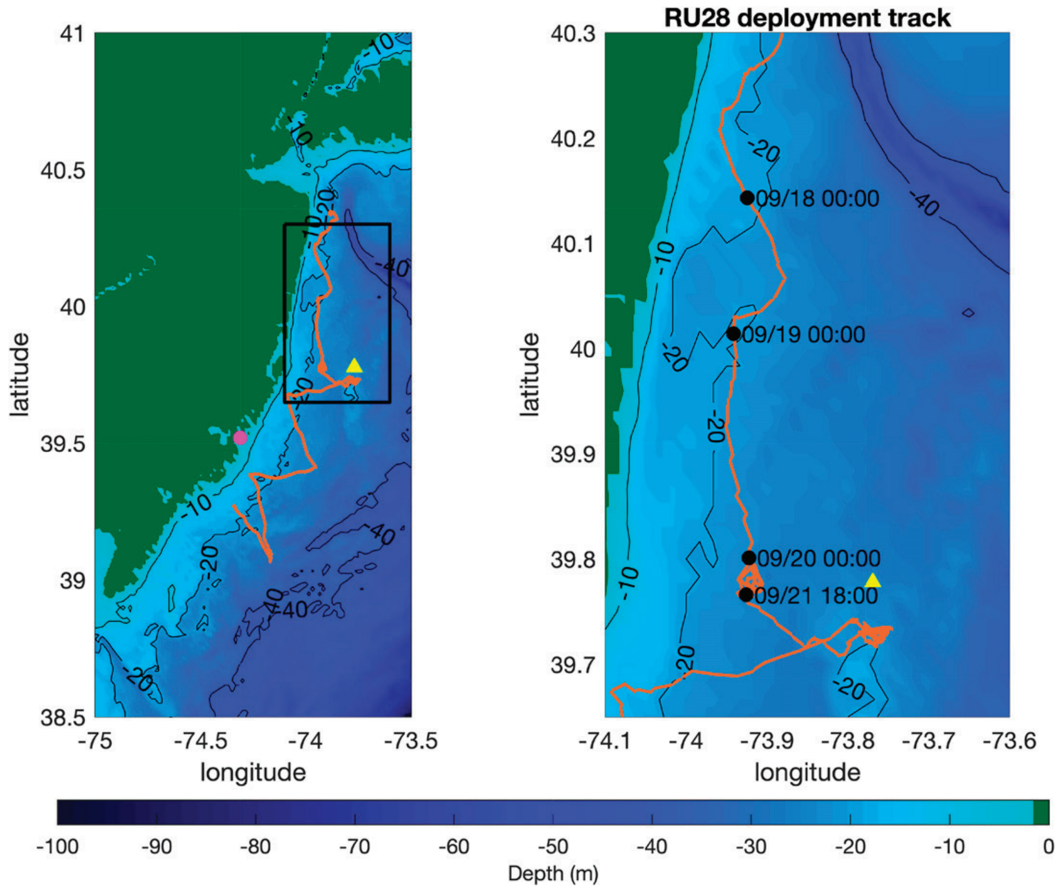

FIG. 2. (left) RU28's full deployment track in orange with the Rutgers University Marine Field Station Met Tower (magenta circle) and Buoy 44091 (yellow triangle); the black-outlined box represents (right) the zoomed area where the glider was located during the storm period.

New Jersey. These deployments target the autumn transition period (September–November) in late summer and early autumn. During this time, summer stratification leads to low oxygen in the bottom cold pool, a seasonal subsurface feature characterized by cold temperatures (<10°C) isolated from the atmosphere (Houghton et al. 1982). Extratropical cyclones, colloquially referred to as ''nor'easters'' or fall transition storms, pass through the region and incrementally erode stratification (Lentz 2017), redistribute oxygen and nutrients, and mobilize and transport sediment (Glenn et al. 2008).

Glider RU28 was a shallow water glider with a 30-m pump designed for rapid inflection at the surface and bottom. This gearing for shallow water allows it to maintain greater speeds at inflections and to more quickly return to a nominal flight speed. RU28 was equipped with a suite of sensors in addition to the LISST-Glider system. This included a Sea-Bird Scientific Co. pumped conductivity–temperature–depth (GPCTD) sensor; a Sea-Bird ECO Triplet that measured chlorophyll fluorescence, optical backscatter at 700 nm (bb700), and colored dissolved organic matter (CDOM); and an Aandera Data Instruments AS oxygen optode that measures oxygen concentration and saturation. These sensors are maintained and calibrated following an Environmental Protection Agency Quality Assurance Project Plan (QAPP) (Kohut et al. 2014) and following protocols detailed in the Mid-Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) Regional Information Coordination Entities (RICE) certification (https://maracoos.org/certification.shtml). This includes factory calibrations of the GPCTD and optode following manufacturer recommendations (calibration every 1–2 years), predeployment comparisons with laboratory-based instruments and measurements, and comparisons with calibrated instruments in situ at deployment and recovery.

c. Glider deployment

Slocum glider RU28 was deployed on 15 September 2017 and recovered on 3 October 2017, near Sandy Hook and Atlantic City, New Jersey, respectively (Fig. 2a). The glider carried out a nearshore survey with onshore and offshore zigzags near the 20-m isobath as it transited southward along the New Jersey coast. RU28 was programmed to surface at ~2-h intervals to obtain new waypoints, telemeter real-time data, and calculate dead-reckoned current velocities at sufficient resolution to resolve tidal variability. This resulted in 201 segments over 18 days with a mean of 60 profiles collected per ~2-h segment. The glider was piloted to collect data while

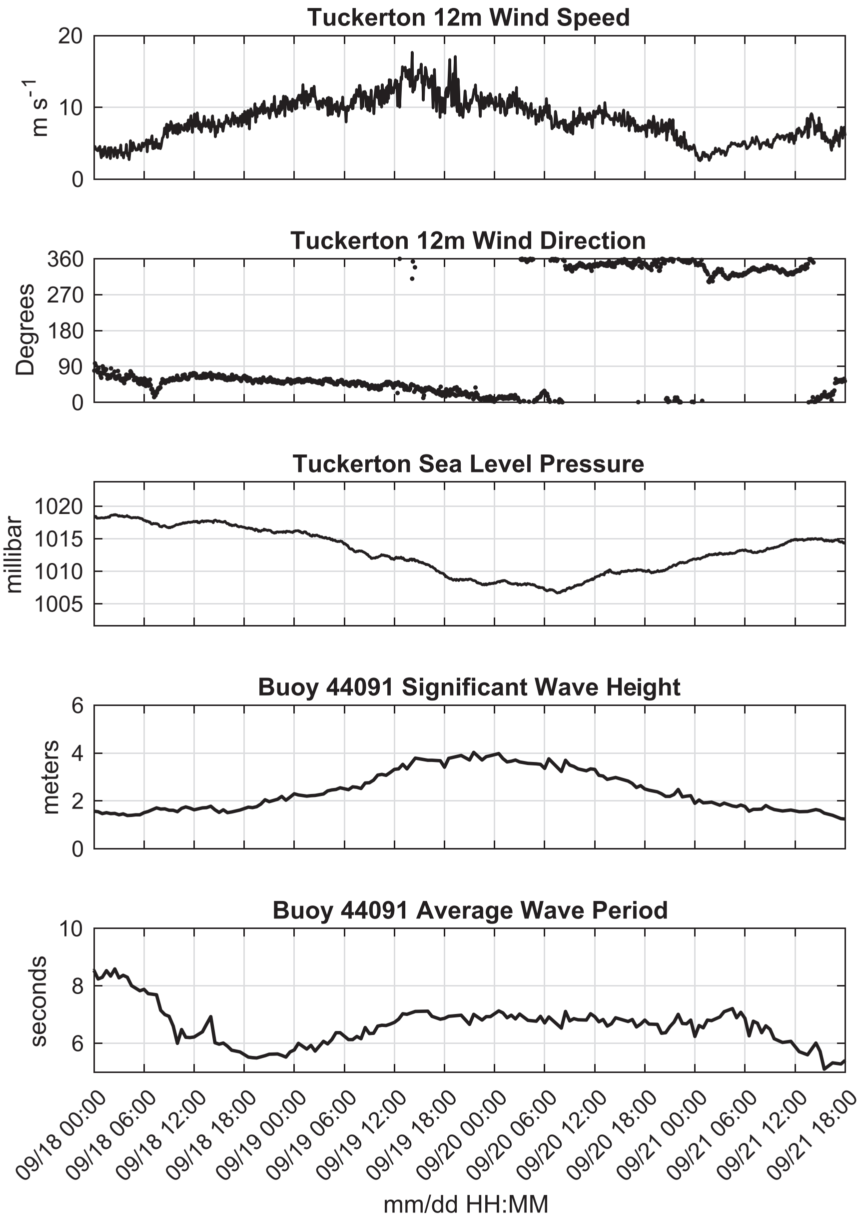

FIG. 3. The RUMFS Tuckerton Met Tower (top) wind speed, (top middle) wind direction from, and (middle) sea level pressure, and Buoy 44091 (bottom middle) significant wave height and (bottom) average wave period.

transiting for the majority of the deployment. However, a coastal storm event passed through the region on 18–22 September (Fig. 3). By 0000 UTC 20 September RU28 was programmed to hold position just offshore of the 20-m isobath at 39.78°N and 73.92°W (Fig. 2b) east of Barnegat Bay, New Jersey. This station-keeping location was approximately 45 km to the northeast of the Rutgers University Marine Field Station (RUMFS) Met Tower and 13 km west of National Data Buoy Center (NDBC) Buoy 44091. For the majority of this time period, the glider maintained a small watch circle (<2.5 km). Our analysis of the LISST-Glider output focuses on the short period from 0000 UTC 18 through 1800 UTC 21 September. This time period includes large vertical density gradients while the glider was in transit, and strong storm forcing during unstratified conditions while the glider was station keeping (Fig. 4).

d. Deployment site sediment characteristics

The sediment characteristics and resuspension processes throughout the region that RU28 sampled during the storm event has been extensively studied (Keen and Glenn 1995; Traykovski et al. 1999; Styles and Glenn 2002; Gargett et al. 2004; Styles and Glenn 2005; Glenn et al. 2008; Goff et al. 2008; Miles et al. 2013, 2015). These additionally include some of the earliest studies with the LISST (Agrawal and Pottsmith 2000; Agrawal 2005)

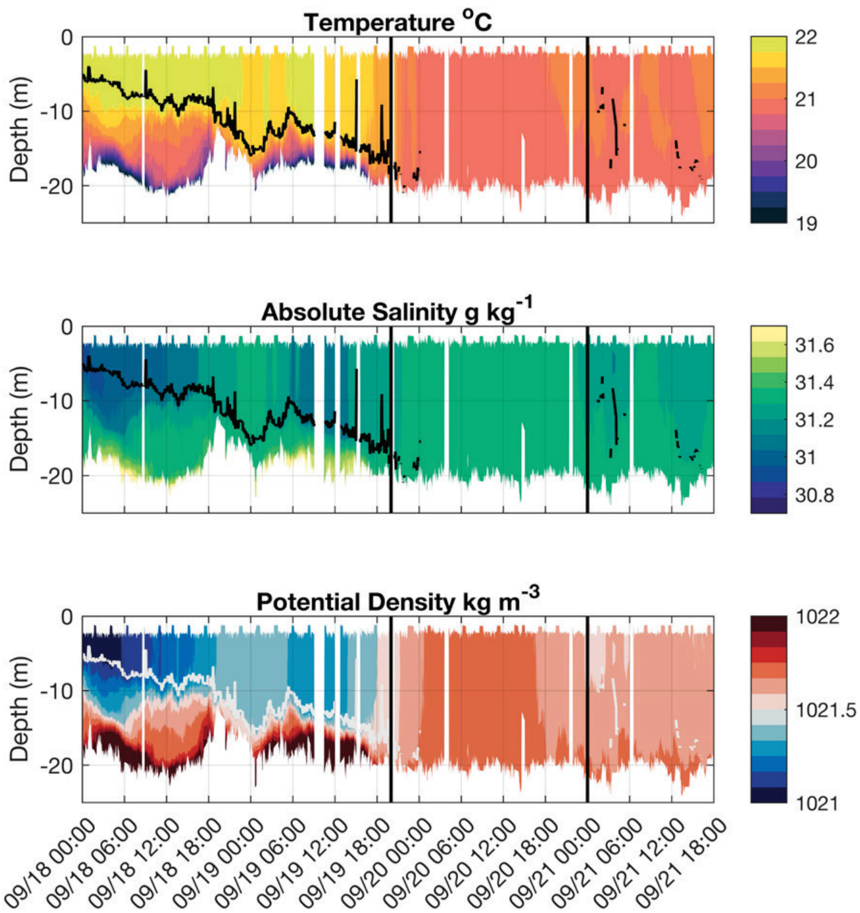

FIG. 4. Glider cross sections of (top) temperature, (middle) absolute salinity, and (bottom) potential density. Contour lines (black in the top and middle panels and gray in the bottom panel) represent the surface mixed layer depth. Vertical black lines represent the primary resuspension event time period.

deployed at the Long-term Ecosystem Observatory (LEO-15) site. These and other studies have characterized the New Jersey inner shelf as a region with a typically sandy bottom with median particle diameters of near 400 μm; however, significant patchiness exists (Goff et al. 2008; Miles et al. 2013) with typically larger grain sizes on the inner shelf to the north, and smaller to the south. For estimates of sediment transport in this study we assume particles during the main storm event are noncohesive sands with a density of 2650 kg m^{-3} when converting from volume concentration to mass concentration, ideally future LISST-Glider deployments should include in situ sampling of sediment type at deployment and recovery at a minimum, coincident with water column calibration information.

e. Meteorological and wave data

Wave data are from NDBC Buoy 44091 (39.78°N and 73.77°W), a Coastal Data Information Program (CDIP) buoy owned and operated by the U.S. Army Corp of Engineers with data provided by Scripps Institute of Oceanography. This system is a Datawell directional buoy (Mark 3) that collects wave energy, wave direction, and sea surface temperature. Significant wave height, wave period, and bottom orbital velocities were estimated following linear wave theory using measured spectra (Wiberg and Sherwood 2008), with bottom orbital velocities estimated at 20-m depth, the approximate water column depth during RU28's station-keeping time period.

Additionally, we use wind data from the RUCOOL-operated 12-m meteorological tower located near the RUMFS in Tuckerton, New Jersey. The tower is equipped with a suite of atmospheric sensors including an R. M. Young Co. sonic anemometer model 81000 mounted at 12 m above ground level. The sonic anemometer collects wind speed at 0.01 m s^{-1} resolution with an accuracy of 0.05 m^{-1} within the 0–30 m s^{-1} range. Wind direction measurements have a 0.1° resolution with a 2° accuracy at speeds of 1–30 m s^{-1}.

3. LISST-Glider postprocessing

a. Background correction

Typical ship-based LISST operations include clean water background measurements either before each profile, daily, or

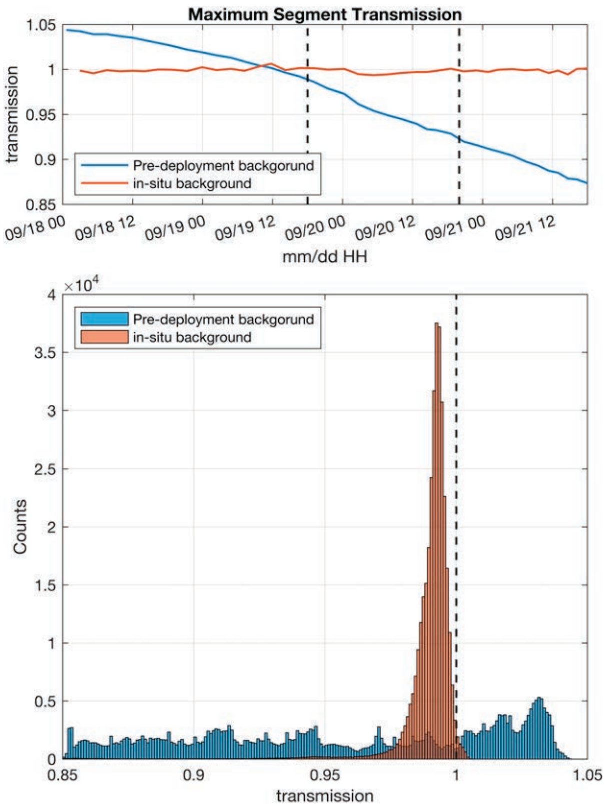

FIG. 5. (top) A comparison of the maximum transmission per ~2-h glider segment using only the predeployment background correction (blue) and the in situ correction method (red). The vertical black lines indicate the storm sediment resuspension time period. (bottom) Histograms of all transmission measurements using only the predeployment background correction (blue) and the in situ correction method (red). The vertical black line shows a value of 1 for reference.

as needed depending on environmental conditions. While this approach is not possible for an autonomously deployed vehicle, we demonstrate a method for carrying out in situ background corrections to account for biofouling and other mechanisms of sensor drift. LISST-Glider background measurements were taken in the laboratory predeployment on 13 September. The instrument windows were cleaned with lens paper and isopropyl alcohol, taking care not to scratch windows. The sample volume was covered with black tape to create a watertight dark chamber. In this case we used degassed deionized water for background measurements, although if it is available, for highest accuracy Sequoia Scientific recommends using filtered seawater from the study site, allowed to degas overnight if needed (Boss et al. 2018b; Agrawal and Pottsmith 2000). Sensor windows were visually inspected to ensure that no bubbles were present. Standard LISST background correction procedures were carried out according to the LISST-200X user's manual (https://www.sequoiasci.com). Three consecutive passing background measurements were taken before being saved to the instrument. Maximum transmission values using only the predeployment calibration from each segment are shown in Fig. 5 in blue. The resulting maximum transmission values show progressively decreasing transmission as well as initial transmission values greater than 1. The transmission values greater than 1 suggest poor laboratory calibration relative to in situ water clarity despite the methods noted above. The progressive decrease in transmission indicates some combination of fouling and sensor drift over time. Linear biofouling over time scales of a few weeks is not unexpected; see, for example, Manov et al. (2004). In their deployments with open sensors such as transmissometers and fluorometers without antifouling treatment, data showed level-1–3 biofouling over ~3 weeks, with stationary sensors.

To mitigate the progressive decrease in transmission, in postprocessing we utilize in situ data to carry out dynamic background corrections similar to those utilized by Barone et al. (2015). Specifically, for each glider segment we find the time point with the maximum transmission within each ~20-h period. If coincident bb700 measurements from the ECO Triplet were $< 0.005\,\mathrm{m^{-1}}$ the raw data were extracted and used as a background for that particular segment. Segments with coincident bb700 values $> 0.005\,\mathrm{m^{-1}}$ were contained to the main storm sediment resuspension period between 1800 UTC 19 and 2000 UTC 20 September. During this storm-sampling period, we interpolate background information linearly from the last segment before the resuspension event to the first clear segment following resuspension. The resulting values of maximum transmission are shown as a red line in (Fig. 5a), with the full distributions shown in the Fig. 5b. The maximum transmissions now plot at a horizontal line near one, and the full distribution of the in situ corrected data falls mostly between 0.95 and 1. Our focus for this study is on a large resuspension event; thus, we do not expect potential errors in in situ backgrounds to have significant impacts on our findings, and the correction far outweighs the alternative of using only the prestorm background correction. This approach should be used with caution when studying smaller concentrations in shallow water and will likely be more effective in deep ocean deployments with long durations of clear water measurements.

After background correction, we apply a four-point median filter on raw 1-s angular scattering data to remove measurements of spurious large particles. After filtering, angular scattering data were inverted into a volume PSD with a Sequoia Scientific–provided algorithm (Agrawal and Pottsmith 2000). We used the inversion kernel developed empirically for randomly shaped natural particles (Agrawal et al. 2008). All inversions were performed on the full-resolution datasets then linearly interpolated to align with glider science computer time stamps. The inverted solutions result in 36 log-spaced size classes from 1.00- to 500-μm diameters. We evaluate the impacts our correction method by comparing PSDs using only the predeployment background measurements, and after applying our dynamic in situ corrections. Volume concentrations are presented at three time points, ahead of the resuspension event at 1200 UTC 18 September, during peak sediment resuspension at 1200 UTC 19 September, and after sediment resuspension at 1200 UTC 21 September. Pre-event and postevent time points were bin averaged over 2 m at 5-m depth, and the storm time point was bin averaged at 19-m

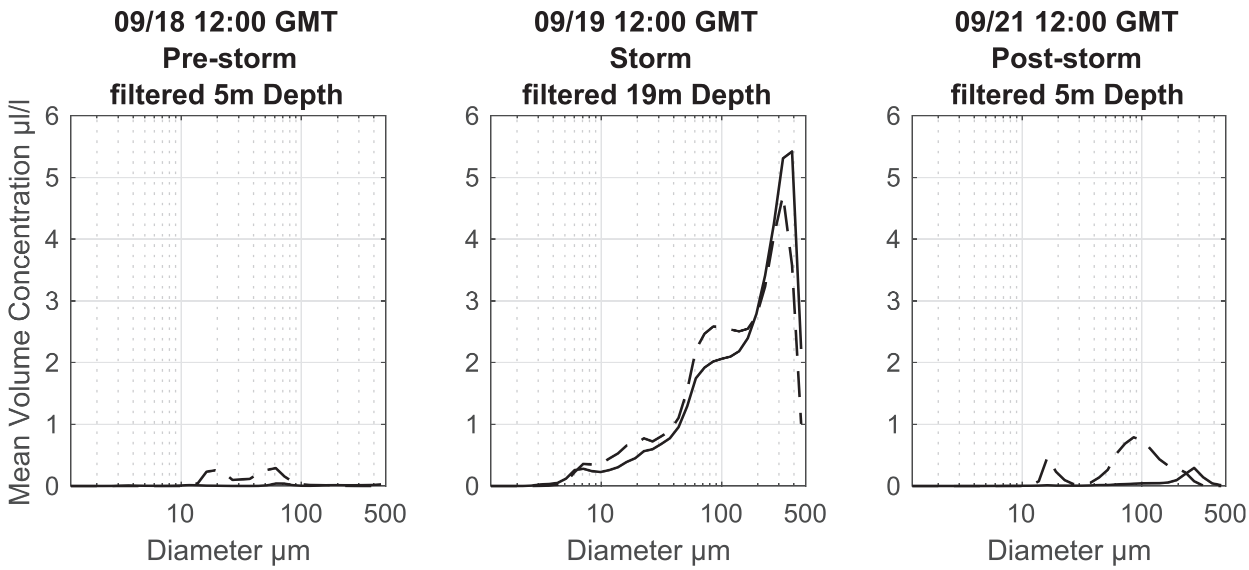

FIG. 6. Two-hourly and 2-m bin center-averaged mean volume concentrations at 5-m depth (left) ahead of and (right) after the storm event as well as (center) near the bottom at 19-m depth during the storm resuspension event.

depth, near the bed. Each bin was calculated as a center average in time over 2 h, containing between 44 and 96 samples each. These time periods and depths were selected in unstratified regions to limit potential schlieren impacts. Dynamic in situ background corrections show a clear removal with two peaks between 10 and 100 μm in all three time periods (Fig. 6). This persistent feature was likely due to contamination on the instrument windows during the prestorm background that was subsequently removed, or a scratch or persistent contamination throughout the deployment. Regardless of the correction, it is small relative to the observed resuspension signal shown in the middle time period (Fig. 6b). Future studies should utilize water and bottom sediment sampling at glider deployment and recovery to more clearly assess background corrections, specifically when sampling in time periods and locations with low concentrations. The remainder of this paper uses volume concentrations that have had the dynamic and interpolated in situ corrections applied.

b. Schlieren corrections

Microscale turbulent shear can lead to changes in index of refraction in proximity to large density gradients (Mikkelsen et al. 2008). This well-known effect, commonly referred to as schlieren, can result in measurement of forward scattering by optical instruments without the presence of suspended particles. In the LISST family of instruments this leads to elevated estimates of beam attenuation and the volume scattering function for the innermost ring detectors, corresponding with large particle sizes. Previous analyses have identified schlieren as contributing to increases in beam attenuation and increase in particle volume for buoyancy frequencies N ranging from 0.02 to 0.05 s^{-1} (Mikkelsen et al. 2008; Tao et al. 2017) with contamination likely outside these ranges in a variety of other field sites. A study (Styles 2006) using a type-C LISST identified schlieren effects on the nine innermost rings, corresponding to particle sizes greater than 128 μm. We calculate correlation coefficients of each of the 36 size bins with N during periods where N exceeded 0.02 s^{-1} to evaluate schlieren impacts on volume concentration estimates. This approach of calculating conditional correlation coefficients has similarities to Tao et al. (2017).

Total volume concentrations are plotted in (Fig. 7a). There are two distinct regions of elevated concentrations, beneath the pycnocline during stratified conditions (0000 UTC 18–2000 UTC 19 September), and throughout the unstratified time period during peak storm conditions (2000 UTC 19–0000 UTC 21 September). During the stratified time period, measurements of bb700 only show limited suspended particles ~1–2 m above bottom (mab) (Fig. 7c), while buoyancy frequencies are elevated throughout the entire bottom layer (Fig. 7b). This suggests that the observed total volume concentrations measured by the LISST in the bottom stratified layer may be contaminated by schlieren effects.

To evaluate particle size ranges that may be affected by schlieren, we compared volume concentrations from each LISST size bin with $N > 0.02\ s^{-1}$ (Fig. 8). During the full storm time period (0000 UTC 18–1800 UTC 21 September) correlation coefficients between volume concentrations and $N > 0.02\ s^{-1}$ (Fig. 8) were elevated between 0.2 and 0.6 for the four innermost rings, while all remaining sizes bins, both for $N < 0.02\ s^{-1}$ and $N > 0.02\ s^{-1}$, were uncorrelated (<0.1). These data indicate that schlieren effects are present during stratified conditions when bb700 values (not expected to be affected by schlieren) are low (Figs. 7b,c) and are not present when the water column becomes unstratified and the main storm-driven sediment resuspension event occurs. Scattering by density fluctuations scale with the Kolmogorov scale, mostly affecting inner rings. Thus, to mitigate the effects of schlieren on total volume concentration estimates, measurements from the four innermost ring detectors (particle diameters > 250 μm) were excluded from raw scattering data and inversion when N was

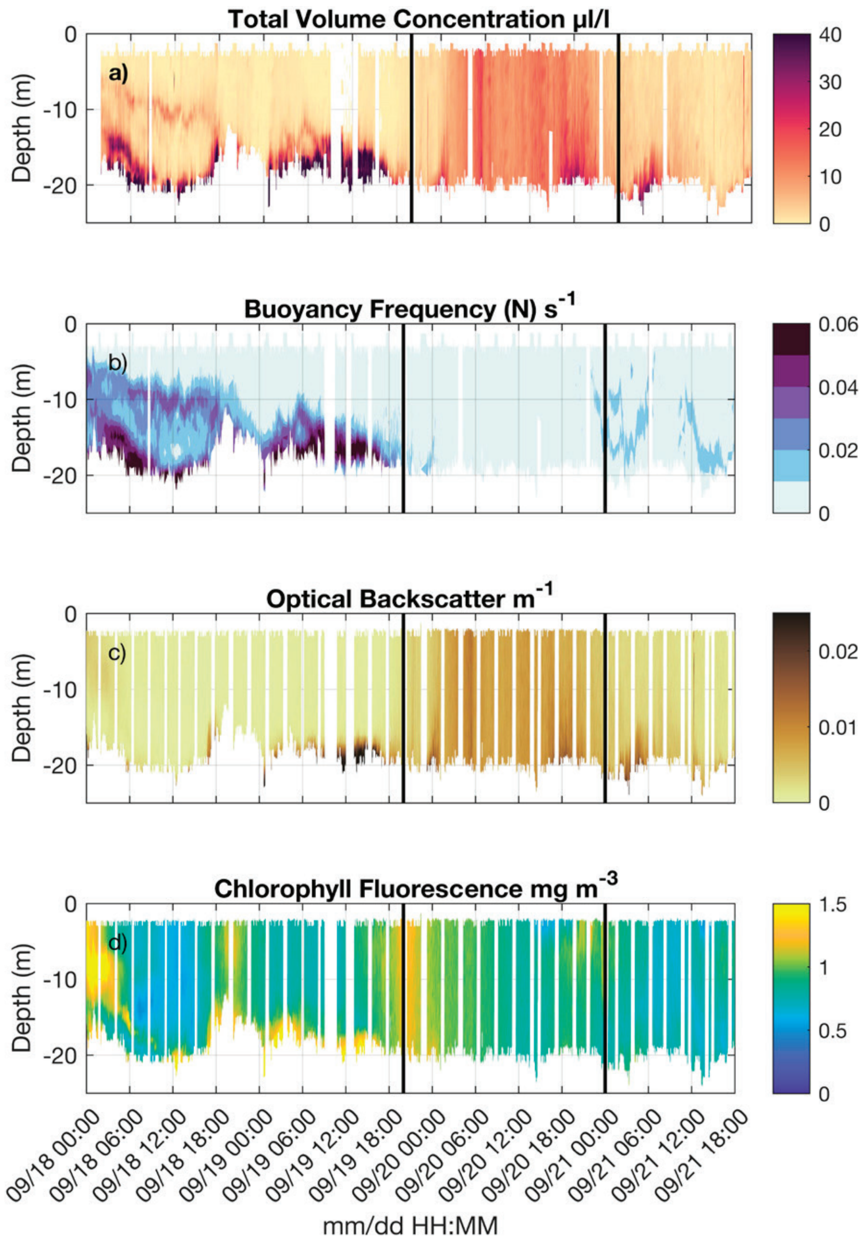

FIG. 7. Glider cross sections of (a) total volume concentration, (b) buoyancy frequencies, (c) optical backscatter, and (d) chlorophyll fluorescence. Vertical black lines represent the primary resuspension event time period.

greater than 0.02 (Fig. 9e) and thus are also not included as contributions to total volume concentrations throughout the remainder of the study (Fig. 9a).

4. Storm-driven sediment resuspension and transport

As described in section 2c, RU28 was programmed to station keep near Buoy 44091 and just offshore of the Tuckerton RUMFS meteorological station throughout the duration of an extratropical storm event. The storm event transited northeastward through the mid-Atlantic region typical of an early season nor'easter. Wind speeds (Fig. 3) measured at RUMFS showed an increase from 5 m s^{-1} on 0000 UTC 18 September to a peak near 15 m s^{-1} just after 1200 UTC 19 September. Winds rotated from due east to north throughout the storm event. Peak waves at Buoy 44091 coincided with peak winds, with significant wave heights reaching 4 m. Average wave periods were short, between 6 and 7 s, for the duration of the storm event. Wind and wave conditions gradually reduced to prestorm conditions throughout 20 and into 21 September.

During prestorm conditions at 0000 UTC 18 September the water column was vertically stratified (Fig. 4). The surface

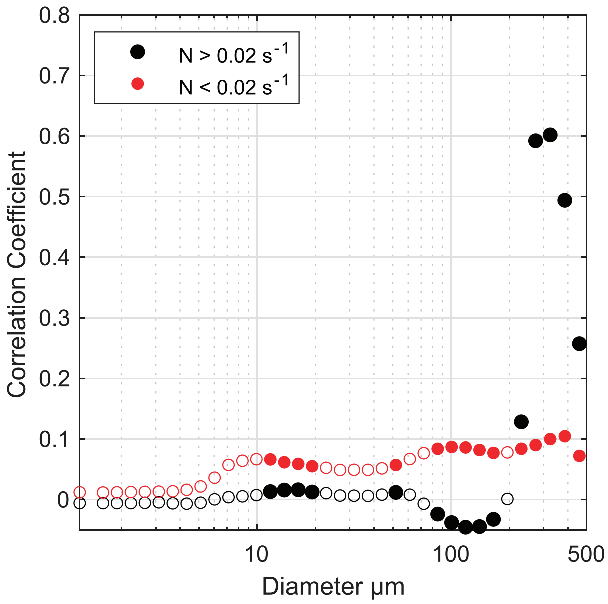

FIG. 8. Correlation coefficients between buoyancy frequency and scattering for each particle diameter measured. Analysis was separated out for values of $N < 0.02\,\mathrm{s}^{-1}$ (red) and $N > 0.02\,\mathrm{s}^{-1}$ (black). Closed circles are significant with $P > 0.05$.

mixed layer depth (SMLD) was calculated following Evans et al. (2018) using a vertical density gradient criteria of $0.1\,\mathrm{kg\,m^{-3}\,m^{-1}}$ to identify the base of the mixed layer. The surface mixed layer initially was found at 5-m depth on 0000 UTC 18 September and steadily fell until it reached the bottom on 1800 UTC 19 September. Above the SMLD temperature, salinity, and density were vertically uniform near 22°C, $30.9\,\mathrm{g\,kg^{-1}}$, and $1021\,\mathrm{kg\,m^{-3}}$, respectively. Below this surface layer the water column was continuously stratified with temperatures decreasing with depth to 19.5°C, salinities of $31.2\,\mathrm{g\,kg^{-1}}$, and densities of $1022\,\mathrm{kg\,m^{-3}}$. After 1800 UTC 19 September the temperature, salinity, and density were vertically uniform throughout the water column at 21°C, $31.1\,\mathrm{g\,kg^{-1}}$, and $1021.5\,\mathrm{kg\,m^{-3}}$ during this period. After 0000 UTC 21 September the water column began to restratify following the cessation of storm conditions. The near-bottom stratification ahead of the storm is characteristic of remnant bottom summer cold pool waters, which are seasonally eroded by storm-driven mixing and reductions in surface heat flux during the transition into autumn (Castelao et al. 2008).

With both background corrections applied and effects of schlieren removed we can now use the LISST-Glider data to evaluate storm-driven sediment resuspension and transport. Particle volume concentrations were binned according to phi unit size class ranges for silts (phi > 4 or grain sizes < 64 μm; Fig. 9b), very fine sands (phi 4–3 or 64–125 μm Fig. 9c), fine sands (phi 3–2 or 125–250 μm; Fig. 9d), and medium sands (phi 2–1 or 250–500 μm; Fig. 9e). On 2000 UTC 19 September, following water column destratification, total volume concentrations increased throughout the full water column (Fig. 9a) and remained elevated until 0000 UTC 21 September. Elevated concentrations were seen across silts, very fine, and fine sands, with little contribution from of medium sands to the total concentration. To demonstrate the uniformity of the distribution throughout the water column in more detail we calculate the mean particle size distribution in the surface (<10-m depth) and bottom (>10-m depth) during the initial peak resuspension period from 0000 to 1600 UTC 20 September. Distributions were nearly identical (Fig. 10a), suggesting either uniform turbulence throughout the water column, or more likely that turbulent buoyancy forces exceeded gravitational settling forces for the available sediment supply. During the end of the resuspension period between 1600 UTC 20 and 0000 UTC 21 September (Fig. 10b), surface and bottom particle size distributions showed elevated concentrations near the bottom and decreased concentrations in the surface layer for particle sizes > 72 μm. This indicates that, with weakening storm conditions, gravitational settling forces likely exceeded turbulent buoyancy forces for larger particles, and they began to fall out of suspension.

To evaluate the predicted ratio of turbulence to settling velocities we utilize the standard Rouse profile for resuspended sediment under neutral conditions (Glenn et al. 2008):

$$C(z) = C_r(z/z_r)^{[-\gamma w_f/(\kappa u_*)]}, \tag{1}$$

where $C(z)$ is sediment concentration at depth z, C_r is sediment concentration at a reference depth z_r, w_f is a settling velocity defined below, u_* is turbulent shear velocity, and γ and κ are constants. Von Kármán's κ is set 0.4, while γ is set to 0.8 (Glenn and Grant 1987). Equation (1) can be rearranged to solve for the ratio of settling and turbulent shear velocity:

$$w_f/u_* = -(\kappa/\gamma)\{\ln[C(z)/C_r]/\ln(z/z_r)\}. \tag{2}$$

The right-hand side of the equation can be obtained using the constants above and by taking the slope of a linear fit of the concentration profile in the unstratified region outside the bottom boundary layer. Two hourly-averaged profiles of potential density, total volume concentration, and bb700 are displayed at 3-hourly intervals between 2000 UTC 19 and 1700 UTC 21 September (Fig. 11) in semilog-y (density) and log–log (total volume concentration and bb700) space. We fit a line linearly in log–log space to values of the total volume concentration and bb700 in the bottom mixed layer, in this case contained to the lower 5 m of the water column. Profile fits where r-squared values were less than 0.3 (0500 and 1400 UTC 20 September) were not included. Settling velocities were estimated from the mean profile particle size at each time point (Fig. 11a) following the method of Soulsby (1997) for irregular grains:

$$w_f = \frac{\nu}{d}[(10.36^2 + 1.049D_*^3)^{1/2} - 10.36], \tag{3}$$

where ν is the kinematic viscosity of water, d is the grain diameter, and D_* is a dimensionless grain size:

$$D_* = \left[\frac{g(s-1)}{\nu^2}\right]^{1/3} d, \tag{4}$$

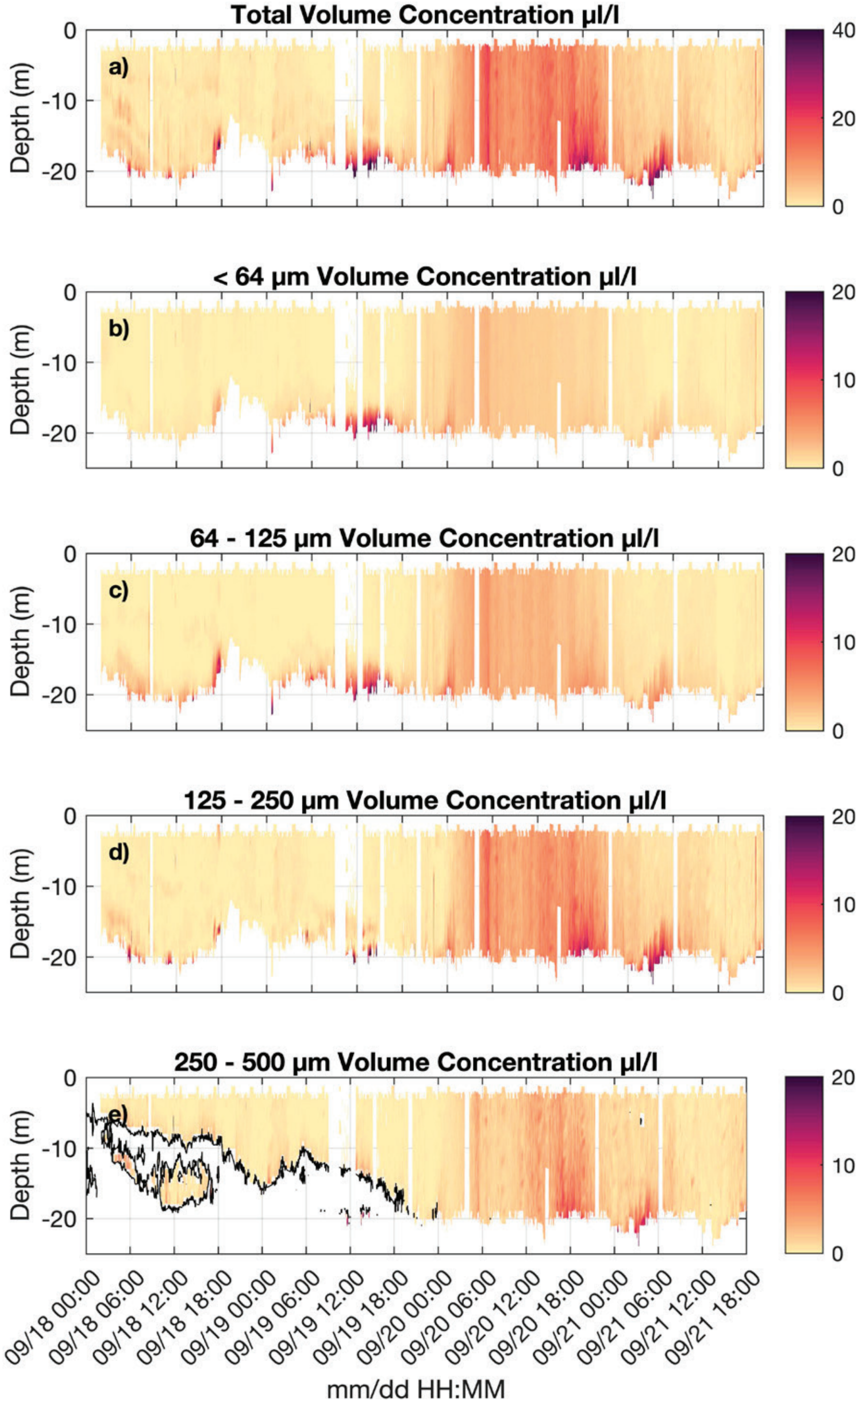

FIG. 9. Glider cross sections of (a) corrected total volume concentration and volume concentration (b) $< 64\,\mu$m, (c) between 64 and 125 μm, (d) between 125 and 250 μm, and (e) between 250 and 500 μm. The black contour in (e) denotes the region where $N > 0.02\,\mathrm{s}^{-1}$ and data were removed.

with g being the acceleration due to gravity and s the ratio of densities of sand and water. Solving w_f from the LISST mean grain size measurements and an assumed density of 2650 kg m^{-3} for the predominantly sandy site, leaves u_* as the only remaining unknown. We then solve Eq. (2) using slopes from both total volume concentration and bb700 fits for two estimates of u_*. Estimates of settling velocities for the fixed particle sizes of 150 μm (w_{f150}, the maximum observed mean particle size) and

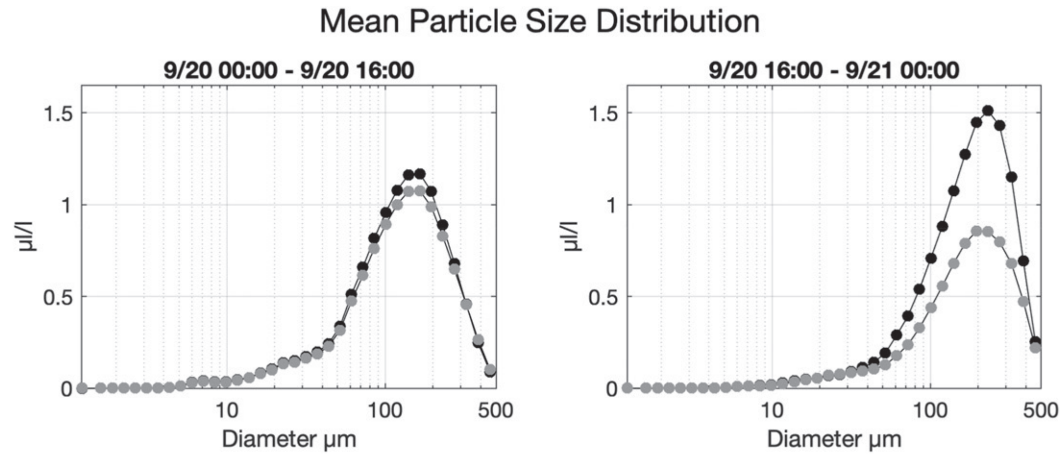

FIG. 10. Mean volume concentrations in the upper 10 m (gray) and below 10 m (black), showing (left) distributions during the initial resuspension phase and (right) distributions during the beginning of the settling phase.

500 μm (w_{f500}, the maximum size range sampled by the LISST-Glider) are plotted for reference on Fig. 11b.

There is good agreement between u_* estimates from both the LISST and ECO Triplet sensors for the majority of the storm forcing period with u_* reaching values of nearly 0.5 m s^{-1} at peak storm forcing. The good agreement between the slopes and u_* from the LISST and ECO Triplet suggest that both sensors have similar sensitivity to particle size for the unimodal sands sampled at this study site. This approach should be used with caution at other locations with different particle characteristics. At the first two time points (2000 and 2300 UTC 19 September), u_* was low below both w_{f150} and w_{f500}. Profiles show a limited bottom mixed layer extending up to 5 mab. Below this depth, slopes were shallow and the associated particle sizes were small, close to 50 μm. Between 0200 and 1400 UTC 20 September the bottom mixed layer extended throughout the full water column. Slopes of the total volume concentrations were steep and nearly vertical throughout this time period, corresponding to peak values of u_*, representing a significant increase in turbulence throughout the water column. As storm conditions are reduced after 1700 UTC 20 September the u_* values fall and profiles shallow consistent with sediment falling out of suspension. As mentioned above, these estimates of u_* and interpretation of the profiles are based on the solution for Eq. (1) under neutral conditions. As described in Glenn and Grant (1987), this assumption holds when the stability parameter z/L (with z being the depth and L the Monin–Obukhov length), multiplied by the constant $\beta \sim 4.7$ is $\ll$ than γ. We calculate $\beta(z/L)$ at the top and bottom of the fit profiles at 1 and 5 m following Eq. (43) presented in Glenn and Grant (1987) to evaluate the range of the potential stability parameters above the wave bottom boundary layer. The equation is adapted here where we use only the mean particle size estimate of fall velocity and the u_* estimated from the LISST-Glider only:

$$\frac{z}{L} = \frac{\kappa z}{u_*^3} g(s-1) w_f C(z). \quad (5)$$

Results are plotted in Fig. 11c and show that for all but four time points $\beta(z/L)$ at both depths is much less than γ, indicating that the neutral solutions are valid. Values of $\beta(z/L)$ were close to, or exceeded γ at four time points, 2000 UTC 19 and 0200, 1400, and 1700 UTC 21 September. All time points where assumptions of neutral conditions were invalid fell outside the main resuspension event, with the measurement 0200 UTC 21 September being associated with a peak in a secondary event (Fig. 9) seen across all size classes. This secondary event is an ideal candidate for future investigation of suspended sediment stratification, which is described in detail in Glenn and Grant (1987) but has not been previously observed in the field.

The above results and estimated sediment transport from the LISST-Glider are summarized in Fig. 12. Volume concentrations, plotted at three heights (5, 7, and 10 mab, Fig. 12a) show initially low concentrations despite high bottom orbital velocities (Fig. 12e), and high depth-averaged velocities (Fig. 12d). The elevated buoyancy frequencies (Fig. 12c) highlight that stratification likely restricts the full resuspension of sediment throughout the water column. As buoyancy frequency drops when the water column becomes unstratified, volume concentrations increase at all three depths. As bottom orbital velocities fall on 1400 UTC 20 September the concentrations at the three depths begin to separate, with elevated concentrations near the bed and reduced concentrations near the surface consistent with what was shown in Fig. 11 with sediment falling out of suspension. While all values fall by 0000 UTC 21 September, there is a brief increasing period for the near bed measurements that is timed with our findings that $\beta(z/L)$ exceeded γ, as described above. There are two main peaks in suspended load transport at 0300 UTC 20 September and approximately 12 h later at 1500 UTC 20 September. The peaks align with peak depth-averaged velocity and are consistent with the M_2 tidal period of 12.42 h, the dominant tidal constituent within the MAB. Tidal modulation of sediment transport is similar to what was observed in Glenn et al. (2008), with tidal forcing increasing resuspension and transport even after peak storm conditions. We do not expect these currents to be driven by inertial oscillations as the peaks appear with a frequency shorter than

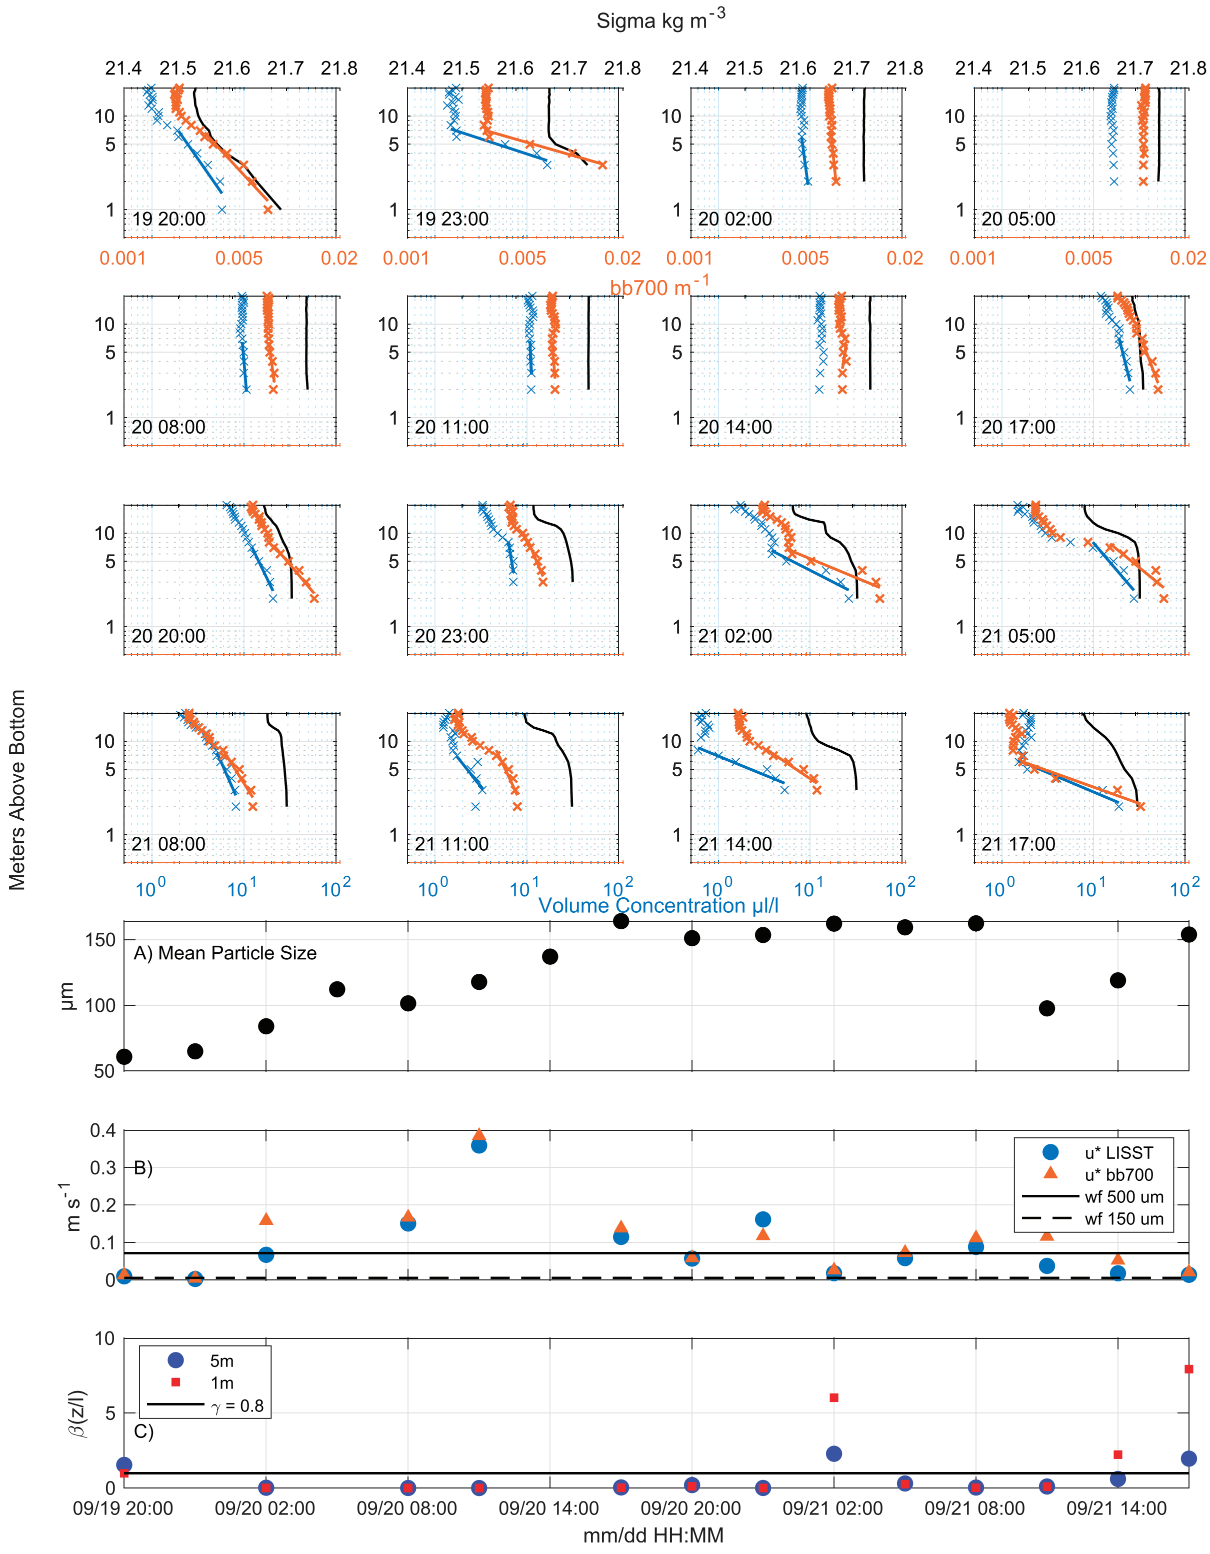

FIG. 11. (top) Hourly-averaged profiles at 3-h intervals of density in sigma units (black), bb700 (orange), and volume concentration (blue). Blue lines are linear regressions of volume concentration in the bottom mixed layer, excluding profiles where r-squared values are < 0.3. (a) The mean particle sizes averaged over the lower 5 m, (b) estimates of u_* derived from the linear fits to LISST total volume concentration profiles (blue) and bb700 (orange), with horizontal lines indicating fall velocities for particles of 500 (solid black) and 150 (dashed black line) μm, and (c) estimates of $\beta(z/L)$ at the 5-m depth (blue) and 1-m depth (red) with constant γ (horizontal black line).

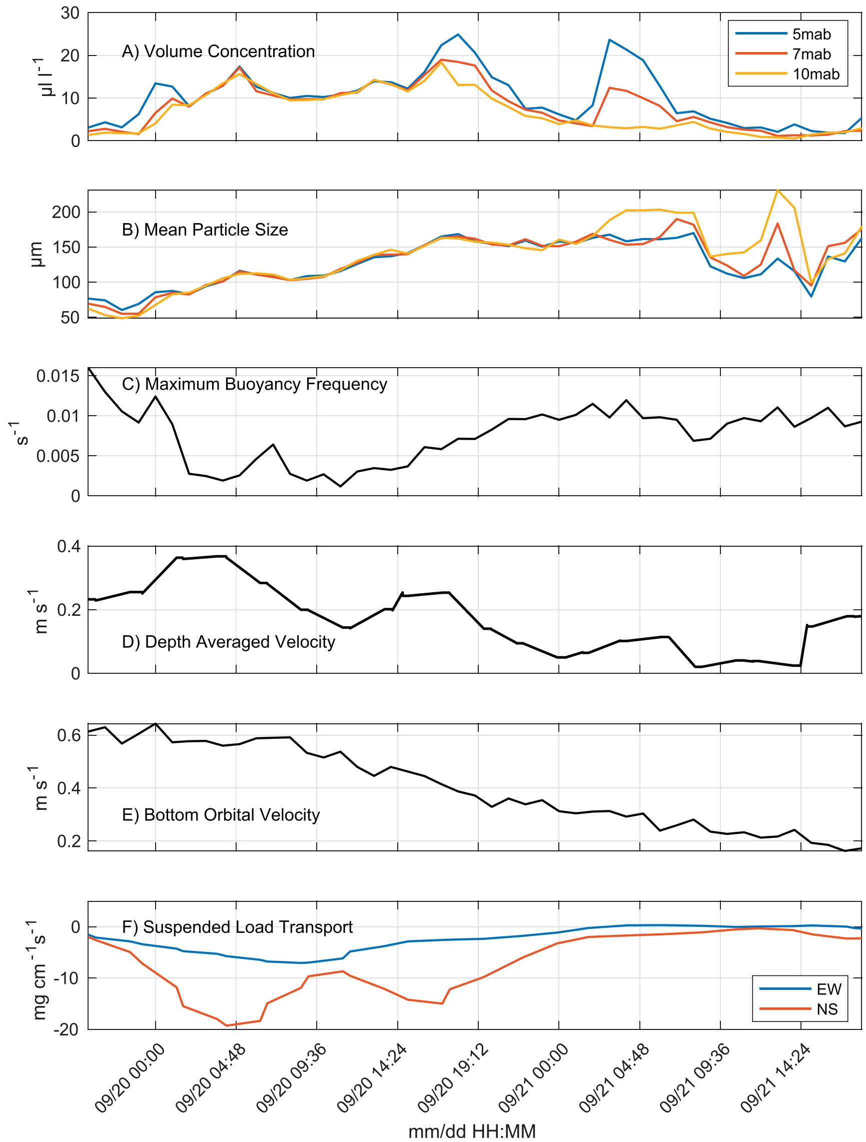

FIG. 12. Time series of (a) volume concentration and (b) mean particle size at depths of 5 (blue), 7 (red), and 10 (yellow) mab, (c) maximum buoyancy frequency, (d) depth-averaged velocity, (e) bottom orbital velocities at 44091, and (f) LISST-Glider estimated suspended load transport.

the local inertial period (~18 h). The total depth- and time-integrated suspended sediment load estimated for this particular event is 311 mg cm^{-1}, which is within the range of what has previously been estimated on the inner MAB shelf (Styles and Glenn 2005).

5. Discussion and conclusions

This study presents the first measurements from a Sequoia Scientific LISST integrated into an autonomous underwater glider and includes initial procedures for quality assurance and control on board this unique platform. This included implementation and demonstration of in situ background corrections similar to those for shipboard measurements (Barone et al. 2015). This combination of the LISST, along with additional optical sensors, on the glider platform allowed for a fuller description of the optical properties and sediment environment than previously deployed optical instruments on profiling gliders (Glenn et al. 2008; Miles et al. 2013; Many et al. 2016; Bourrin et al. 2015). This capability represents a significant advance in our ability to obtain detailed high-quality optical measurements from a single profiling sensor platform that was previously only possible from ship-based or moored platforms.

As an example of these capabilities, we characterized sediment resuspension and transport during a coastal storm on the MAB. A region regularly impacted by storm events and with a long history of sediment resuspension and transport studies (Styles and Glenn 2005; Agrawal 2005; Boss et al. 2004; Traykovski et al. 1999; Gargett et al. 2004). In addition to enabling in situ monitoring of sediment characteristics these data enabled us to infer bottom turbulent shear velocities based on the slope of the concentration and bb700 profiles combined with fall velocities from the mean particle size. These measurements and analyses will be particularly useful in calibrating sediment resuspension and transport models and their associated parameterizations, such as the Community Sediment Transport Model coupled to ROMS (Warner et al. 2010; Wu et al. 2011), which have been regularly used to study storm-driven sediment resuspension and transport (Warner et al. 2008; Ralston et al. 2013; Miles et al. 2015; Yang et al. 2015; Warner et al. 2017).

Despite these successes, limitations remain, in particular with regard to our ability to make regular background corrections with equivalent certainty as those used in shipboard or laboratory studies. Methods utilizing pre- and postdeployment background measurements and in situ data during optically clear conditions remain viable methods for determining vicarious background corrections and mitigating the effects of fouling over long-term deployments. Additional use of paired optical backscatter and fluorescence measurements are strongly encouraged to help interpret the effects of schlieren as well as to monitor potential biofouling, especially if LISST-Gliders are deployed for the full range of a glider's duration, from a month up to a year.

This study represents the first of these paired technologies, narrowly focused on storm-driven sediment resuspension. However, there are significant opportunities to expand these analyses with other paired bio-optical measurements to quantify additional particle characteristics, potentially including particle composition, shape, and color. In addition to other bio-optical sensors, coincident measurements with physical sensors such as glider-integrated acoustic Doppler current profilers or turbulent microstructure can enable better quantification of turbulent production and near bottom turbulent shear for resuspension studies. Even more promising is the use of LISST-Gliders as a distributed network to calibrate and validate satellite remote sensing over a broad array of conditions and environments for sustained periods. These advances will only be possible with continued collaboration and development among academic institutions, private companies, and a diverse set of federal and state funding agencies and laboratories.

Acknowledgments. This work was supported by the Office of Naval Research (ONR) Award N00014-16-1-2553 as well as a leveraged glider deployment supported by the New Jersey Department of Environmental Protection. The authors acknowledge the dedicated work of the engineers at both Sequoia Scientific, Inc., and Teledyne Webb Research in performing the sensor integration, as well as technicians at the Rutgers University Center for Ocean Observing Leadership. The Tuckerton Met Tower is maintained by Weatherflow, Inc. (https://weatherflow.com/), which includes biannual repair and maintenance. We give thanks to Oscar Schofield for providing commentary on early versions of the analysis presented herein. We also thank reviewers Emmanuel Boss, an anonymous reviewer, and the journal editor for their constructive and thoughtful comments and suggestions.

Data availability statement. Glider delayed-mode data, including onboard processed LISST data, are publicly available through a NOAA designed ERDDAP server hosted at the Rutgers University Center for Ocean Observing Leadership (http://slocum-data.marine.rutgers.edu/erddap/tabledap/ru28-20170915T1416-profile-sci-delayed.html). Real-time data from the deployment can be found within the NOAA Integrated Ocean Observing System (IOOS) glider Data Assembly Center (DAC; https://gliders.ioos.us/). Raw binary LISST data files were downloaded postdeployment and can be found via the open data repository Zenodo (https://doi.org/10.5281/zenodo.4325447).

***Abstract*— Ocean mixing by tropical cyclones (TC) can cool the sea surface and reduce heat flux from the ocean to the atmosphere ahead of the eye. This ahead of eye cooling has been shown to play a significant role in weakening as TCs translate over stratified, continental shelves. Typhoon Soulik weakened over the northern East China Sea prior to landfall at 8/23 14:00 UTC on the Korean Peninsula. This weakening was attributed to cooling of the sea surface ahead of the storm. Significant sea surface cooling was corroborated through a collaborative deployment of a Slocum underwater glider with the Korean Institute of Ocean Science and Technology. This glider collected data on the state of the ocean ahead of and throughout the duration of the forcing and observed 8°C of SST cooling. The glider was flown in the vicinity of a Korean Meteorological Association surface meteorological buoy, which collected data on wind and heat flux forcing on the ocean. This study investigates the physical mechanisms driving the ocean's response to this extreme forcing using the Price-Weller-Pinkel (PWP) one-dimensional ocean mixed layer model and an Oceananigans.jl Large Eddy Simulation (LES). An LES resolves turbulence in the flow field which allows for the study of its onset and evolution throughout the duration of the forcing. The configurations of PWP and the LES in this study are unable to capture the ocean's response to Typhoon Soulik which implies that there are processes critical to the response that are not captured by the models.**

Keywords—Underwater gliders, Large Eddy Simulation, Ocean mixing, Tropical Cyclones, Air-Sea interactions

I. Introduction

Tropical cyclones (TCs) are one of the costliest and deadliest natural disasters globally. In the US alone, damages have exceeded \$1 trillion USD and 6593 lives have been lost since 1980 [1]. Globally, the loss of life can be orders of magnitude larger with individual storms, such as Cyclone Nargis killing over 138000 people [2]. Coastal communities require days of advance notice to implement disaster mitigation plans such as coastal evacuations, thus it is vital that they have accurate information on both the track and intensity of approaching TCs. Over the last 40 years, there has been a marked improvement in forecasting TC tracks [3][4]. In spite of recent improvements in the accuracy of TC intensity forecasting in the US, the 72-hour forecast intensity error is ~15 knots which is equivalent to a difference between a Category 2 and a Category 3 hurricane on the Saffir Simpson Hurricane Wind Scale which is used to communicate risk to the public [5]. Additionally, these improvements have not been seen internationally by other TC forecasting agencies [3][6]. Error in intensity forecasts also leads to errors in prediction of storm surge and inundation caused by TCs.

TC intensity is coupled to the state of the surface ocean through fluxes of heat and momentum at the air-sea interface [7]. This heat and moisture cause local increases in buoyancy which incite convection in the eyewall of the TC, forming deep convective structures, and supporting intensification [8][9][10]. Surface wind speeds, the ocean state, and air-sea thermodynamic gradients control the magnitude of these fluxes to the TC [11][12][13]. TC intensity is also sensitive to atmospheric factors such as vertical wind shear and dry air intrusion [14][15][7], yet the state of the ocean and air-sea interactions remain a significant source of uncertainty in intensity forecasts of mature TCs [16].

While warm ocean temperatures can rapidly intensify TCs, ocean mixing can cool the sea surface and reduce heat flux from the ocean to the atmosphere ahead of the eye [11][17][18][19][20][21]. A cooled sea surface ahead of and under the eye can weaken the warm core of the TC which can weaken the storm [18][22][23]. Over stratified continental shelves, extreme ahead of eye cooling (> 6°C) has been shown to play a significant role in weakening TCs in the hours just before landfall [18][19][22]. In the case of Hurricane Irene, sea surface cooling was driven by entrainment processes including coastal downwelling causing shear at the pycnocline [18][20]. New studies using Large Eddy Simulations (LES) of the ocean under Hurricane Irene have additionally shown Ekman layer instabilities working to homogenize the surface layer with and Kelvin-Helmholtz instabilities at the pycnocline [24]. This rapid co-evolution of the ocean and TC intensity is a major challenge in TC intensity forecasting because the ocean and the storm change on the same time scale.

Typhoon Soulik (2018) translated across the Kuroshio Current into the East China Sea (ECS), eventually making landfall over the South Jeolla Province of the Republic of Korea [25][26]. The Kuroshio is a western boundary current with a deep, warm surface layer that persists year-round,

978-0-692-93559-0 ©2021 MTS

while the ECS is a seasonally thermally stratified, shallow sea located East of China and South of the Korean Peninsula [27]. Cold water produced during the winter in the Yellow Sea expands southward into the ECS forming Yellow Sea Bottom Cold Water. During the summer, surface heating enhances the thermal stratification in the ECS. The presence of the Yellow Sea Bottom Cold Water allowed Typhoon Soulik to cool the surface of the ECS by a maximum of 8.1°C [19]. Typhoon Soulik entered the ECS at its peak intensity of 950 mbar and weakened by 25 mbar as it slowly translated (Uh=~4 m/s) across the ECS toward land [25][26][19]. This weakening was attributed to the reversal of the enthalpy flux caused by cooling of the sea surface ahead of the storm's eye [19]. This cooling was driven in part by local mixing, but the drivers of the mixing have not been identified.

Ocean mixing under storm forcing is a long-studied topic that is still actively growing. A previous study in the open ocean has shown that ahead of eye cooling can be represented by a simple, one-dimensional shear mixing parametrization [28]. However, three-dimensional ocean models are required, in some cases, to capture TC-driven sea surface cooling because of the potentially important role of upwelling in slowly translating storms [29][30][21]. In this study, we propose that there are critical vertical mixing processes that drive the ocean's response to the forcing of Typhoon Soulik (2018) which are not captured by one-dimensional shear parameterizations. Typhoon Soulik induced significant ahead of eye sea surface cooling (7.4°C) which caused the storm to weaken [19]. We present novel observations of both the TC forcing, measured by a surface meteorological buoy, and the upper ocean cooling it caused, measured by an autonomous underwater glider. We employ both a one-dimensional mixed layer model and a three-dimensional Large Eddy Simulation to investigate what drove the ocean's response. Our aim is to identify the relevant physical processes that drove the observed sea surface cooling ahead of the eye of the storm which led to Typhoon Soulik's weakening hours before landfall.

II. Methods

A. Glider observations

Autonomous underwater gliders have been used in a number of studies to sample the ocean under extreme weather conditions [31][32]. Teledyne Webb Research (TWR) Slocum gliders move vertically through the water column at ~15-20 cm/s by adjusting their buoyancy using a pump in their fore section to draw in or expel ambient water. Wings and their nominal pitch angle of 26.5° allow them to use the changes in their buoyancy to move horizontally at a rate of ~20 km/d relative to the ambient current. As they glide through the water, they sample the ocean at a rate of 0.5 Hz, resulting in vertical data resolutions of < 1m. The glider used in the present study was a Slocum G1 system RU22 equipped with a Seabird Electronics (SBE) unpumped conductivity, temperature, depth (CTD) sensor; two SBE ECO-pucks with one measuring chlorophyll fluorescence, optical backscatter at 880nm, and colored dissolved organic matter concentration (CDOM); the second ECO-puck measured optical backscatter at 3-wavelengths (470,532, and 660 nm). The CTD was factory calibrated prior to deployment on March 17, 2017. The CTD data were used to calculate the potential temperature, practical salinity, and potential density using the GSW-Python package's implementation of the Thermodynamic Equation of Seawater 2010 (http://www.teos-10.org/publications.htm).

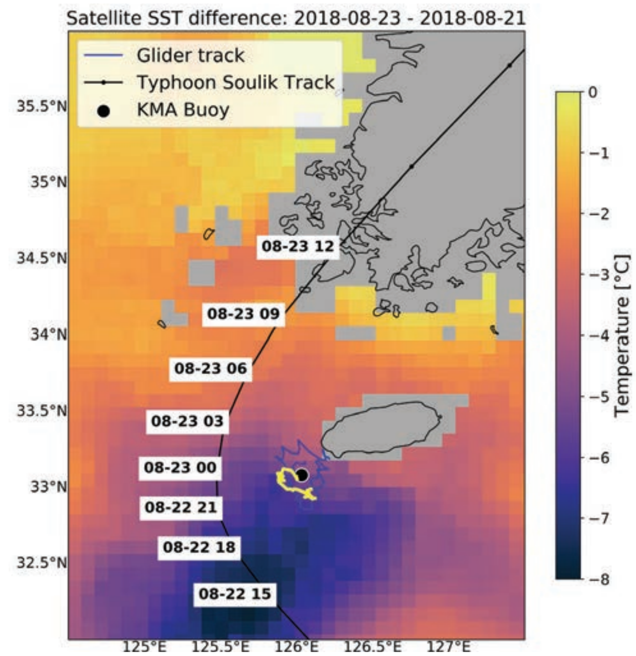

Fig. 1. A map of the study region with the track of Typhoon Soulik (black line), glider track (blue line) with the forced period highlighted (yellow line), buoy position (black circle), and change in SST from 8/21 to 8/23 in °C (color map) [25][26]

B. Additional observational datasets

The meteorological data presented in this study were collected by a Korean Meteorological Administration (KMA) buoy located southwest of Jeju Island Fig. 1. This buoy recorded hourly measurements of wind speed, wind direction, gust wind speed, atmospheric pressure, humidity, air temperature, sea surface temperature (SST), maximum wave height, significant wave height, average wave height, wave period, and wave direction. Based on the wind speed and atmospheric pressure data, we determined the forcing period of Typhoon Soulik at the buoy location to be 8/22/2018 00:00 UTC to 8/23/2018 04:00 UTC. Coefficients of drag and enthalpy flux were calculated from these data following [33][34][13]. Bulk thermodynamic fluxes of latent and sensible heat flux were calculated from these data following [35].

Satellite-derived SST provides a spatial context to the point observations of the glider and buoy. The satellite SST shown in Fig. 1 comes from a global, merged, multisensor, data product from Remote Sensing Systems (remss.com) following Fig. 1 in [19]. This product blends the through cloud measurements of microwave radiometers with the high resolution and near coastal infrared radiometer data. This is advantageous when assessing the change in SST under a large meteorological feature such as a TC. This product provides daily images of SST with a 9km resolution.

Identify applicable funding agency here. If none, delete this text box.

The best track data from the International Best Track Archive for Climate Stewardship (IBTrACS) were used to characterize the location and intensity of Typhoon Soulik over time [25][26].

C. Price-Weller-Pinkel model

This study employs the one-dimensional Price-Weller-Pinkel (PWP) ocean mixing model [36]. This idealized ocean mixing model has been used extensively to study ocean mixing during hurricane conditions [37][38][39][28][40]. PWP is initialized from user provided temperature and salinity profile and forced with either realistic or idealized wind stress, freshwater flux, heat flux, and current drag due to internal or inertial wave dispersion. The system uses both the bulk and gradient Richardson numbers to determine mixed layer stability and shear stability, respectively. The model uses the boundary conditions to solve the momentum equation for velocity, temperature, salinity. During the implementation of forcing, the model will check both stability criteria and if there is an instability present, the water column will be partially mixed until the criteria are satisfied.

In this study, one-dimensional PWP is forced at the surface by wind stress, latent heat flux, and sensible heat flux derived from the KMA buoy observations. The initial profiles of temperature and salinity are taken as the average profile of each parameter measured by the glider between 8/21 22:00 UTC and 8/22 00:25 UTC, averaged into 1m bins. The vertical resolution of the model is 1m with a full column depth of 100m and the model steps forward with 15-minute time steps. The model is not forced with freshwater flux due to data limitations. Model runs with drag from wave dispersion were tested, however results were insensitive to its inclusion and therefore are not described here.

D. Oceananigans.jl Large Eddy Simulation

This study utilizes the newly developed Oceananigans.jl Large Eddy Simulation (LES) (Ramadhan et al., 2020)(Oceananigans.jl) to investigate the physical mechanisms driving the ocean's response to the forcing of Typhoon Soulik. Oceananigans.jl is a flexible, user friendly flow solver based in the programming language Julia. Julia allows this modeling system to be controlled entirely through a script-based interface without the need for compiling or configuration files. Oceananigans.jl solves the Navier-Stokes equations under the Boussinesq approximation. Using an LES allows us to resolve the turbulence in the flow field and study its onset and evolution throughout the duration of the forcing. In this study, the Oceananigans.jl LES is forced at the surface by wind stress, latent heat flux, and sensible heat flux derived from the KMA buoy observations. These fluxes are applied uniformly over the horizontal extent of the domain. A no flux condition was used for salinity at the surface boundary. The initial profiles of temperature and salinity are taken as the average profile of each parameter measured by the glider between 8/21 22:00 UTC and 8/22 00:25 UTC, fit to the resolution of the model domain using a 1D spline interpolator. The full domain is initialized from the same initial profiles of temperature and salinity so there are no initial horizontal gradients. The vertical velocity was initialized with a random noise profile of $O(10^{-6})$ m/s to aid in model spin up. The domain extent in (x,y,z) is (32m, 32m, 84m) with a uniform resolution of 1m in each direction. For compactness and ease of comparison with PWP and the glider data, the LES output has been horizontally averaged at each time step. The maximum model timestep is set to 128s and the LES closure used is the Anisotropic Minimum Dissipation closure. The lateral boundary conditions are periodic. The model employs a linear equation of state to calculate buoyancy and we assume an f-plane because of the small horizontal scale of the domain.

III. Results

A. Observations

Glider RU22 was deployed off the southwest coast of Jeju Island, Republic of Korea on 8/14. The glider was deployed for 13 days and sampled in the vicinity of the KMA surface meteorological buoy Fig.1 throughout the duration of Typhoon Soulik's approach and landfall. At the buoy, wind speeds rose steadily starting from 8/22 00:00 UTC to 8/22 22:00 UTC reaching 24.3 m/s Fig. 2a and a minimum sea-level pressure of 975.9 hPa (data not shown). This coincides with the time of the closest proximity between Typhoon Soulik and buoy and we refer to this as eye passage [25][26]. Wind speeds begin to fall after eye passage. Both latent and sensible heat flux are positive (upward from the ocean to atmosphere) until 8/22 20:00 UTC, just two hours before eye passage, Fig. 2b. The glider observed 7.4°C of SST cooling ahead of the eye of the storm, Fig.2c. The most rapid period of cooling was 6 hours before eye passage, when the wind speed was near its peak value, Fig.2a.

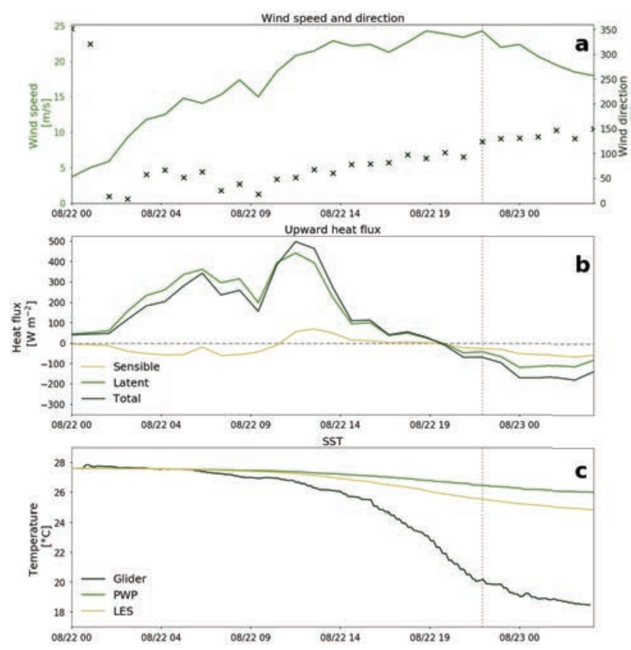

Fig. 2. Surface meteorological data from a Korean Meteorological Agency buoy deployed off the southwest coast of Jeju Island, Republic of Korea during the forcing period of Typhoon Soulik (2018). [a] Wind speed and wind direction reported as direction-from in degrees from North. [b] Sensible heat flux, latent heat flux, and their total enthalpy flux (positive into the atmosphere) with the horizontal dashed line indicating zero heat flux. [c] Sea surface temperature measured by the glider and modeled the PWP and LES experiments. In panels [a-c], the grey dotted line indicates the time of minimum Sea Level Pressure at the buoy location which coincides with the time of closest proximity to the TC.

The buoy and glider SST are misaligned ahead of eye as the buoy SST cools more slowly and steadily, but they converge 6 hours after eye passage.

Based on the observed glider profiles, Fig. 3b, we split the observed water column into three thermal layers separated by distinct thermoclines. To identify the depths of these thermoclines, we first average individual profiles into 1m depth bins and then calculate the vertical temperature gradient, $\partial T/\partial z$. We then employ a spike detection algorithm (scipy.signal.find_peaks) to identify local maxima in each profile of $\partial T/\partial z$. If any point in the profile has a value greater than both its neighboring points, it is labeled as a spike. We constrain this algorithm by requiring a minimum $\partial T/\partial z$ of 0.02°C/m [42] and that all spikes be at least 5m apart. This ensures that distinct thermoclines are detected. Now, with the list of distinct spikes, we chose the two most prominent spikes and recorded their position and magnitude which represent the depth and the strength of the thermoclines, respectively. We chose two spikes based on the observed, 3-layer structure of the initial temperature profiles.

We define the upper and middle layers by the interfaces shown in Fig. 3b. The upper layer deepened by 26m ahead of eye passage, while the middle interface oscillated, around 60m throughout the forced period. The mean layer temperature of the middle and bottom layers both remain nearly constant throughout the duration of the storm (data not shown).

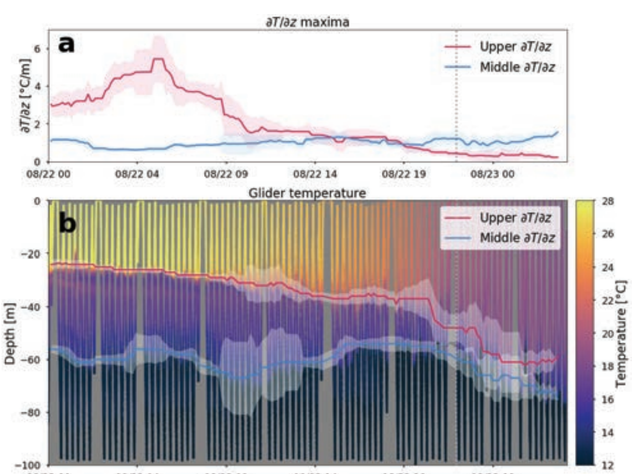

Fig. 3. [a] The maximum stratification at each interface over time with the upper interface in red and the middle interface in blue. These data were passed through a median filter with a 5-point moving window. [b] The observed temperature transect with the upper interface (red line) and the middle interface (blue line) depths marked for each profile. These interface depths were smoothed using a median filter with a 5 profile wide moving window. In both panels, the shading around each line indicates one standard deviation of each set of filtered points. Dotted line is as in Fig. 2.

Both the position and the strength of the interfaces are critical to understanding their evolution. Fig. 3a shows how the layers' stratification strength change over time. The upper interface reaches peak stratification at 8/22 06:00 UTC, 6 hours after forcing began. After its maximum, the stratification rapidly weakens until it falls below 1°C/m and the strength of the middle interface at 8/22 19:00. This is coincident with an increase in the standard deviation of the upper layer depth seen in Fig. 3b. The middle layer stratification remains relatively constant ahead of eye passage, near 1°C/m.

B. Model output

The maximum thermal stratification strength modeled by PWP, Fig. 4a, remains at its initial value until 10 hours into the experiment when it enters a cycle of strengthening and weakening. This cycle continues through eye passage and peak forcing (indicated by the vertical grey line) until it returns to its original value at 8/23 00:16. Both the PWP and the LES experiments showed a weaker SST cooling signal, Fig. 2c, and less change in the thermal structure of the profile, Fig. 4b and Fig. 5b, than was seen in the glider observations. The initial profile shows a maximum stratification at -25m, Fig. 4b, which indicates the upper layer depth. The upper layer begins to deepen 08/22 12:00 UTC and continues to deepen for the duration of the experiment, reaching -30m by eye passage, the dashed grey line in Fig. 4, and -35m by the end of the run at 08/23 04:00 UTC.

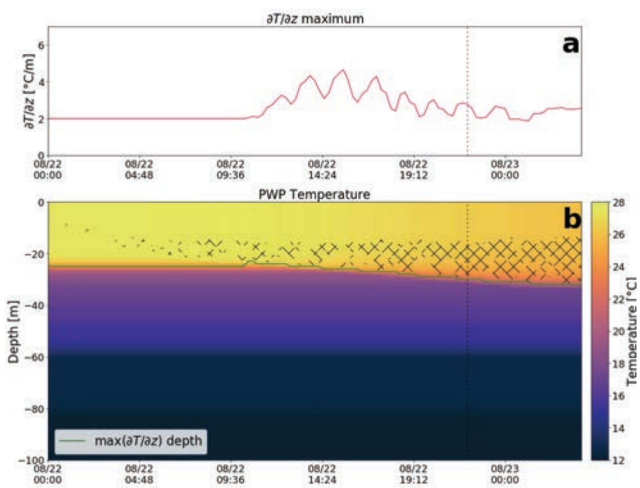

Fig. 4. [a] The maximum stratification strength in the PWP profile. [b] The temperature profile over time output by PWP. The depth of maximum stratification is indicated by the green line. The hatched area represents where the condition in (3) is met. Dotted line is as in Fig. 2.

Shear instabilities occur in PWP when the gradient Richardson number falls below 0.25. This criterion is transformed to (3) for convenience,

$$S^2 = (\partial u/\partial z)^2 + (\partial v/\partial z)^2 \quad (1)$$

$$N^2 = (g/\rho_0) * (\partial \rho/\partial z) \quad (2)$$

$$S^2 - 4N^2 > 0 \quad (3)$$

where g is the gravitational constant, 9.81 m/s^2, ρ_0 is a reference density of 1025 kg/m^3, ρ is the calculated density, and (u,v) are the velocities in the (x,y) direction. Areas of shear mixing are indicated by the hatched pattern in Fig. 4c. Shear mixing begins early in the run and the mixing region deepens and until 8/22 4:48. The mixing region then begins to widen, with the shallow extent maintain a depth near 15m and the deep extent tracking the depth of maximum stratification strength.

The maximum stratification strength captured by the LES experiment, Fig.5a, begins to weaken starting at 8/22 02:00 and reaches a minimum at 08/22 11:00. The LES shows the upper layer starting to deepen at 08/22 12:00, with a depth at eye passage of 35m, and a final depth of 39m by end of the run, Fig.5b. Shear mixing begins in the LES experiment immediately after the start in the surface 10m. The depth over which the mixing is occurring deepens until approaching the thermocline at 08/22 12:00 and then follows the thermocline depth until after eye passage.

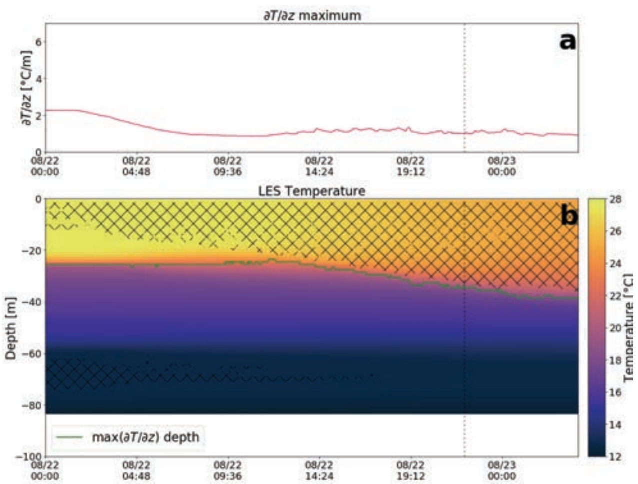

Fig. 5. [a] The maximum stratification strength in the mean LES profile. [b] The mean temperature profile over time output by the LES. The depth of maximum stratification is indicated by the green line. The hatched area represents where the condition in (3) is met. Dotted line is as in Fig. 2.

IV. Discussion

The observed and modeled responses of the ocean to Typhoon Soulik were vastly different. Both the PWP and LES experiments showed less SST cooling and less upper layer deepening than was observed by the glider. Additionally, neither model experiment captured the extent of the weakening of the observed upper layer thermocline with PWP showing an increase in the stratification strength over time and the LES experiment showing steady stratification after moderate weakening. These stark differences in the observed and modeled oceans' responses imply that there are processes causing changes in the upper layer that are not present in the model.

If we consider a one-dimensional water column, the initial observed profile can be described as a three-layer system with two thermoclines, shown in Fig. 3. Equation 4 details a temperature budget for the upper layer of this system, which is representative of the SST,

$$T_{upper,\,f} = Q/(c_p\, \rho_0\, a)\, \Delta t + 1/a\; K_T\, \partial T/\partial z\, \Delta t + F + T_{upper,\,i} \quad (4)$$

where Q is the total enthalpy flux at the surface in W/m^2, c_p is the specific heat of seawater 3850 J/(kg °C), ρ_0 is a reference density of 1025 kg/m^3, *a* is the upper layer depth, K_T is the thermal diffusivity, and Δt is change in time in seconds. The first term on the left-hand side (LHS) represents the change due to surface heat fluxes. Surface heat fluxes could cause warming or cooling of the upper layer, depending on the direction of the heat flux. The second term represents the change due to mixing across the interface between the upper and middle layers. *F* represents the change in the upper layer temperature due to advection, which we are not able to calculate directly from observations. $T_{upper,\,i}$ is the initial upper layer temperature. We will use this framework to identify the role of each process in the observed cooling of the upper layer.

Using the first term on the LHS from (4), a conservative estimate of the change in SST due to surface heat flux can be calculated by assuming the upper layer depth, *a*, is constant throughout the duration of the forcing. This is conservative because *a* deepens over time and the change in temperature due to heat flux is inversely proportional to *a*. The resulting change in the SST is on the order of 0.1°C. This shows that the role of the surface heat flux in changing SST in TC forcing is small.

In order to determine the role of vertical mixing in the change in the upper layer temperature, we employ a linear mixing model following [19],

$$T_{upper,\,f} = a/h\; T_{upper} + (h-a)/h\; T_{middle} \quad (5)$$

where *a* is the initial upper thermocline depth, *h* is the upper thermocline depth at eye passage, T_{upper} is the depth average temperature in the upper layer, and T_{middle} is the depth average temperature in the middle layer. $T_{upper,\,f}$ is the final average temperature of the upper layer after mixing. The linear mixing approach assumes that as the upper layer deepens, the entrained water is homogenized with the upper layer water. Using this model, the cooling due to vertical mixing is 5.1°C. This is more than double the cooling seen in the model results. This would imply that 2.3°C of the observed cooling was driven by other physical processes described in (4). However, if we take *h* to be the final depth of the middle layer then, the cooling due to vertical mixing is 7.4°C, which is the same amount of cooling observed in the glider SST. Approximately 3 hours before eye passage, the standard deviation of the upper layer depth begins to increase Fig. 3b as the strength of the stratification of the interface decreases, Fig. 3a. This indicates that the upper thermocline is less defined and may have been mixed away. These two linear mixing hypotheses provide us with a range of SST cooling due to vertical mixing of 5.1 - 7.4°C. Observations of the SST from the left-hand side of Typhoon Soulik show 6.2°C cooling with 70% attributed to vertical mixing [19].

Hurricane Irene was another case of storm driven mixing leading to massive ahead of eye SST cooling and weakening of the storm [18][20]. This ocean response was driven by coherent mixing structures working to (i) broaden the pycnocline and (ii) homogenize the upper layer [24]. Rapid rotation of the winds during the fast approach of Irene shut down the surface homogenization [24] but observations from Typhoon Soulik show a slow rotation of the wind vector, due to the slow translation speed of the storm, which may have allowed for the sustained surface homogenization seen throughout the duration of the forcing in Fig. 4d.

Although the PWP did not capture the observed response of the ocean to Typhoon Soulik, the experiment produced similar results as seen in [28] where a one-dimensional implementation of PWP captured the observed ocean's response to the wind forcing of Super Typhoon Nepartak. In both cases, shear mixing developed early in the experiment near the surface, the maximum stratification strength increased over the duration of the experiment, and the mixing region deepened and widened throughout the experiment. Super Typhoon Nepartak was a stronger and faster moving storm and the initial ocean profile had a deeper, broader initial pycnocline than in the Typhoon Soulik case [28]. These differences in initial conditions and forcing could explain the difference in the ability of PWP to capture the ocean's response. The shear in the wind driven flow was not able to overcome the stratification in the case of Typhoon Soulik. This implies that there were other sources of mixing such as surface gravity wave breaking, wave-current interactions, coherent mixing structures, or shear in the background flow. Future LES experiments on this case will investigate the roles of wave breaking, wave-current interactions, and coherent mixing structures.

V. Conclusions

In this study we see that Typhoon Soulik (2018) drove mixing that caused a massive amount of SST cooling ahead of the eye of the storm as observed by an underwater glider. The SST cooling, thermocline deepening, and thermocline weakening observed by the glider were not reproduced by the one-dimensional PWP or LES experiments. This leads us to conclude that processes not captured by these model experiments (i.e. surface gravity wave effects, coherent mixing structures, and shear in the ambient flow) were essential to the ocean's response to Typhoon Soulik. Our next steps will be to run LES experiments with surface gravity wave effects implemented.

Acknowledgments

The deployment of RU22 was possible through a collaboration between the Korean Institute of Ocean Science and Technology (KIOST) and the Rutgers University Center for Ocean Observing Leadership (RUCOOL) supported by a NOAA Joint Program Agreement (JPA) project. Satellite derived SST was acquired from http://www.remss.com/measurements/sea-surface-temperature/oisst-description/.

INTRODUCTION

In the United States alone, hurricanes have been responsible for thousands of deaths and over US$1 trillion in damages since 1980 (https://www.ncdc.noaa.gov/billions/). These impacts are significantly greater globally, particularly in regions with limited hurricane early warning systems and where large portions of the population live at or near sea level. The high socioeconomic impacts of tropical cyclones will increase with a changing climate, rising sea level, and increasing coastal populations. To mitigate these impacts, efforts are underway to improve hurricane track and intensity forecasts, which drive storm surge models and evacuation orders and guide coastal preparations. Hurricane track forecasts have improved steadily over past decades, while intensity forecasts have lagged until recently (Cangialosi et al., 2020). Hurricane intensity changes are influenced by a combination of large-scale atmospheric circulation, internal storm dynamics, and air-sea interactions (Wadler et al., 2021, and references therein).

Components of the sustained ocean observing system (e.g., profiling floats, expendable bathythermographs, drifters, moorings) are useful for understanding the role of the ocean in hurricane intensity changes. However, gaps in the ocean observing system, particularly collection of data near the air-sea interface and in coastal regions, boundary currents (e.g., the Gulf Stream, Kuroshio, among others), and areas with complex currents and seafloor topography (e.g., the Caribbean Sea), have led to difficulties in accurately representing upper ocean features and processes in numerical ocean models. Employment of uncrewed ocean observing platforms has begun to fill these gaps by offering rapid relocation and adaptive sampling of regions and ocean features of interest. These platforms include autonomous underwater gliders (Figure 1; Testor et al., 2019) and surface vehicles (Meinig et al., 2019). Uncrewed surface vehicles (USVs), such as saildrones and wave gliders, are systems designed for data collection in hazardous conditions. Data collected by these platforms have improved our understanding of upper ocean temperature and salinity stratification and mixing processes and are becoming critical in improving operational ocean and coupled air-sea hurricane forecast models (Domingues et al., 2021).

This paper provides a broad overview of the ongoing US hurricane glider project and details of a new effort with the Saildrone USV during the 2021 hurricane season. While this article focuses on the US East Coast, Gulf of Mexico, and Caribbean Sea, similar efforts are underway in Korea, the Philippines, Japan, and China, among other countries.

THE OCEAN AND HURRICANES

The ocean influences hurricane development through the transfer of heat and momentum across the air-sea interface (Le Hénaff et al., 2021; Wadler et al., 2021, and references therein). Warm sea surface temperatures are conducive to hurricane intensification while cool temperatures often lead to weakening. Research shows that upper ocean temperature and salinity ahead of and during hurricanes can evolve rapidly (Glenn et al., 2016). The evolution of the upper ocean depends on various factors, including wind speed and direction, wave state, upper ocean stratification, and interactions with the coastal ocean, among others. To accurately forecast hurricane intensity in the western Atlantic, coupled ocean and atmosphere operational forecast models must resolve large-scale warm ocean currents (e.g., the Gulf Stream, the Gulf of Mexico Loop Current, and their associated meanders and eddies; Todd et al., 2018); freshwater layers from large rivers such as the Amazon-Orinoco and Mississippi (Domingues et al., 2021), which can inhibit ocean mixing and maintain warm upper ocean temperatures ahead of storms; and shallow

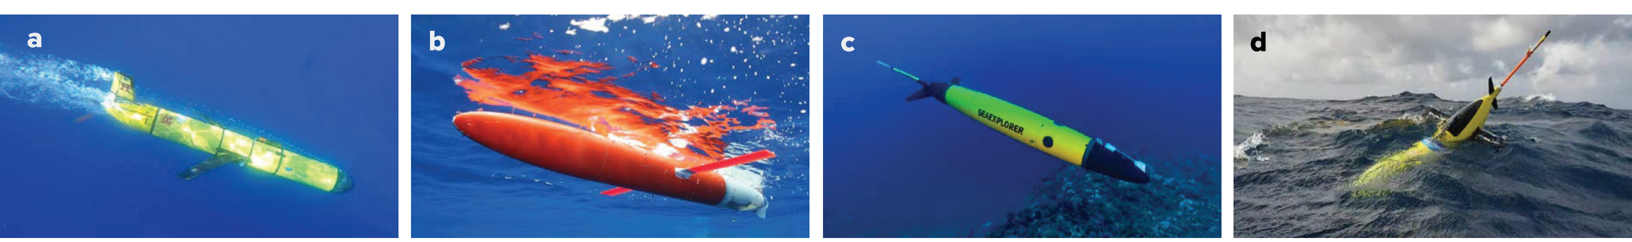

FIGURE 1. Underwater gliders: (a) Slocum. (b) Spray. (c) SeaExplorer. (d) Seaglider. For more information on gliders, go to https://ioos.noaa.gov/project/underwater-gliders/. *Photo credits: (a) Matt Souza, University of Virgin Islands (b) Robert E. Todd, WHOI (c) ALSEAMAR (d) NOAA AOML*

continental shelf features like the Mid-Atlantic Cold Pool, a cold bottom water mass that can rapidly mix to the surface and weaken storms before landfall (Glenn et al., 2016). New technologies such as uncrewed ocean gliders and surface vehicles, alongside more established components of the Global Ocean Observing System (e.g., Argo floats, air-launched expendable bathythermographs, and satellite sensors), will improve existing hurricane forecast and warning systems and support critical research to develop the next generation systems.

UNDERWATER GLIDERS

Gliders (Figure 1) have emerged as a major component of US and international multi-hazard warning systems. Since 2014, the operation of gliders for hurricane research and forecasts has been a joint effort by the US National Oceanic and Atmospheric Administration (NOAA), the US Integrated Ocean Observing System (IOOS) Regional Associations, academic institutions, the US Navy, the National Science Foundation, private companies, and other regional and international partners. Gliders are unique in their maneuverability, able to profile through the water column as deep as 1,000 m with vertical and horizontal speeds of ~10–20 cm/s and ~25 cm/s, respectively. Standard glider sensor packages include temperature, salinity, and density, while some gliders also collect profiles of water speed and direction. Biogeochemical measurements can include oxygen, phytoplankton, and particle concentration for water quality assessment. Numerous advanced sensor packages continue to be developed and integrated. Gliders can collect data as frequently as every two seconds, providing submeter-scale measurements in the vertical, though lower sample rates are typically used to conserve power and minimize surface time.

While opportunistic glider deployments were carried out for hurricane research in the first decade of this century, coordinated regional fleets were first used for hurricane research and operational model development in 2014. These experiments were supported by the congressionally authorized Disaster Recovery Act following the devastation of Superstorm Sandy in October 2012. Studies from this time period (Glenn et al., 2016; Domingues et al., 2021, and references therein) demonstrated the unique capabilities of gliders to contribute to our understanding of ocean feedbacks on hurricane intensity and to the improved accuracy of coupled hurricane model forecasts.

Following the coastal impacts of Hurricanes Irma and Maria in 2017, large multi-institution fleets of gliders have now been deployed to collect data. These efforts, and other leveraged glider observations, have resulted in over 280 deployments, collecting nearly 600,000 ocean profiles during 13,000 glider days in hurricane seasons from 2018 to 2021 in the open Atlantic Ocean, the Caribbean Sea, the Gulf of Mexico, and off the US East Coast (Figure 2).

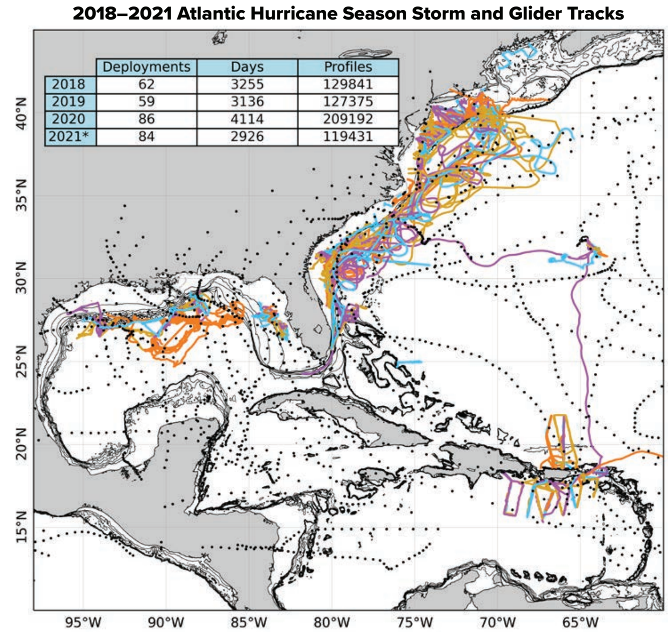

FIGURE 2. Glider tracks from the 2018 (orange), 2019 (purple), 2020 (yellow), and 2021* (blue) hurricane seasons (May to November) generated with data from the Integrated Ocean Observing System Glider Data Assembly Center (https://gliders.ioos.us), with an overlay of tropical cyclone tracks (black dots) from the International Best Track Archive for Climate Stewardship (IBTrACS, https://www.ncdc.noaa.gov/ibtracs/). The table in the upper left indicates the yearly breakdown of glider deployments, glider days at sea, and collected profiles. (*2021 data were extracted on 09/17/2021 prior to the completion of the Atlantic hurricane season.)

These gliders were strategically deployed in regions with high probabilities of hurricane passage, near ocean features that impact hurricane intensity, and near vulnerable coastal population centers.

Gliders have collected data in the ocean under more than 30 Atlantic tropical cyclones. These data are provided to the publicly accessible IOOS Glider Data Assembly Center (DAC; https://gliders.ioos.us), where they are accessed in real time and distributed through the World Meteorological Organization Global Telecommunication System (GTS). This distribution pathway allows NOAA to access the glider profiles for assimilation into the operational numerical models, such as the global Real Time Ocean Forecast System, used to initialize the ocean component of coupled hurricane forecast models such as the NOAA Hurricane Weather Research and Forecasting model.

A data impact study of Hurricane Maria (2017) showed that, out of the suite of in situ ocean observing platforms, glider data locally generate the largest error reduction in intensity forecasts within NOAA operational forecast models (Domingues et al., 2021). Additional model improvements were achieved when glider data were used alongside other ocean observations (Halliwell et al., 2020). Gliders have also contributed to new understanding of hurricane-forced coastal ocean circulation (Glenn et al., 2016), impacts on boundary currents (Todd et al., 2018), ahead-of-eye mixing processes (Glenn et al., 2016), and impacts of these processes on hurricane intensity. With the development of new sensors and public data repositories, gliders additionally contribute to the understanding of regional ecosystems, fisheries, water quality, harmful algal blooms, ocean warming and climate change, and renewable energy, among other coastal processes, stressors, and solutions.

A NEW UNCREWED SURFACE VEHICLE FOR HURRICANE OPERATIONS AND RESEARCH

To continue making significant progress toward understanding and predicting hurricane intensity changes, new technologies are being tested to provide improved estimates of air-sea fluxes in a hurricane environment. Efforts by public-private partnerships have rapidly advanced development of USVs into air-sea interaction observing platforms (Meinig et al., 2019). The use of renewable wind, surface wave, and solar energy for propulsion and instrumentation has increased USV endurance up to 12 months and enabled installation of more sensors (Zhang et al., 2019). Specifically, Saildrone USVs (Figure 3) are equipped with 15 sensor packages that measure 22 essential ocean and climate variables, such as sea surface temperature, salinity, oxygen, wave height and period, near-surface winds, air temperature, relative humidity, solar and longwave radiation, and barometric pressure (Zhang et al., 2019).

During the 2021 hurricane season, NOAA supported for the first time deployment and operation of five specially designed Saildrone USVs to measure air-sea interaction in regions where Atlantic tropical cyclones occur frequently. Compared to conventional Saildrone platforms, these extreme weather systems have shorter wings for increased stability, allowing them to operate in hurricane-force winds and in the presence of large breaking waves (Figure 3). For the 2021 mission, the five extreme weather Saildrone USVs were strategically located in regions of the western tropical Atlantic, the Caribbean, and near the US East Coast to maximize the probability of encountering at least one hurricane or tropical storm. The USVs continuously measured properties in the near-surface atmosphere and ocean and transmitted one-minute averaged data to the GTS and data centers in real time for assimilation into forecast models and for other public use.

The extreme weather Saildrone USVs travel at speeds of about 30–150 km per day, depending on winds and currents, and can be directed to locations directly in tropical cyclone paths. For example, during the 2021 mission, Saildrone SD-1031 traveled 35 km to the east during the 24 hours before the arrival of Hurricane Henri, bringing it within 50 km of the eye of the storm. The ability to move the USV into storm paths increases the chances of acquiring ocean-atmosphere measurements in high-wind conditions. These measurements are extremely valuable because the rates of heat and momentum exchange between the ocean and tropical cyclones, and storm dependence on the states of the ocean and atmosphere, are not well known, in part because there are so few measurements. The highlight of the mission was the passage of Category 4 Hurricane Sam directly over Saildrone SD-1045 on September 30 (Figure 4), when winds up to 56 m/s (at a height of 5 m) and waves as high as 14 m were recorded in the hurricane's northern eyewall. Saildrone SD-1045 then traveled across the eastern edge of the eye and through the southern eyewall, recording the first-ever video from the sea surface of the eyewall of a major hurricane (https://www.saildrone.com/press-release/ocean-drone-captures-video-inside-category-4-hurricane).

During the August–October 2021 Atlantic hurricane mission, two other tropical storms passed close to saildrones: Grace passed directly over Saildrone SD-1048 south of Puerto Rico, and Fred passed about 140 km to the north of the same saildrone. When they were not being directed toward tropical cyclones, the mission scientists worked with Saildrone Inc. pilots to keep four of the Saildrone USVs close to gliders to obtain nearly collocated measurements of the upper ocean and near-surface atmosphere (Figure 4). In addition, NOAA's hurricane reconnaissance aircraft acquired collocated profiles of atmospheric

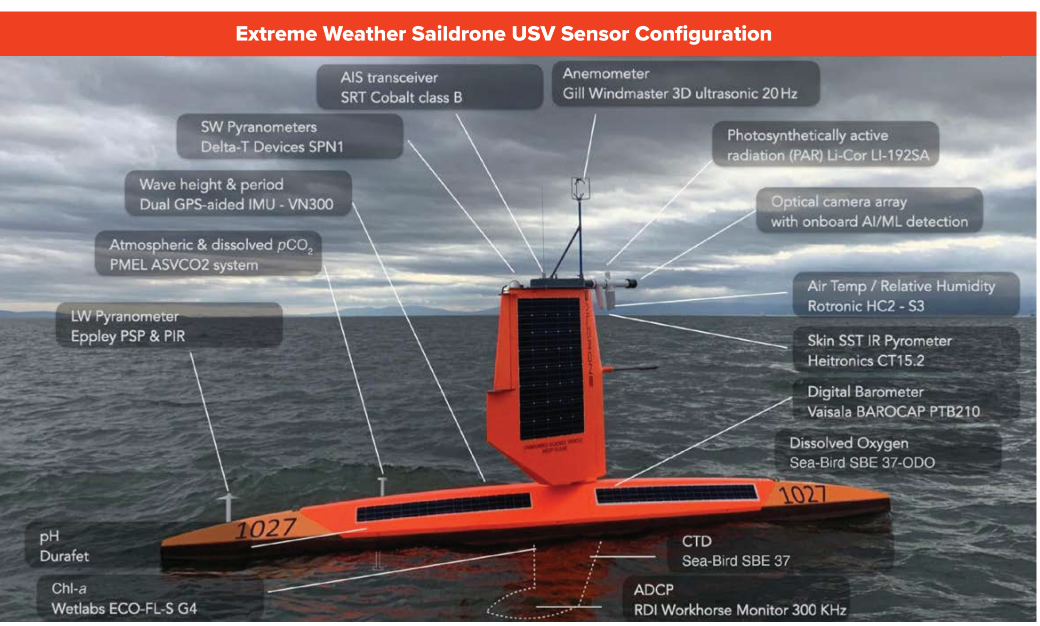

FIGURE 3. Extreme weather (short-wing) Saildrone and its measurement capabilities (https://www.saildrone.com/news/what-is-saildrone-how-work).

temperature, humidity, and winds from dropsondes together with ocean temperature profiles collected from air-launched expendable bathythermographs in Hurricane Henri. NASA aircraft also launched dropsondes near some of the Saildrone USVs during its Convective Processes Experiment – Aerosols & Winds (CPEX-AW) field campaign. These unique data sets will be valuable for advancing knowledge of interactions between the subsurface ocean and tropical cyclones.

CONCLUSIONS

Both autonomous underwater gliders and uncrewed surface vehicles such as saildrones represent advanced ocean observing technologies that are revolutionizing both our understanding of and ability to forecast hurricane track and intensity. To realize their full potential, these technologies will continue to be more closely integrated with established regional and global ocean and atmosphere observing platforms. One of the main objectives of these projects during the 2021 Atlantic hurricane season was to obtain collocated and simultaneous measurements of the upper ocean and air-sea coupling within a hurricane. These combined observations will provide new insights into the coevolution and coupling of the ocean and atmosphere to better predict storm intensity. Future hurricane observations should encourage more closely coordinated deployments of underwater, near-surface, and airborne observations in order to better understand rapid hurricane intensity changes. As ocean, atmosphere, and coupled model architecture and data assimilation capabilities continue to coevolve and improve, these observing systems and their shoreside cyberinfrastructure will become critical components of operational forecasting systems in the United States.

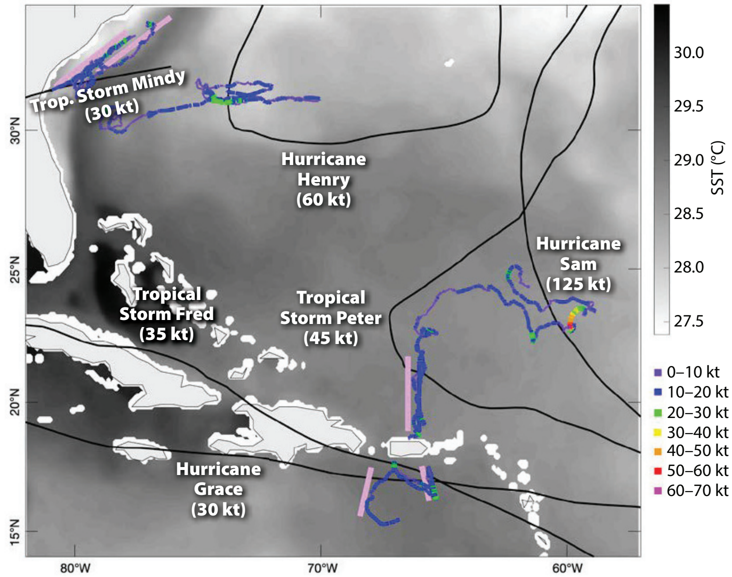

FIGURE 4. Colored Saildrone tracks during August to October 2021 represent one-hour averaged wind speed measured at a height of 5 m. Saildrone data from the mission are available at https://www.pmel.noaa.gov/saildrone-hurricane2021/. Black lines show tracks of tropical cyclones that passed close to one or more Saildrones. Storm names and their maximum sustained one-minute wind speeds at locations of closest approach to a Saildrone are also indicated. Thicker pink lines indicate repeat tracks of ocean gliders that obtained collocated measurements with Saildrones. Background shading is sea surface temperature averaged during August to September 2021.

ABSTRACT: The future Surface Water and Ocean Topography (SWOT) mission aims to map sea surface height (SSH) in wide swaths with an unprecedented spatial resolution and subcentimeter accuracy. The instrument performance needs to be verified using independent measurements in a process known as calibration and validation (Cal/Val). The SWOT Cal/Val needs in situ measurements that can make synoptic observations of SSH field over an $O(100)$ km distance with an accuracy matching the SWOT requirements specified in terms of the along-track wavenumber spectrum of SSH error. No existing in situ observing system has been demonstrated to meet this challenge. A field campaign was conducted during September 2019–January 2020 to assess the potential of various instruments and platforms to meet the SWOT Cal/Val requirement. These instruments include two GPS buoys, two bottom pressure recorders (BPR), three moorings with fixed conductivity–temperature–depth (CTD) and CTD profilers, and a glider. The observations demonstrated that 1) the SSH (hydrostatic) equation can be closed with 1–3 cm RMS residual using BPR, CTD mooring and GPS SSH, and 2) using the upper-ocean steric height derived from CTD moorings enable subcentimeter accuracy in the California Current region during the 2019/20 winter. Given that the three moorings are separated at 10–20–30 km distance, the observations provide valuable information about the small-scale SSH variability associated with the ocean circulation at frequencies ranging from hourly to monthly in the region. The combined analysis sheds light on the design of the SWOT mission postlaunch Cal/Val field campaign.

1. Introduction

The Surface Water and Ocean Topography (SWOT) mission is a pathfinder mission that will demonstrate the next-generation satellite altimeter based on a Ka-band radar interferometer (KaRIn) (Durand et al. 2010; Fu and Ubelmann 2014). The major thrusts of the mission are the low noise and wide-swath sea surface height (SSH) measurements of the KaRIn instrument. After its launch in 2022, understanding the performance of the KaRIn instrument against a ground truth of dynamical SSH is crucial for subsequent scientific applications. This emphasizes the importance of the mission's ocean topography calibration and validation (Cal/Val), which focuses on the wavenumber spectrum of SWOT SSH measurement errors.

In the past, the ground truth for satellite altimeters was typically produced using point measurements from ground stations such as tide gauges, a method that has been used successfully for all previous nadir-altimeter missions, such as the Jason-series altimeters (e.g., Haines et al. 2021; Bonnefond et al. 2019; Quartly et al. 2021). However, the SWOT mission requires a new approach for calibration and validation because the SWOT science requirement is specified in terms of the wavenumber spectrum over 15–1000 km wavelengths (Fig. 1; Desai et al. 2018). As such, validation of the sensor requires capturing a synoptic SSH field along a line covering 15–1000 km wavelengths. Validation of wavelengths ranging from ~120 to 1000 km will be accomplished by the onboard Jason-class altimeter (Wang and Fu 2019), whose performance in wavenumber space is known (e.g., Dufau et al. 2016). The ground truth over the short wavelength (15–150 km) may be achieved by airborne instruments such as lidar (Melville et al. 2016) for geodetic validation and in situ oceanographic measurements (Wang et al. 2018) for oceanographic validation. For the latter, we need an observing approach designed specifically for SSH wavenumber spectrum validation at scales between 15 and 150 km with subcentimeter accuracy.

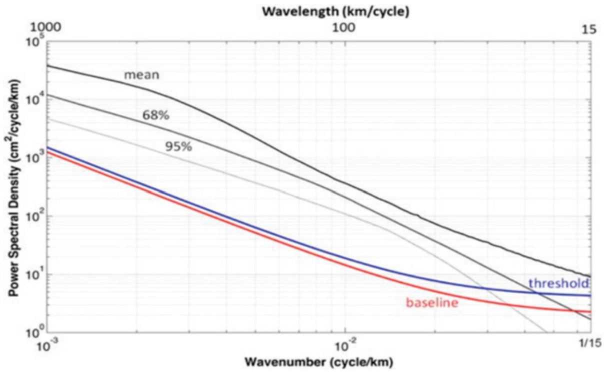

FIG. 1. The SSH baseline requirement spectrum (red line) as a function of wavenumber (Desai et al. 2018). The thick black line is the mean spectrum of the *Jason-2* altimeter track 159, which extends from the Southern Ocean to North Pacific. The 68th and 95th percentiles are marked by the thin black line and the gray line; i.e., 68% and 95% of the spectra are above the corresponding curve. The red curve defines the baseline requirement represented by $E(k) = 2 + 0.001\,25k^{-2}(\mathrm{cm}^2\ \mathrm{cpkm}^{-1})$. The blue curve represents the threshold requirement $E(k) = 4 + 0.0015k^{-2}(\mathrm{cm}^2\ \mathrm{cpkm}^{-1})$.

An observing system simulation experiment (OSSE) was conducted as a first step to evaluate the feasibility of an array of moorings to meet the Cal/Val requirement (Wang et al. 2018). Based on the OSSE, the top challenges in reconstructing the small-scale synoptic SSH field over a 150 km distance come from the emerging dominance of superinertial high-frequency SSH variability at spatial scales <150 km, and the weak SSH signal itself at those scales. These challenges led to a series of field campaigns to identify the relevant ocean processes at the Cal/Val site (near 35.6°N, 125°W) and to evaluate the performance of different in situ platforms and instruments in meeting the SWOT requirement.

Here we report the results from a recent field campaign conducted between September 2019 and January 2020. The rest of the paper is organized as follows. Section 2 summarizes the past development of SWOT oceanographic Cal/Val and the in situ field campaigns. The summary provides the background and motivation of this study. Section 3 discusses the instrumentation of the 2019/20 field campaign. Results are shown in section 4. Uncertainties in the observations and quantifications exist and are discussed in section 5. Summaries are presented in section 6.

2. The development of SWOT SSH Cal/Val

This section reviews the previous work in developing an in situ observing array for the SWOT oceanographic Cal/Val. Section 2a introduces the nature of the SWOT SSH Cal/Val. Section 2b discusses the theoretical basis for conducting oceanographic Cal/Val through in situ mooring platforms. Section 2c reviews the previous OSSE results. Section 2d discusses the transformation of the measurement errors from wavenumber spectrum to time series measurement at a single point and provides accuracy requirements imposed on individual observing platforms used in the field campaign. Section 2e briefly reviews a pilot field campaign that took place prior to the recent 2019/20 field campaign.

a. *SWOT SSH Cal/Val*

After the SWOT satellite launch, the first 90 days will be dedicated to instrument hardware checkout. The second 90 days will be for the mission Cal/Val along a 1-day-repeat orbit (Desai et al. 2018). The 90-day Cal/Val orbit provides more frequent SSH measurements at certain locations for both the validation of the instrument and to develop an understanding of the SWOT measurements from an oceanographic perspective at a very early stage. The SWOT mission Cal/Val has two aspects: 1) characterizing the performance of the instrument KaRIn from a *geodetic* perspective and 2) characterizing the SWOT-observed variability from an *oceanographic* perspective.

Recent studies have shown that the superposition of eddies and internal gravity waves in SSH may make the interpretation of SWOT observations complicated (Rocha et al. 2016; Qiu et al. 2018; Torres et al. 2018; Morrow et al. 2019). When considering the exploratory nature of the SWOT mission as the next-generation altimeter, it is crucially important that we use this 1-day repeat fast-sampling period, in which the satellite will overfly ground-track crossover region twice a day. The results will shed light on the connection of the SWOT SSH to the dynamics of ocean circulation beneath the sea surface (e.g., d'Ovidio et al. 2019), which is the mission's ultimate science goal for oceanography.

b. *Closing the SSH budget using in situ observations*

The ocean dynamics governing the large and mesoscale SSH variability have been the subject of intensive research over the past few decades, stimulated in part by satellite altimetry (e.g., Fu and Cazenave 2001). The SSH signal that has spatial scales smaller than mesoscale, however, has not yet been fully explored, largely because of lack of observations. The first task is to understand the observability of SSH at scales of ~150 km and smaller. To what level of accuracy can we close the SSH budget (formulated below) using available in situ instruments and platforms?

Integrating the hydrostatic equation $dp/dz = \rho g$ from the ocean floor to the free surface, the SSH budget equation can be written as

$$p(-H) = \int_{-H}^{\eta} g\rho(z)\, dz + p_a,$$

in which $-H$ is the depth of the ocean floor, η is the free sea surface height, p_a is the atmospheric pressure. We are interested in the temporal variability. Decomposing each term into a temporal mean (overline) and an anomaly (prime) gives

$$\begin{aligned} \overline{p}(-H) &= \int_{-H}^{0} g\overline{\rho(z)}\, dz + g\rho_0\overline{\eta} + \overline{p_a}, \\ p'(-H) &= \int_{-H}^{0} g\rho'\, dz + g\rho_0\eta' + p'_a, \end{aligned} \tag{1}$$

where ρ_0 the reference density, ρ' the in situ density anomaly, η' the sea surface height anomaly referenced to $\overline{\eta}$, p'_a the atmospheric pressure anomaly. The term $g\eta'\rho'$ is second order and neglected. $\overline{\eta}\rho'$ is implicitly included in the first term on the right hand by taking $z = 0$ at $\overline{\eta}$. The four terms in Eq. (1) represent temporal anomalies of bottom pressure, dynamic height, sea surface pressure due to the free surface, and atmospheric pressure. These terms from left to right can be assessed by bottom pressure recorders (BPR), moorings with CTDs, GPS buoys, and barometers, respectively. We test the closure of Eq. (1) using GPS, BPR, and mooring CTDs in section 4b.

Note that the dominant variability in both the bottom pressure and the free sea surface elevation is nonsteric, such as the barotropic tides. The steric component is much weaker, typically only on the order of a few centimeters.

Denote the steric and nonsteric components of the sea surface height and bottom pressure as η', $\eta'_{\rm ns}$, $p'_{\rm bs}$, and $p'_{\rm bns}$, respectively. We further expand Eq. (1) into

$$p'_{\rm bs} + p'_{\rm bns} = \int_{-H}^{0} g\rho'\,dz + g\rho_0 s'_\eta + g\rho_0\eta'_{\rm ns} + p'_a. \qquad (2)$$

The cancellation of the nonsteric components is written as $p'_{\rm bns} = g\rho_0\eta'_{\rm ns} + p'_a$. After removing the nonsteric components, Eq. (2) becomes

$$p'_{\rm bs} - g\rho_0\eta'_s = \int_{-H}^{0} g\rho'\,dz. \qquad (3)$$

Equation (3) means that the dynamic height due to the density change can be calculated directly from density profiles or indirectly calculated from bottom pressure and steric sea surface height (after the atmospheric pressure correction). In reality, the steric and nonsteric components are impossible to separate from bottom pressure or GPS free sea surface based on a single mooring as a result of an underdetermined problem. Equation (3) is only used to illustrate the meaning of the closure of the SSH equation. It is worth noting that deriving $O(1)$ cm steric height from $O(100)$ cm GPS SSH and BP-derived SSH requires extreme accuracy in both instruments. For this reason, one of the objectives of the SWOT prelaunch campaigns (sections 2e and 3) was to examine the closure of the hydrostatic equation [Eq. (1)] and to quantify the errors associated with different platforms and instruments.

c. An OSSE

An OSSE was first conducted to understand the SSH signal at SWOT scales and the performance of different instruments and platforms in meeting the SWOT requirement (Wang et al. 2018). We used a tide-resolving high-resolution global ocean simulation as a virtual ocean and simulated the performance of several instruments/platforms commonly used in modern observational physical oceanography, i.e., underway CTDs (UCTD), gliders, fixed-CTD moorings, pressure inverted echo sounders (PIES). The model simulation is the high-resolution global ocean simulation using MITgcm with 1/48° horizontal resolution, llc4320, used in several recent studies (e.g., Rocha et al. 2016; Torres et al. 2018; Su et al. 2018; Yu et al. 2019). One conclusion was that in the Cal/Val region (near 35.7°N, 124.7°W) the total SSH over the 15–150 km wavelength range (SWOT scale) can be represented by the upper-ocean steric height after the large-scale barotropic signal and inverted barometer (IB) influence are removed through a high-pass filter. The residual is well below the mission error requirement shown in the error wavenumber spectrum in the OSSE study.

The OSSE study also found that internal gravity waves and internal tides (IGW) might be strong enough to mask the eddy field SSH signal over the small spatial scales and impose an observational challenge (Wang et al. 2018). This dominance of IGWs over small scales is simply because the SSH wavenumber spectrum of eddies (balanced motions) is steeper than that of IGWs (Qiu et al. 2018; Chereskin et al. 2019; Callies and Wu 2019). The presence of internal gravity wave motions on these scales poses a challenge for designing an in situ observational network. For example, through the OSSE we found that slow platforms such as ship-towed UCTD are unable to meet the Cal/Val requirement. An array of station-keeping gliders can marginally meet the requirements, but the errors are mostly over small spatial scales (~50 km) due to the high-frequency motions. PIES can empirically convert the travel time of an acoustic signal to steric height but have about 5 cm uncertainty (D. R. Watts 2016, personal communication; Wang et al. 2018), which is larger than SWOT's subcentimeter requirement. The OSSE study concluded that an array of CTD-equipped moorings could produce a steric height field that is sufficiently accurate to meet the requirement.

The numerical ocean simulation used in the OSSE, however, has excessive tidal energy (C. Wunsch 2017, personal communication; Savage et al. 2017; Yu et al. 2019), which introduces large uncertainties in the OSSE results. It is also not clear how well the deep-ocean variability is reproduced. Field experiments are necessary to test the performance of different platforms and instruments. In addition, while the OSSE focused on oceanographic Cal/Val, the geodetic SSH such as measured by GPS buoys needs to be evaluated to synthesize the oceanographic and geodetic objectives. It led to two objectives of the field campaigns: 1) quantify the performance of oceanographic in situ platforms and 2) test the GPS measurements and their relationship with those derived from hydrographic measurements.

d. SWOT measurement error requirement

In the two field campaigns described in the next section, we do not have a full-scale mooring array that enables a wavenumber spectrum calculation. To evaluate the performance of an in situ instrument, the SWOT error requirement in wavenumber space needs to be integrated over a range of wavenumbers $\int E(k)$ to assess time series in situ measurement. The mission requirement is specified between 15 and 1000 km wavelengths. The baseline error[1] is

[1] The "baseline error" is the error the mission currently plans to achieve. The "threshold error" is the error level that the mission must achieve to address the minimum science goals.

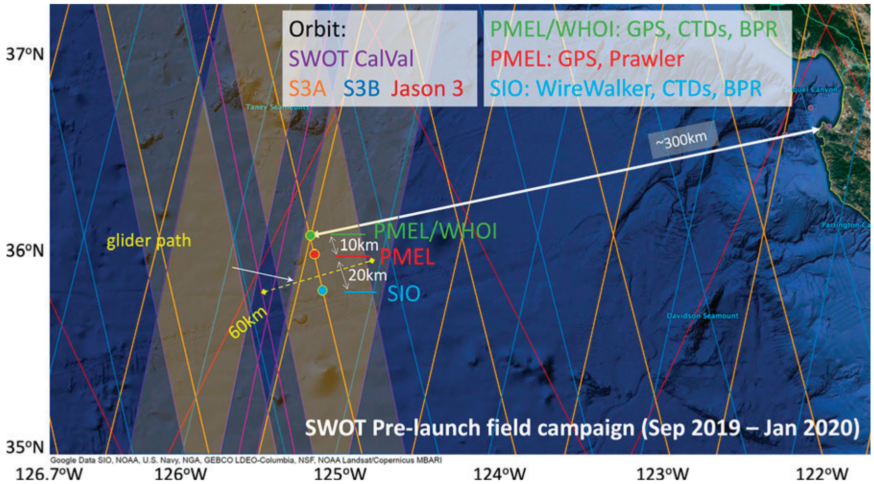

FIG. 2. Map of the field campaign instrumentation. The three moorings are marked by the three colored dots. From north to south, they are the PMEL/WHOI mooring, the PMEL Prawler mooring with GPS on the buoy, and the SIO full-depth mooring. The separation distance is 10 and 20 km. The dashed yellow line is the glider target path of 60 km wide. Two bottom pressure recorders were deployed near the PMEL/WHOI and SIO moorings.

$E(k) = 4\ \mathrm{cm}^2\ \mathrm{cpkm}^{-1} + 0.00125k^{-2}$, where k is the wavenumber with a unit of cycle km^{-1} (cpkm) and $2\ \mathrm{cm}^2\ \mathrm{cpkm}^{-1}$ is the KaRIn instrument noise averaged across a swath over 7.5 km distance for significant wave height (SWH) of 2 m (Fig. 1, red line). The threshold error requirement is similar: $E(k) = 4\ \mathrm{cm}^2\ \mathrm{cpkm}^{-1} + 0.0015k^{-2}$ (Fig. 1, blue line).

For the spatial range between 15 and 1000 km, an integration of the error based on the requirement is $\int_{1\times10^{-3}}^{1/15} E(k)\,dk = 1.36\ \mathrm{cm}^2$, i.e., 1.17 cm RMS. If only the 15–150 km range is considered, the total integrated error has 0.29 cm^2 variance (0.54 cm RMS), the integrated random KaRIn noise is 0.12 cm^2 (0.35 cm RMS), and the integrated correlated error (cpkm) is 0.17 cm^2 (0.41 cm RMS). The 0.54 cm number represents a target accuracy needed for validating SSH measurements in the presence of oceanographic "noise," i.e., an upper limit for errors in observing ocean processes including those which are correlated on the scales of interest. These are the signals analyzed in this study. The 0.35 cm value is a requirement for inherent sensor/platform/sampling error at a single location that is uncorrelated from platform to platform.

The postlaunch Cal/Val approach involves calculating the wavenumber spectrum of the difference between the SWOT SSH measurement and the mooring-derived SSH during the SWOT overflight of the mooring array. A spatial linear trend over the length of the mooring array will be removed before calculating the wavenumber spectrum. This detrending operation minimizes the effects of the scales longer than those of the in situ Cal/Val. Such a difference spectrum is considered a snapshot of the measurement error spectrum, which will be averaged over the 90-day Cal/Val period to achieve statistical assessment of the SWOT performance.

Ideally, we would like to test the mooring capability using an array of moorings covering ~150 km. However, owing to the limited budget, we deployed three moorings spanning 30 km (Fig. 2). The evaluation of the mooring capability discussed in the following sections will be unavoidably influenced by the large-scale signals that are irrelevant to SWOT short-wavelength Cal/Val. It is thus difficult to rigorously define measurement requirement for a single mooring. However, from analysis of ocean model simulations (Torres et al. 2018), the temporal scales corresponding to 15–150 km wavelengths are roughly 2–14 days. We therefore impose the following for the requirement for the in situ SSH observations: Integrated over periods of 2–14 days, the RMS error shall not exceed 0.54 cm. A caveat is that this criterion is not rigorously derived due to insufficient mooring measurements and is only used as a guideline. The spatial–temporal separation can be directly calculated during the postlaunch Cal/Val where an order of 10 moorings will be deployed along a line under a SWOT swath (section 5).

e. The 2017 pilot field campaign

The first field campaign was conducted in Monterey Bay, California, during June/July 2017. Two gliders, one BPR, and a GPS buoy (Haines et al. 2017) were deployed near the Monterey Bay Aquarium Research Institute (MBARI) M_1 mooring. The two gliders sampled the upper 500 m near the mooring at 36.75°N, 122.03°W. The first objective was to quantify the capability of station-keeping gliders in constructing the high-resolution steric height derived from a fixed instrumented mooring. The second objective was to examine the connection between GPS-observed SSH that resembles spaceborne measurements and steric height that represents the ocean circulation.

The 2017 pilot campaign successfully tested the first objective, but not the second one. In particular, the results have not yet yielded satisfying closure between the GPS-derived SSH and upper-ocean steric height. The campaign took place 20 km from the shore, with the GPS buoy situated over the steep walls of the Monterey submarine canyon. One of the challenges was the large mean sea surface (geoid) gradient, which contributes to the time variation in GPS-derived SSH as the buoy meandered over the canyon wall and within the watch circle. This nearshore location was also dominated by nonsteric processes, making the site less representative of the open-ocean conditions expected near the SWOT Cal/Val crossover location. The campaign, however, shed new light on the challenges of reconciling SSH (from surface GPS or satellites such as SWOT) with steric height (from gliders and moorings), and the outcomes helped to inform the architecture of the subsequent 2019/20 prelaunch campaign reported in this paper. The next section provides the general information about this campaign.

3. The 2019/20 prelaunch field campaign

The 2019/20 prelaunch field campaign was conducted near the SWOT Cal/Val crossover location, about 300 km west of Monterey, California (Fig. 2), between September 2019 and January 2020. It was designed to mainly 1) test the closure of the SSH equation, which was not satisfactorily addressed in the 2017 field campaign, and 2) quantify the error in steric height using different platforms. There are six specific objectives: 1) test the SSH budget closure with GPS buoy, CTD mooring, and BPR following Eq. (1); 2) evaluate the vertical scale of SSH at the SWOT scales for different frequency bands; 3) evaluate the role of bottom pressure in SWOT SSH signals; 4) evaluate the small-scale steric height information; 5) evaluate the reconstruction of the upper-ocean circulation; and 6) provide information for the design of the postlaunch in situ observing system. We will mainly focus on 1–4 in this paper. The outcome will aid the design of the postlaunch in situ field campaign for SWOT Cal/Val.

Six institutions participated in the campaign: Jet Propulsion Laboratory, NOAA Pacific Marine Environmental Laboratory, Wood Hole Oceanographic Institution, Scripps Institution of Oceanography, Rutgers, and Remote Sensing Solutions. Three moorings and two BPRs were deployed between 1 and 7 September 2019, and recovered between 16 and 21 January 2020. One Slocum glider was deployed from Monterey Bay and piloted to the mooring locations around mid-September 2019.

The three moorings are 1) the PMEL/WHOI (*northern mooring*) configured with a GPS buoy and 18 fixed CTDs from surface to the bottom, 2) the PMEL GPS mooring (*middle mooring*) with a Prawler (Osse et al. 2015) sampling the upper-500-m temperature and salinity (*T*/*S*), and 3) the Scripps Institution of Oceanography (SIO) mooring (*southern mooring*) with a Wirewalker (Pinkel et al. 2011) sampling the top 500 m and fixed, real-time telemetered CTDs between 500 m and ocean floor. The mooring array was placed along a *Sentinel-3A* ground track, which fortuitously was in the middle of a SWOT swath along the Cal/Val orbit. The separation distances are 10 and 20 km for the northern and southern pairings, respectively, to support testing of small-scale SSH variability not resolved by conventional satellite altimeters. During the first phase of the campaign, the glider sampled a 60-km-long section perpendicular to the mooring line (Fig. 2) with a 1000 m dive depth, which was chosen to minimize the travel time for the 60 km section. During the second phase, the glider performed station keeping near the three moorings for cross calibration. The glider stayed at each mooring for about 5 days. The PMEL BPR is near the northern mooring and a PIES was deployed at the southern mooring location.

a. GPS measurements of SSH

A modular, low-power, high-accuracy GNSS measurement system was designed for long-term, continuous, and autonomous measurements of SSH on ocean- and cryosphere-observing platforms (Haines et al. 2017; Guthrie et al. 2020). It results from a joint project between NASA JPL, NOAA PMEL, and the University of Washington. The project aims to probe the limit of new kinematic precise-point positioning (PPP) techniques for accurately determining sea surface height and recovering neutral and charged atmosphere characteristics; and explore the potential scientific benefits—in the fields of physical oceanography, weather, and space weather—of accurate GNSS observations from a global ocean network of floating platforms. It integrates a Septentrio dual-frequency GPS receiver and a PMEL buoy. The receiver is low power (~1 W) and is accompanied by a miniaturized digital compass (for attitude information) and a load cell (to measure force on the mooring line). The buoy communicates using Iridium, and the payload is adaptable to multiple floating platforms such as surface buoys, wave gliders. When coupled with advanced precise point positioning techniques (Bertiger et al. 2010), the observations collected by the GPS buoy enable geodetic-quality solutions in remote locations without nearby reference stations.

The GPS level-2 data have 1-Hz temporal frequency, processed to accurate 3D positions using the GipsyX software (Bertiger et al. 2020) with units of meters for the height component. These high-frequency data were binned to hourly average to remove the surface gravity waves (Fig. 3). The hourly data were then corrected for an apparent systematic sea-state bias (estimated empirically), solid tides, line tension, mean sea surface (MSS), and IB effect. The MSS correction is important for comparing GPS-SSH with steric height because the horizontal displacement of the GPS buoy within its watch circle can project geoid variations into the GPS time series. This spatial-to-temporal projection is especially significant over steep bathymetry, which was the case during the 2017 field campaign, where the GPS buoy was placed near the Monterey submarine canyon and the spatial geoid variations were as large as 10 cm within the mooring watch circle of 2 km radius, but less significant over the prelaunch campaign region where ocean bathymetry is rather flat. The IB correction (Wunsch and Stammer 1997) follows IB (mm) = $-9.948p'$, where p' is the sea level pressure anomaly. The final derived SSH after the MSS and IB corrections was then detrended over the 4-month period (mid-September 2019 to mid-January 2020).

The GPS buoy system has developed from campaigns undertaken in progressively more challenging conditions.

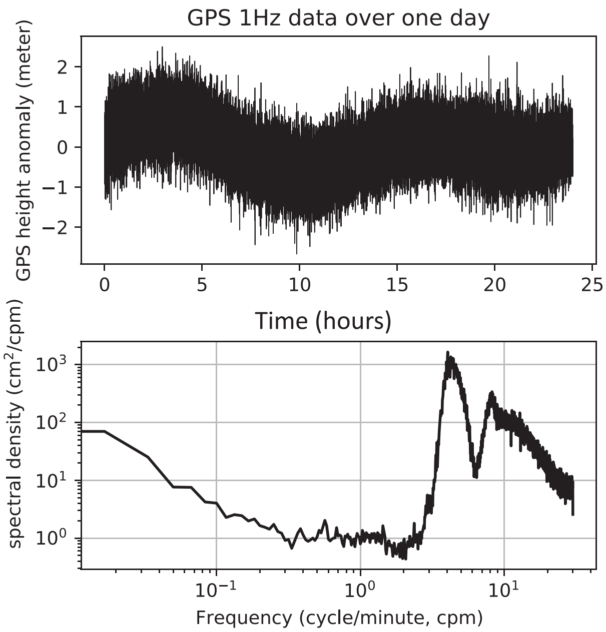

FIG. 3. (top) The 1-Hz GPS measurement of SSH. (bottom) The frequency spectrum of the 1-Hz GPS SSH.

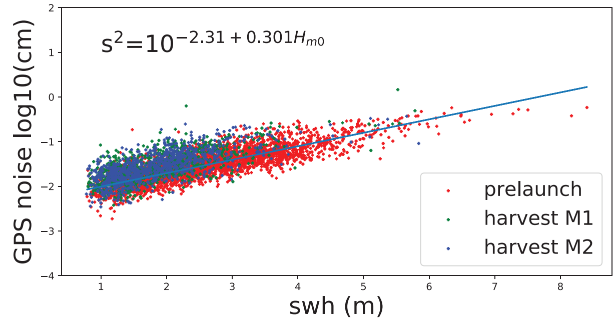

FIG. 4. The GPS error as a function of SWH derived from two SWOT prelaunch field campaigns described in section 2. The red dots are from the 2019 prelaunch field campaign and the green and blue dots are from the two GPS buoys of the 2017 pilot field campaign.

Nearly 1000 buoy days of data have been successfully collected since 2015, over SWH ranging from calm to 9 m. The GPS buoys have been an integral part of the SWOT pilot experiment in 2017 (Monterey Bay) and the prelaunch field campaign (2019/20). An example of the processed 1-Hz data is shown in Fig. 3. The 1-Hz sampling frequency is high enough to reveal detailed expressions of surface waves. The amplitude of the high-rate (1-Hz) height estimates reach 5 m for this day. The frequency spectrum illustrates the wind wave and swells by the two spectral peaks. SWH can also be derived from this 1-Hz data following SWH = 4 × RMS(SSH), where SSH is high-pass filtered with a cutoff frequency of 1 cycle min^{-1}.

We tried to estimate the GPS measurement errors in the context of the SWOT requirements. Without a true reference, we need to make assumptions in order to derive the error from the GPS measurement itself. We assume the minimum in the spectrum near 1 cycle min^{-1} reflects random instrument noise. As we are interested in ocean signals that are of periods longer than 1 h, the GPS error can be estimated by integrating the random noise spectrum, assumed constant taken as the value of the spectrum minimum near 1 cycle min^{-1}, over the frequency range (0–1 cycle h^{-1}). The SWH can be derived from the surface wave spectrum. We can split a long time series into 1-h-long segments, then derive an empirical relationship between GPS error and SWH. Based on the two SWOT prelaunch field tests, there is a clear relationship between SWH and GPS errors following a logarithmic function as shown in Fig. 4. The relationship is $S^2 = 10^{-2.31+0.3H_{m0}}$, where H_{m0} represents the SWH, and S^2 is the noise variance. Under these assumptions, the GPS error from a single buoy meets the SWOT mission geodetic requirement, i.e., 0.13 cm^2 for SWH < 4.1 m, which corresponds to 2 cm^2 cpkm^{-1} instrument noise in the wavenumber space (Fig. 1).

Other errors exist in addition to those induced by the surface waves. Those errors are correlated but difficult to unravel with a single GPS buoy. They will contribute to the total error presented in section 4. Residual atmospheric refraction delays are one of the dominant correlated error sources. As the ionospheric refraction is corrected to first order using the two GPS frequencies, the primary concern here is refraction from the troposphere. Taking advantage of mapping functions, the wet troposphere delay in the zenith direction is estimated along with the buoy position. Despite the relatively small magnitude, the wet component of the troposphere delay is highly variable and sometimes difficult to capture, especially during intense weather fronts with large atmospheric gradients. Other important systematic errors for the buoy technique are related to the platform altitude and to the force on the mooring line, both of which impact accurate modeling of the buoy's waterline and thus the SSH (Zhou et al. 2020). Here we use, respectively, the digital compass and load cell data from our payload package to mitigate these errors.

b. Hydrographic measurements

1) MOORINGS WITH FIXED-DEPTH CTD INSTRUMENTATION

The fixed-depth CTD mooring is one of the most conventional in situ platforms for observational oceanography. The CTDs used in the campaign are the Sea-Bird Electronics, model SBE-37. The SBE-37 can be configured with and without a pressure sensor. The pressures for those instruments without the corresponding sensors (from the northern mooring) were determined through interpolating from the next instruments above or below, using the known wire lengths between the instruments. For these fixed-depth CTDs, the distances between instruments along the mooring line are fixed, but the actual depths of the CTD instruments change over time. The amount of vertical excursion depends on the currents and winds as well as the mooring design: the northern mooring was a "slack mooring" (i.e., mooring line much longer than water depth) of an inverse catenary design with vertical sensor excursions up to about 300 m, while the southern mooring had a taut lower section that limited vertical excursions to about 60 m. The nominal depths of the fixed CTDs are (505, 618, 810, 1182, 1690, 2365, 3202, 4384) m on the southern mooring and (20, 30, 59, 107, 174, 261, 367, 492, 609, 805, 1180, 1408, 1692, 1909, 2189, 2488, 2750, 4545) m on the northern mooring.

A climatological mean in situ density profile is removed before the density anomalies are interpolated onto a uniform vertical grid to avoid interpolation error in calculating steric height. We have also used the mean profile constructed from all the measurements in the campaign instead of the climatological mean. No quantitative difference is observed. This procedure removes the spurious deep-ocean variability introduced by the vertical-to-temporal projection due to the vertical movement of the CTD sensors. The bottom CTD on the northern mooring was corrupted so the full-depth steric height was calculated with the assumption that the ocean below 3000 m has no temperature and salinity variability.

2) MOORINGS WITH PROFILERS

Two moorings had profilers with CTD instruments. The middle mooring had a Prawler that covered the upper 500 m with a Sea-Bird Electronics (SBE-PRAWLER) CTD, and the southern mooring had a Wirewalker in the upper 500 m with an RBR Concerto CTD. Profiling methods are not subject to errors due to vertical resolution, but the temporal resolution is less favorable. The Prawler was set to 8 profiles per day on average during the 2019/20 campaign. The number of profiles per day can be higher, but was chosen to test the endurance of the Prawler mooring. The Wirewalker on the southern mooring yielded about 80 up- and downcast profiles per day (i.e., ~7000 profiles, or 3500 vertical kilometers profiled over 86 days of deployment). The profiler CTDs pass through vertical gradients of temperature and conductivity in the upper ocean, which requires data processing to remove spikes in salinity, and to adjust for lagged sensor responses. After this alignment, vertical profiles of density with 1 and 0.25 m vertical resolution over the upper 500 m are produced for the Prawler and Wirewalker, respectively.

Below the profiler, the southern mooring featured additional, vertical fixed instrumentation. It used a taut mooring between the seafloor and 600 m, connected to the surface buoy via a reverse catenary inductive connection and the Wirewalker profiling wire. The taut mooring has a very small watch circle (<250 m) and so the fixed instruments stay within a narrow depth range. The inductive connection allowed real-time data from the fixed instruments all the way to the seafloor. This experimental mooring design is less tested, and the catenary wire parted after 86 days of the intended 90-day deployment.

3) UNDERWATER GLIDERS

The hydrography data collected by the gliders are similar to the moored profilers. Vertical resolution is high and requires no additional interpolation steps, although the same precautions against mismatched sensor response times and resulting spikes in salinity data need to be taken. Gliders have the advantage of mobility, but they may experience large horizontal deviation from target locations due to strong currents. A station-keeping glider can act as a virtual mooring. A glider that performs station keeping at different mooring locations can also be used for cross-mooring calibration and validation. The Slocum glider used in this campaign has a vertical speed of about 18–20 cm s^{-1} yielding ~30 profiles per day for 500 m dives.

4) APPROACH TO CALIBRATION AND VALIDATION OF CTD DATA

An effort was made to cross calibrate all CTD data to a common reference. For the fixed-depth, moored CTD instruments, this was done by attaching the mooring instruments to a recently calibrated, ship-based CTD and Rosette system, and then collecting vertical profiles with 10 min stops at several depths. At these dwell depths, water samples were taken for laboratory salinity measurements to provide an absolute salinity reference. This approach was carried out for mooring instruments both before mooring deployment and after mooring recovery. The method is described by Kanzow et al. (2006), and has the key advantage that all three sensors (conductivity, temperature, pressure) are adjusted independently of one another. Over the course of the mooring deployment, the corrections applied to the mooring data are shifted linearly from the predeployment to the postrecovery values. For temperature data, the adjustments are offsets added to the raw data. For conductivity data, the adjustments are gain factors multiplied by the raw data. For pressure data, the adjustments are a combination of a gain factor and an additive offset (Kanzow et al. 2006).

The glider was flown to the vicinity of each mooring on several occasions. A comparison of the glider data against the fixed-depth, cross-calibrated moored CTDs was used to adjust the glider conductivity with a gain factor, such that the temperature–salinity curves derived from the glider would best match those from the nearby mooring. This assumes that the glider temperature and pressure sensors are correct.

For the two moored profilers, two different approaches were done: The Prawler conductivity data were adjusted against the (adjusted) glider data, based on nudging the conductivity such that the temperature–salinity curves would be matched. For the Wirewalker on the southern mooring, a spare fixed-depth instrument that had the ship-based corrections was attached to the profiling body. The profiler conductivity was nudged against the data from this collocated instrument, again to best match the temperature–salinity relationship, but the comparison was restricted to deeper depths because the fixed-depth instrument does not have a sensor response time suitable for the upper-ocean profiles. For both moored profilers, the result is that the conductivity data are adjusted, while the temperature and pressure data are assumed correct, as for the gliders.

c. *Ocean bottom pressure*

There were two ocean bottom pressure instruments: the northern one was a system based on the DART tsunami detection technology (Meinig et al. 2005), and the southern one a PIES (pressure-sensing inverted echo sounder) (Watts and Rossby 1977). The actual pressure sensors are identical in the two systems (Paroscientific Digiquartz) that are operated at about 15-s acquisition times. The DART-based systems operate nearly continuously, while the PIES have a 10-min sampling interval. When subsampling a near-continuous DART-like record at 10-min resolution, hourly averages can be reproduced to about 0.5 mm accuracy. Availability of the data in near–real time depends on the available underwater communication systems, which typically operate acoustically at low bandwidth. For PIES, hourly data were telemetered on an irregular schedule during the 2017 field campaign, typically with several days' latency. The data transfer uses the nearby glider as a communication device. The northern ocean bottom pressure data were telemetered four times per day during the 2019/20 field campaign using an acoustic modem.

The absolute magnitudes of the pressure data are not particularly useful in the context of SWOT Cal/Val, for two reasons: first, calibration uncertainties typically result in offsets to the data, which are not constant but drift with time; second, the exact depths where the sensors are on the seafloor are not known, i.e., one cannot assign a known vertical coordinate to the data. Therefore, a time mean that includes sensor drift is subtracted from the record. Following Eble and Gonzalez (1991), the preferred trend removal involves the sum of an exponentially decaying function and a linear trend. The variability in the residuals is then dominated by tidal signals. From comparing different tide removal algorithms, such as harmonic fits with different tidal constituents as well as low-pass filters of the data, coherent tidal signals can be removed.

d. Auxiliary datasets

GPS measures total SSH, so it is the closest equivalence of SWOT SSH. GPS SSH and SWOT SSH will share the same MSS and IB corrections. For the MSS correction, we used an MSS height model (MSSCNESCLS19), which is based on all available radar altimeter data (Schaeffer et al. 2018) with 16–20 km spatial resolution. The hourly ERA5 atmospheric pressure (Copernicus Climate Change Service 2017; Hersbach et al., 2020) used for IB correction and the gridded DUACS-DT2018 L4 SSH product (Pujol et al. 2016; Taburet et al. 2019) and *Sentinel-3A* L2P data are provided by Copernicus Climate Change Service (2017).

4. Results

a. Large and mesoscale background during the campaign

The campaign was conducted in the California Current system, a typical eastern boundary current system that comprises a wind-driven coastal upwelling and equatorward surface current. It is one of the best-studied and longest-observed regions in the world oceans (e.g., Hickey 1979; Flament et al. 1985; Ikeda and Emery 1984; Capet et al. 2008a,b; Collins et al. 2013; Rudnick et al. 2017; and many others). The coastal upwelling driven by the equatorward alongshore wind during summer brings cold waters to the surface (Fig. 5d), which introduces strong thermal fronts next to the warmer open ocean to form a southward California Current. This upwelled water also contains abundant nutrients to support the dynamic ecosystem indicated by the high chlorophyll concentration (Fig. 5e).

Mesoscale and submesoscale eddies are ubiquitous in the California Current System (CCS). The cold coastal water often pinches off from the coastal current and drifts westward into the open ocean supporting the coastal–open-ocean exchange of water masses (e.g., Strub and James 2000, among numerous others). Meanwhile, this offshore transport of mass and heat is balanced by the onshore transport of the deep open-ocean water that feeds the upwelling and the horizontal onshore transport by mesoscale and submesoscale eddies.

During the period of the 2019/20 prelaunch field campaign, the mooring array observed the formation of a warm-core anticyclonic mesoscale eddy. The process started from a southward flow meander at the beginning of the campaign around early September 2019 (Fig. 5a). The meander started to stretch and fold, a typical evolution of baroclinic instability, during October 2019 (Fig. 5b), which eventually detached from the initial meander to form a coherent mesoscale eddy near the end of the campaign (Fig. 5c). The mature mesoscale eddy trapped the warm, nutrient-scarce open-ocean water and drifted shoreward to resupply and mix with coastal water. During this evolution, the three moorings were within the meander at the start of the deployment and on the edge of the formed eddy by the end of the deployment. From the mesoscale perspective, then, the observations during the campaign were skewed toward ocean dynamics of a meander and the edge of a mesoscale eddy in CCS. Detailed in-depth analyses of the underlying mesoscale dynamics are not a focus of this paper and will be reported elsewhere.

b. SSH closure

As discussed in section 2b, one can derive an equivalent full-depth steric height from GPS, BPR, and atmospheric pressure through the hydrostatic equation. The derived full-depth steric height is then compared with the steric height derived from hydrographic measurements through mooring CTDs. Their differences contain the errors in both GPS-derived and CTD-derived steric heights.

Figure 6 shows the hourly steric height derived from GPS/BPR (red) and 6-min-resolution steric height from hydrographic measurements (blue). The top panel shows the full-time series for four months. The bottom panel shows the details of the time series over a 10-day period. The two independently derived steric height time series agree over low frequencies (top panel) and over major tidal frequencies (bottom panel). Note that the barotropic tides are eliminated by the difference between the GPS SSH and BPR-derived SSH, leaving the residuals at tidal frequencies, the baroclinic internal tides.

The total RMSE between the two derived steric heights is 2 cm, but they also depend on the sea state as shown by the single GPS analyses (Fig. 4). To our knowledge, this is the first demonstration that the GPS-/BPR-derived sea surface height is equivalent to the steric height measured concurrently in

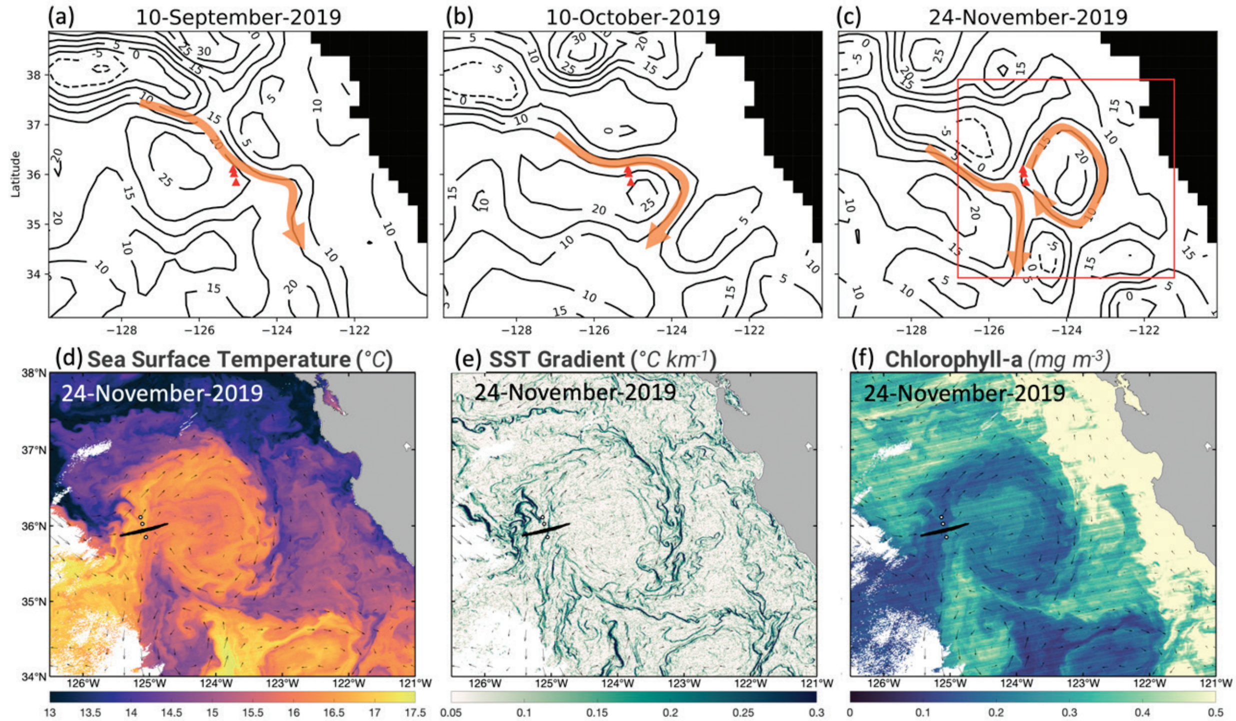

FIG. 5. (a)–(c) The altimetric sea level anomaly (SLA) on 10 Sep, 10 Oct, and 24 Nov 2019 corresponding to the beginning, middle, and end of the campaign, respectively. The thick orange arrows show the pinch-off of mesoscale eddy from the meander of the California current. The three red triangles mark the three mooring locations. The red box in (c) marks the domain boundary for (d)–(f) he SST and surface chlorophyll-a after the eddy formed approximately on 24 Nov (an ascending 750 m resolution swath from VIIRS *Suomi NPP* L2 taken at 2100 UTC). The black lines (60 km long) in (d)–(f) mark the glider flight path.

situ, indicating that the GNSS GPS system is accurate enough to measure the oceanic baroclinic signals.

The difference between the two steric height time series is further binned into different sea states characterized by SWH. As expected, the RMS difference between the two is a function of sea state (Fig. 7). The RMS difference is about 1 cm for calm seas with SWH $<$ 1 m, 1.7 cm for SWH = 2 m, and 3 cm for SWH $>$ 6 m. These GPS errors may be of large scale and not contribute to 15–150-km-scale errors that are of primary interest here. Detailed discussions are given in section 5.

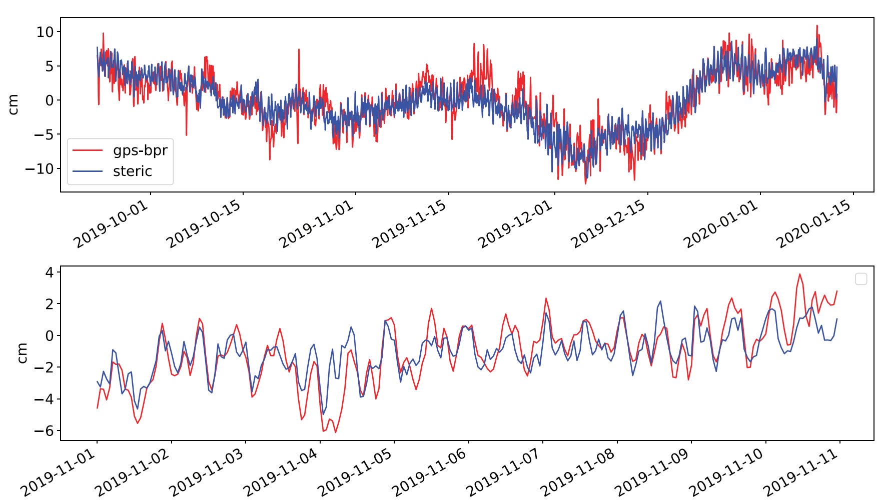

FIG. 6. (top) The steric height from the hydrographic measurements (blue) and the GPS-BPR-derived dynamic SSH. (bottom) As in the top panel, but for a short period (10 days).

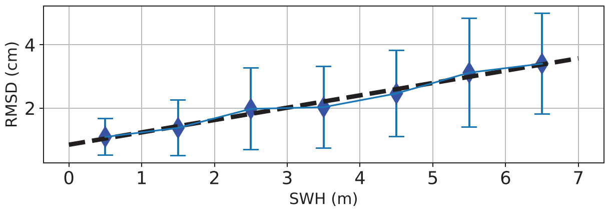

FIG. 7. The RMS difference (RMSD) between the steric heights derived from GPS/BPR and mooring CTDs as a function of significant wave height (SWH). The diamond symbols represent the mean RMSD binned to SWH values with a 1 m bin width. The error bars show the standard deviation of the absolute difference as an uncertainty measure. The line is the linear fit to the mean following RMSD=0.84 + 0.4SWH (cm).

The difference between GPS-derived and CTD-derived steric height can be scrutinized in frequency space, where we may identify the error sources. The GPS-based and CTD-based steric heights match at low frequencies with equal power spectral density within the 95% uncertainty bounds (Fig. 8). The major difference starts to show for periods less than 10 days, except for several major tidal periods such as M_2 and M_4 where the spectral peaks and coherence are significant. This is visible from the time series in Fig. 6. It is interesting to note that the coherence is high at 7.6-h period, which corresponding to the frequency of nonlinear interaction between inertial motions and semidiurnal tide denoted fM_2 (Mihaly et al. 1998).

The amplification of the differences over short periods less than 10 days is not fully understood, but could be related to the cadence of weather systems. The largest dispersions are sporadic in time (Fig. 6) and have a linear relationship with sea state (Fig. 7), and could also reflect refraction errors for the GPS systems. Errors in CTD-derived steric height exist but should not be a function of sea state and are less likely to be the dominant error source. The major difference between red and blue lines in Fig. 6 probably arises from the GPS-derived steric heights, which reflect not only GPS errors but also the errors in the IB correction through ERA5 and errors from MSS uncertainties. However, these errors may well be of large spatial scales that are less relevant to the SWOT in situ Cal/Val focus in this region (<150 km; Wang et al. 2018). If the GPS and IB related uncertainty/errors have large spatial scales, they can be removed through a spatial high-pass filter or simply by removing a linear trend along a 150 km distance as done in Wang et al. (2018).

c. *The vertical scale*

To minimize the cost of the postlaunch in situ Cal/Val, we may need to tolerate some uncertainties due to missing direct

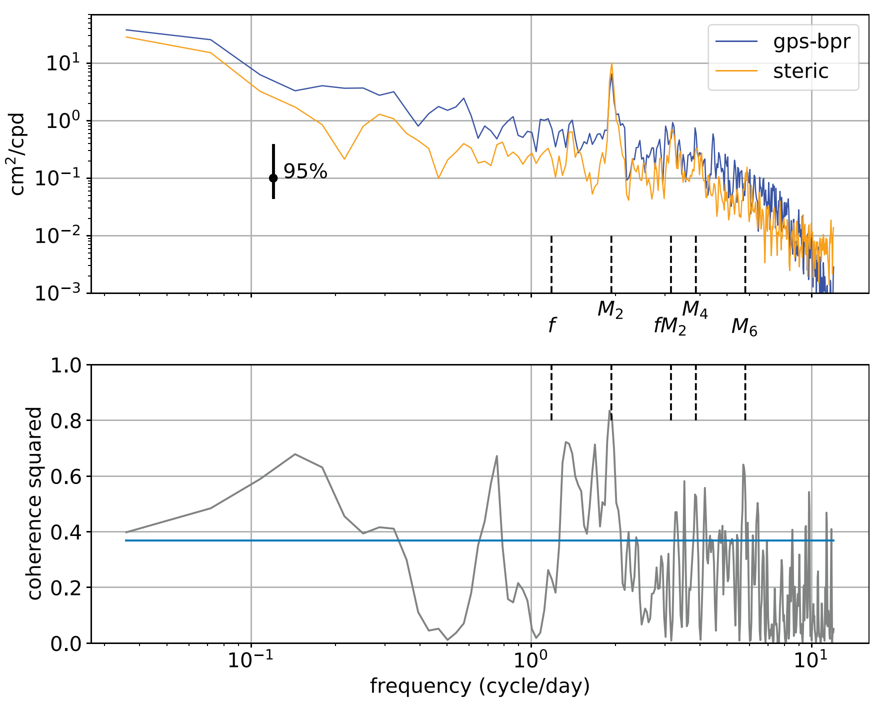

FIG. 8. (top) The frequency spectrum of the full-depth steric height (orange) [right-hand side of Eq. (3)] and the GPS-derived dynamic SSH (blue) [left-hand side of Eq. (3)]. The spectra are calculated using the Welch method with four nonoverlapped segments giving a degree of freedom (DOF) of 8. A Hanning windowing and linear-detrend operation were applied. The 95% significance level with DOF = 8 is shown by the black vertical bar. (bottom) The magnitude-squared coherence between the two time series using the Welch method with the same number of segments and DOF. The blue horizontal line marks the 95% significant level with DOF = 8.

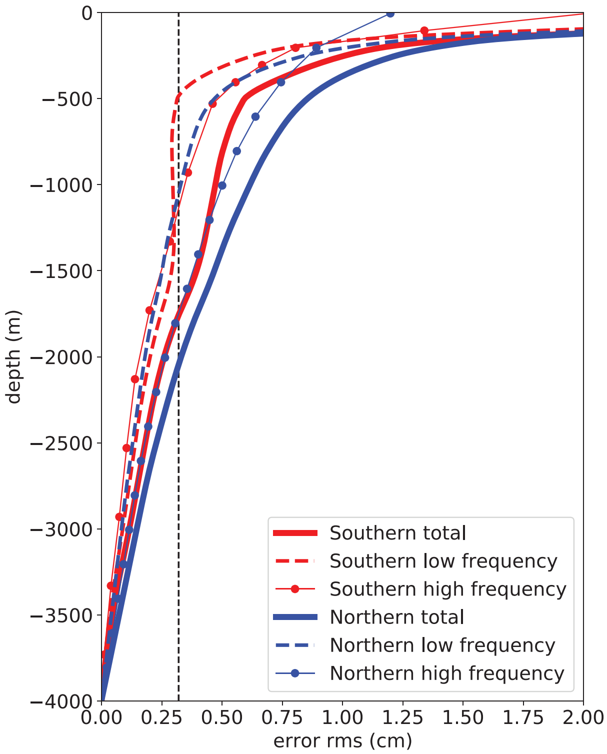

FIG. 9. The RMSE $\epsilon(z)$ of the upper-ocean steric height relative to full-depth steric height as a function of integration depth. Because the bottom CTD on the northern mooring was corrupted, we chose 4000 m as the deep-ocean reference for both moorings. By definition, the error decreases when the integration depth gets deeper and reaches zero at the bottom (4000 m in this case). The southern mooring is shown in red and the northern mooring in blue. The thick solid lines are for the total signals, the dashed lines for low frequency (>48 h), and the thin solid–dot lines for high frequencies (<48 h). The black dashed vertical line marks the 0.32 cm RMS level, which is derived from 2 cm^2 cpkm^{-1} wavenumber spectrum noise level for stations separated by 10 km.

measurements of the deep ocean. How deep do we have to measure the ocean to generate a steric height accurate enough for SWOT Cal/Val?

The uncertainty introduced by missing deep-ocean measurement below a depth z is defined as the steric height integrated between ocean bottom and z:

$$\eta_{\text{deep}}(z) = -\int_{-H}^{z} \frac{\rho'(z')}{\rho_{\text{ref}}}\ dz',$$

where ρ' is the in situ density anomaly deviation from a time-mean density profile $\overline{\rho}(z)$, and ρ_{ref} is the mean in situ density (set to 1035 kg m^{-3} here). We quantify the uncertainty using the standard deviation of this deep-ocean steric height $\epsilon(z) = \text{std}[(\eta_{\text{deep}}(z))]$.

The results based on the northern and southern mooring are shown in Fig. 9. The $\epsilon(z)$ decreases toward the deeper ocean as defined but with a larger rate in the southern mooring (thick red) than the northern mooring (thick blue). The different vertical scales between the northern and the southern moorings may be caused by different dynamic regimes experienced by the two moorings. The 500 m depth is of particular interest because that is roughly the bottom depth of the Prawler and Wirewalker platform. Table 1 lists some relevant numbers about the errors $\epsilon(500)$. The total error $\epsilon(500)$, i.e., the error of missing the deep ocean below 500 m, is 0.61 ± 0.1 and 0.84 ± 0.17 cm for the southern and northern mooring, respectively. The errors represent the mean RMS and the standard deviation in a time series of $\epsilon(500)$ calculated based on segments of a 10-day duration subsampled from either the original or the filtered time series. The error amplitude changes over time. Most of these errors come from high-frequency processes with periods less than 2 days (we will use the format $T < 2$ d hereafter). They are 0.51 ± 0.06 and 0.67 ± 0.14 cm for the southern and northern moorings, respectively. The low-frequency (2–14 d) component on the other hand has errors less than 0.15 ± 0.1 cm for both moorings, accounting for less than 4% of total variance (Table 1). The deep-ocean (<−500 m) steric height has a 0.5–0.7 cm RMS values and accounts for 5% of the full-depth steric height for high frequencies with periods less than 2 days at the southern mooring. This ratio becomes 30% at the northern mooring. The northern mooring particularly presents a higher deep-ocean high-frequency variability. The causality cannot be confirmed without more independent observations. It may be caused by the topographically generated deep-ocean internal tide/wave signal that is strong for the northern mooring, or simply because of the errors in determining the depths of the deep CTDs, which have large vertical excursions.

The spectrum of the upper-500-m steric height and the full-depth steric height and their coherence are shown in Fig. 10. We used the Welch method with a Hanning window. The full time series is split into nonoverlapping segments. The steric heights of the upper 500 m (blue) and of the full depth (orange) agree well over subinertial frequencies with similar spectra density and high coherence for both moorings. The major difference comes from the superinertial frequencies, especially around the tidal frequencies at M_2 (and M_4 for the southern mooring). The errors are relatively high (green lines) but the coherence (red lines) is still large and significant

TABLE 1. Deep-ocean contribution to steric height ϵ(500 m) for the two moorings at different frequency bands. This represents the error by only measuring the upper 500 m.

	Total RMSE (cm)	2–14-day band (cm)	Variance percentage (2–14 days) (%)	High frequency (<2 days) (cm)	Variance percentage (<2 days) (%)
Southern	0.61 ± 0.1	0.14 ± 0.1	1	0.51 ± 0.06	5
Northern	0.83 ± 0.17	0.15 ± 0.07	3.4	0.67 ± 0.14	31

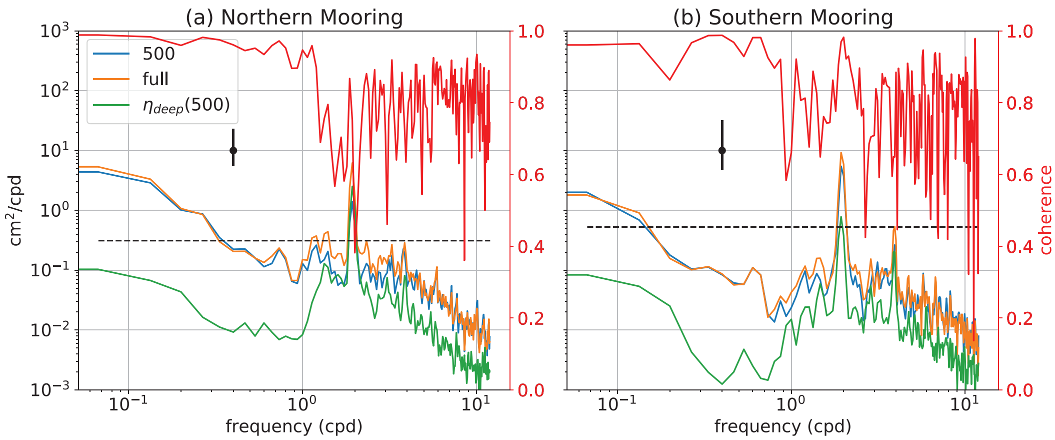

FIG. 10. The frequency spectra of 500 m (blue) and full-depth (orange) steric height and their difference (green) and the magnitude-squared coherence (red). The difference (green) is $\eta_{\text{deep}}(500)$. The spectra were calculated using Welch with nonoverlapping segments, each of which is of 15-day duration. The black error bar represents the 95% confidence interval. The degrees of freedom are 10 for the southern mooring and 18 for the northern mooring (due to its longer duration). The 95% significance level of the magnitude-squared coherence is shown by the dashed line: 0.31 and 0.53 for the northern and southern moorings, respectively.

(above 95% confidence level) for both moorings. This reflects that the superinertial motions, especially the semidiurnal internal tides, are of low baroclinic mode and reach deeper in depth than the subinertial submesoscale and mesoscale motions. [see also Lapeyre and Klein (2006) and LaCasce and Mahadevan (2006)].

The errors presented in this section include all spatial and temporal scales. Because of the SWOT focus on scales smaller than the mesoscale, correlated mesoscale scale error among the moorings can be removed, yielding a much smaller residual error budget. The high-frequency deep-ocean steric height with periods less than 2 days has 0.5–0.7 cm RMS and mostly from baroclinic tides (Fig. 10). If only the subinertial motions (2–14-day period) are considered, missing deep ocean introduce less than 2 mm error (Table 1), which is well below the KaRIn measurement error (0.54 cm RMS). These deep-ocean high-frequency signals require deep-reaching mooring CTDs.

d. Station-keeping glider as a virtual mooring

Gliders, unlike moorings, are mobile and add more flexibility to the campaign. We had one Slocum glider in the 2019/20 campaign for 1) testing the performance of a data assimilation system (Archer et al. 2022) and 2) testing the glider as a virtual mooring for the contingency of a failed mooring.

The glider vertical trajectories generally straight lines underwater, proceeding in a single direction fixed to a magnetic heading. This heading can be chosen to correct for ocean currents if one wishes to hold sampling lines. The downside of a single trajectory underwater means larger errors in station keeping and thus the ability to remain close to a single location. This is because of large distances traversed horizontally underwater, especially while diving deep.

To compensate for this and maintain a fixed position, the glider must have the ability to change heading underwater. It achieves this by maintaining a course of waypoints underwater which can be in any shape, for instance, a square, triangle, or even back and forth with two waypoints. Built into the underwater positioning is an algorithm to correct for estimated depth averaged current. This allows the underwater vehicle to continuously correct for current and maintain the same positions on Earth underwater for periods of several hours or more.

The Slocum glider's dive speed is about 18–20 cm s^{-1} yielding ~45 min per profile for a diving depth of 500 m. This will produce about 30 profiles a day. The capability of a station-keeping glider has been tested in our OSSE study (Wang et al. 2018) and the 2017 field campaign (Clark et al. 2018), where we confirmed that the glider-derived steric height matches the upper-ocean steric height from a nearby mooring for periods longer than 6 h with error-to-signal ratio smaller than 0.5 (figure not shown).

We tested the glider's station keeping again in the 2019/20 campaign and also used the glider as a conduit to connect and test the three moorings. The Slocum glider performed station keeping near the three moorings for three weeks between 27 November and 17 December 2019. The relative location of the glider flight path to three moorings are shown in Fig. 11. The glider stayed for about 3, 5.5, and 6.5 days around the southern, middle, and northern moorings, respectively. The associated mean glider–mooring distances are 1.2 ± 0.2 km, 0.8 ± 0.4 km, and 0.9 ± 0.2 km from south to north. The clusters of the glider surface locations have smaller circles referenced to its own center. The circles have a radius of 233, 350, and 520 m from north to south, respectively. The horizontal spread of the glider surface locations has a comparable size to the watch circle of the southern mooring during this period. A larger spread of the glider paths is expected for a longer duration and/or in a stronger flow field.

The Slocum glider's capability of being a virtual mooring was validated again in this campaign. The RMS difference

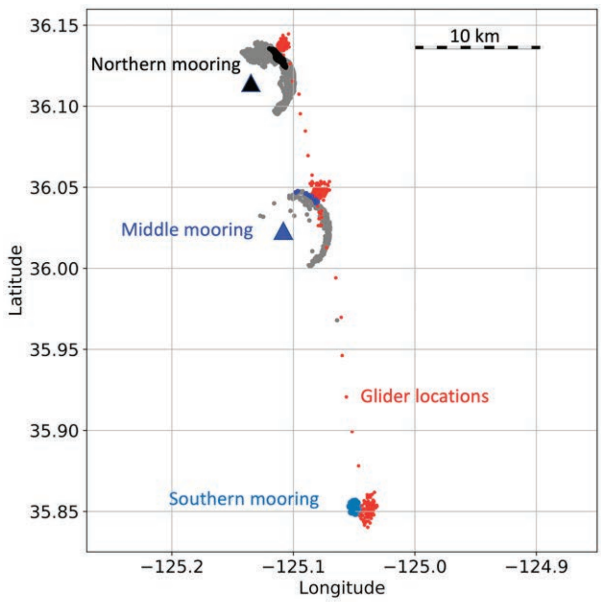

FIG. 11. The locations of the glider (red) and the northern mooring (black), the middle mooring (blue), and the southern mooring (navy blue) during the glider station-keeping phase, 27 Nov–17 Dec 2019. The mean separation distances during station keeping phase are 0.9 ± 0.2, 0.8 ± 0.4, and 1.2 ± 0.2 km for the northern, middle, and southern mooring, respectively. The two triangles show the anchor locations of the middle and northern moorings. The mooring watch circle shown by the gray dots has a radius of 4.5 km.

between glider and mooring upper-ocean (500 m) steric height is about 0.4–0.5 cm. Figure 12 (top panel) shows the time series of the upper-500 m steric height calculated from the glider (blue lines) and the moorings (orange lines). To avoid temporal interpolation errors, we used individual profiles to calculate the steric height without temporal interpolation between the subsurface temperature and salinity profiles. The time associated with the steric height of each profile was taken from the time at 250 m depth.

Figure 12 shows that the upper-500-m steric heights from glider and moorings are closely matched. The RMS differences are 0.4, 0.48, and 0.45 cm for the northern, middle, and southern mooring. The northern mooring has fixed CTDs binned to a 6-min grid close mooring–glider match confirms the capability of gliders to reproduce the upper-500-m steric height to time scales of several cycles per day.

The comparison of the glider to the northern mooring has the least RMS difference. The middle mooring was equipped with a Prawler, similar to a Wirewalker on the southern mooring, but was configured to sample about 8 profiles per day to test the endurance of the mooring. The larger RMS difference is mostly caused by the low temporal resolution (8 profiles per day) in mooring steric height (orange line/symbol in the top-center panel of Fig. 12). Because of the low temporal resolution, the middle mooring undersampled the internal tides especially the peaks that were captured by the glider. For example, the internal tidal variance at the beginning of 12 May 2019 is captured by the glider but not by the mooring (Fig. 12, top-center panel). This indicates the insufficiency of 8 profiles per day sampling frequency.

For the southern mooring comparison (top-right panel), there are superinertial variabilities in the mooring steric height largely captured by the glider except for the tidal peaks on 29 November. The glider dived to 1000 m at this location, so the temporal resolution is half that of the 500 m dives. The resulting lower temporal resolution in the glider steric height introduces an RMS difference 0.45 cm, which is larger than the 0.4 cm at the northern mooring. The time series comparison indicates that mapping the SSH variability due to the internal wave displacement of the density structure of the upper 500 m requires around 24 profiles per day. The spectral and coherence analyses shown in the bottom panel of Fig. 12 confirm the direct visual examination of the steric height time series discussed above. The glider steric height matches the northern mooring steric height in spectral density (bottom left, blue and orange lines) with high coherence (>0.6) down to approximately 5–6-h period (bottom left, purple line). For the middle mooring, because of the low temporal resolution in the mooring steric height, the glider–mooring only matches up to the M_2 tidal frequency, so ~8 profiles per day can resolve M_2 tides but not supertidal variabilities. For the southern mooring location (bottom-right panel), the mooring and glider match with high coherence (>0.6) down to a 6-h period.

In summary, the steric height derived from the glider matched the mooring upper-500-m steric height with 0.4–0.5 cm RMS difference. This largely validated the capability of gliders as a virtual mooring in the Cal/Val region with one caveat that the glider's error is referenced to the mooring's upper-ocean steric height, which itself carries about 0.6 cm uncertainty. Even though this uncertainty can be reduced by nearby deep-reaching CTD moorings with instruments in the deep ocean, the added uncertainty should be emphasized in a contingency scenario that a glider is needed to substitute a failed mooring.

e. *Spatial and temporal variability*

Each mooring produces a steric height time series. We can examine the temporal and frequency content of the signal. The spatial–temporal variabilities can be examined by combining the three moorings separated at 10 and 20 km even though a full wavenumber spectrum cannot be calculated across so few mooring separations.

1) TEMPORAL VARIABILITY

In the time domain, the mooring upper-500-m steric height closely follows the gridded SSH over long periods. Figure 13 shows the direct comparison between AVISO and the steric height of the northern and southern moorings (black solid and dashed lines). At the beginning of the campaign in early September 2019, the mooring steric heights and altimetric SSH are all at about approximately 76 cm level. This is associated with a south–north meandering current, whose SSH gradient is largest east–west perpendicular to the mooring array (Fig. 5a). When the meander curved toward the coast to form

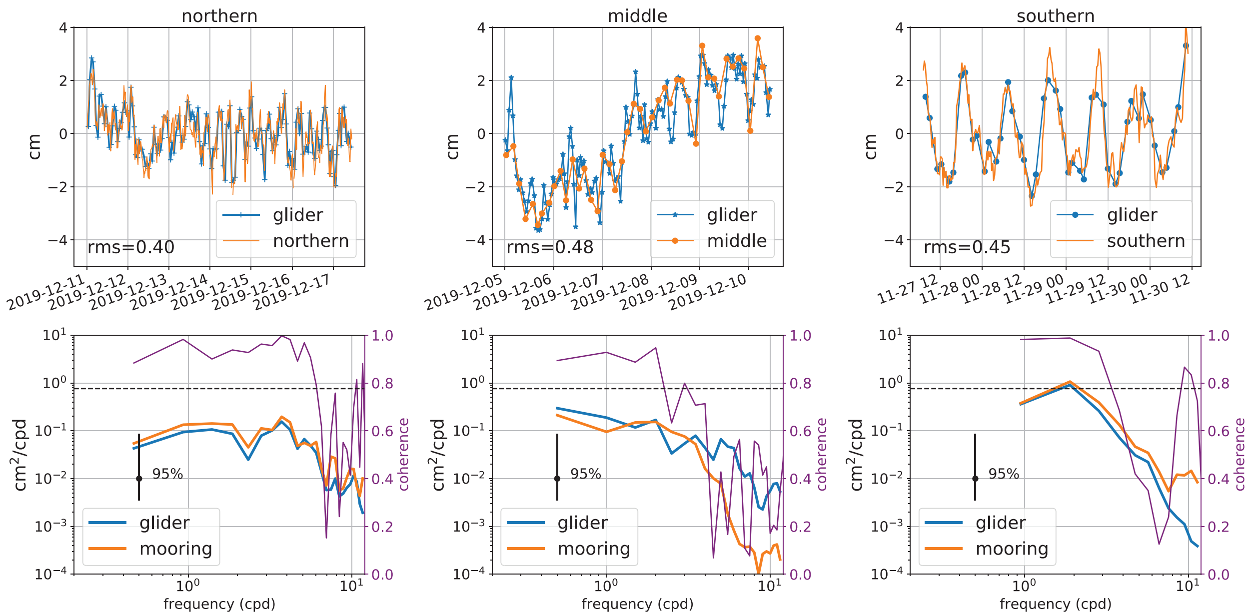

FIG. 12. (top) The upper-500-m steric height reconstructed from the glider (blue lines) and moorings (orange lines). (bottom) The frequency power spectral density for the glider (blue) and moorings (orange). The black vertical lines show the 95% confidence interval with 4 degrees of freedom (three nonoverlapping segments). The magnitude-squared coherence is shown in purple with the *y* axis on the right and the associated 95% confidence level marked by the dashed lines(left to right) The northern, middle, and southern moorings. The duration of the station-keeping phase was longest at the northern mooring (6.5 days) and shortest at the southern mooring (3.5 days).

an isolated mesoscale eddy during the eddy formation, the flow turned zonal (Fig. 5b) and the SSH differences between the three moorings can be as large as 10 cm between the southern and northern moorings, for example, at the end of October 2019 (Fig. 13, top panel). Near the end of November 2019, when the eddy was finally formed and detached (Fig. 5c), the meander regained its original north–south orientation with isolines oriented along the direction of the mooring array, resulting in a minimal SSH difference among the moorings. This eddy development can be seen from both altimetric SSH and mooring steric height, but the two-dimensional altimetric SSH field reveals more of the physical process than the one-dimensional array.

The gridded altimetry product and mooring have high coherence (>0.6) for periods longer than 20 days (figure not shown). The match between altimetric SSH and mooring upper-500-m steric height with less than 2 cm RMS error validates the upper-500-m steric height in representing satellite SSH over low frequencies. For periods shorter than ~20 days, the mooring steric height exhibits more variability than the gridded altimetric product, which is expected. From the example shown in the bottom panel of Fig. 13, the M_2 tide can be coherent and propagate from north to south shown by the gray arrow, but the coherency among the three moorings is intermittent. Over a 2-day period between 11 and 13 November, for example, the M_2 tidal peaks are less obvious at the northern mooring than at the southern mooring (Fig. 13, bottom panel).

The southern and northern mooring time series (Fig. 13, upper panel) reveal that the M_2 tide is stronger and more coherent at the southern mooring than the northern mooring. From a tidal analysis on the two steric height time series (figure not shown), the southern mooring has an M_2 steric height amplitude of 1.7 cm while the northern one has an amplitude of 0.7 cm. The M_2 baroclinic tide represented by the steric height is dominated by the first baroclinic mode that has a large wavelength longer than 100 km.

To address the question of why the M_2 tide is so different between two moorings separated by 30 km, we first eliminated the possibility that the difference comes from different mooring designs. The southern mooring uses a subsurface taut mooring connected to the profiler and surface buoy above by a reserve catenary. This design has a much smaller watch circle (250 m radius) than the northern slackline design mooring (~4 km radius). However, it is unlikely that this contributes to the difference in the M_2 signal at the different moorings, based on the glider results during its station-keeping phases shown in Fig. 12. The time variability at the M_2 tidal period is well characterized by the glider for both the southern and the northern moorings. During the 6-day period where the glider operated near the northern mooring, it confirmed the weak M_2 signal there. Likewise, at the southern mooring, the glider confirmed the elevated M_2 variability in steric height there. This mooring–glider comparison largely eliminates the influence of mooring design on the reconstruction of the coherent tides. As a result, the significantly different M_2 tide between the northern and the southern moorings appears to be real.

One possibility for the different tides between the northern and the southern moorings is that this small-scale difference is expected due to multiwave interference that has been

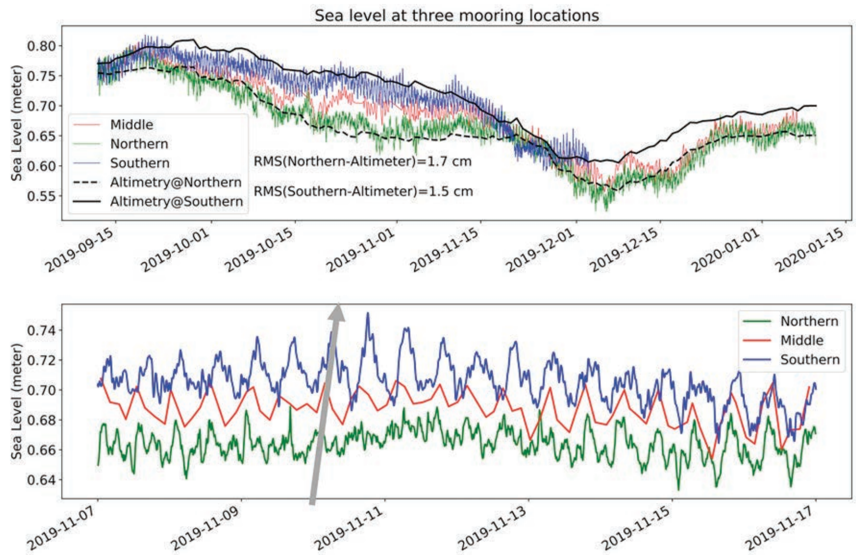

FIG. 13. (top) The time series of the upper-500-m steric height from three moorings (colored lines) offset by a constant 496.91 m, and the altimetric sea level anomaly interpolated at northern mooring (black solid) and southern mooring (black dashed). The RMS differences between WHOI mooring and SIO mooring steric height from their local altimetric sea level anomaly is 1.7 and 1.5 cm, respectively. (bottom) The same mooring steric height time series, but focusing on a 10-day window between 7 and 17 Nov 2019. The semitransparent gray arrow marked the propagation of the internal tides from the northern mooring through the middle mooring and to the southern mooring.

observed in the conventional altimetry (Zhao et al. 2019; Zaron 2019). An altimetry-based internal tide model that fits plane internal waves with multiple directions does also show similar amplitude variation of the mode-1 M_2 internal tide over the 30 km distance between the two moorings (Zaron 2019).

Another possibility is the modulation of coherent tides by balanced motions (e.g., Ponte and Klein 2015). The mesoscale and smaller mesoscale eddies are stronger at the northern mooring location than the southern mooring location, resulting in stronger eddy modulation of the tides and reduced tidal coherency. This can be seen from the frequency spectra of the steric height field of the three moorings (Fig. 14). The stronger M_2 tides at the southern mooring discussed above are illustrated in the frequency spectrum, i.e., the green line is much higher than the blue line at the M_2 frequency. The three moorings have matched energy on the low-frequency end with periods longer than 20 days. However, the spectral energy level at the southern mooring is drastically different from and one order of magnitude weaker than the other two moorings over 1–10-day periods. The gridded altimetry SSH maps (Fig. 5) show that the southern mooring is on the warm side of the meander and inside of the mature eddy at later stage, while the northern mooring spent more time on the further edge of the eddy where sharp horizontal fronts can be more prominent. This is confirmed by the horizontal gradient of SST, which is persistently stronger at the northern mooring location than at the southern mooring (figure not shown). This set of evidence points to the hypothesis that mesoscale eddies can modulate coherent low mode tides within a distance shorter than the tidal wavelength. The 2D SSH field to be observed by SWOT can be very useful to detect these small-scale eddy–wave interactions. Further proof of the hypothesis needs more observations or process-oriented numerical modeling studies and will be pursued elsewhere.

2) SPATIAL VARIABILITY

With two full-depth moorings at the northern and southern locations, we can start to examine the spatial variability from

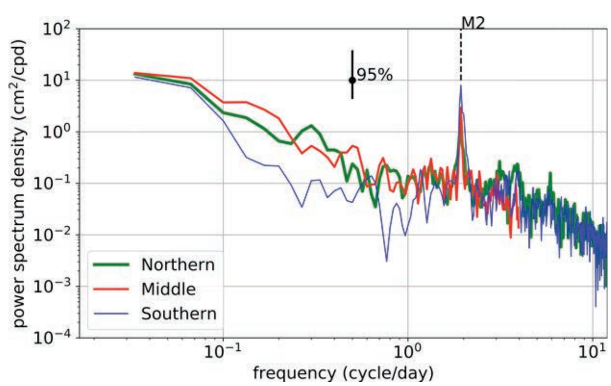

FIG. 14. The frequency spectra of the upper-500-m steric height from the northern (blue), middle (red), and the southern mooring (green). M_2 tidal frequency is marked by the dashed vertical line. The middle mooring spectrum (red) was cut at 4 cycles per day for its limited sampling frequency at 8 profiles per day.

TABLE 2. RMS differences between the northern and the southern moorings for the period 10 Sep–25 Nov 2019 when full-depth measurements are available at both sites. The temporal-scale separation is done in frequency space through Fourier analysis without windowing. The bottom row is done through a three-mooring scale separation described in the text representing a back-of-envelope calculation of the small-scale (<~30 km) variability. The unit for all values is cm.

	Full water column	0–500 m	500–4000 m
All frequencies	3.2	2.8	0.9
<14 days	1.6	1.4	0.8
2–14 days	0.7	0.7	0.2
<2 days	1.5	1.2	0.7
Anomalies to a linear function of the three moorings		0.2–0.7	

the mooring difference. Table 2 shows that the RMS difference over 30 km is 3.5 cm based on the full-depth steric height, among which 2.8 cm is due to the upper 500 m and 1 cm to the deeper ocean. These values include the influence of the wavelengths longer than 150 km, which is beyond the focus of the in situ Cal/Val. With only three moorings spanning 30 km, it is impossible to single out the signals with wavelength less than 150 km, but in general longer wavelengths are associated with longer periods. For example, these RMS differences are reduced for periods less than 14 days and significantly reduced for the 2–14-day band. The variability with periods less than 14 days is dominated by high frequencies (>1/2 cycle day^{-1}). This dependence of RMS difference on time scales is expected for a typical SSH frequency spectrum that is dominated by low-frequency (monthly and longer) variabilities and tidal peaks over high (superinertial) frequencies (e.g., Fig. 14).

The middle mooring does not have deep CTDs below the Prawler and samples only the upper 500 m. If we only focus on the upper-500-m steric height, the three moorings can be used to derive steric height difference for separation distances of 10 and 20 km. The standard deviations of the differences are 1.6 and 2.0 cm for 10 and 20 km, respectively.

These analyses with a single mooring (section 4c, Table 1) or two-mooring differences (Table 2) cannot distinguish different spatial scales, but we have used the above frequency filtering to isolate motions on SWOT spatial scales and thus could estimate the expected RMS differences due to these motions on the single spatial lag of 30 km. This is the size of SSH differences expected due to motions of interest to SWOT over such distances. In addition, with three moorings, we can begin to decipher the spatial–temporal variabilities due to the smallest-scale motions, even without the actual wavenumber spectrum. The main technique is discussed as follows.

Given three moorings with separation distances of 10 and 20 km, we have three points spanning 30 km distance. To examine small-scale signals, we removed the large-scale influence by removing a spatial linear trend through the three moorings for each hourly snapshot as shown in the schematic diagram in Fig. 15a. The middle mooring time series is linearly interpolated from 8 profiles per day to hourly, which inevitably introduces errors. The deviations from the fitted linear trend are considered the SSH anomaly at small scales.

The linear-trend removal is a crude spatial high-pass filter. The effectiveness of removing the local linear trend is evaluated using a Monte Carlo simulation to test a Hanning high-pass filter with different window sizes. We first generate 5000 128-km-long synthetic SSH profiles with certain wavenumber spectral slopes, then sample the profiles in the middle at three locations separated by 10 and 20 km, resembling the prelaunch campaign mooring placement. The synthetic mooring data are separated into large scale and small scale using the same method of fitting a three-point linear trend. The results are compared with results produced by a high-pass Hanning filter of different window widths. We find that for synthetic SSH profiles with k^{-4} wavenumber spectrum, the smallest difference between removing a local linear trend of the three moorings and a Hanning-window filtering occurs at 22 km Hanning-window width. For k^{-2} profiles, it is at 32 km. The SSH profile is "smoother" for steeper wavenumber spectrum, e.g., k^{-4}, so the local linear trend captures and removes large-scale signals more effectively. The anomalies after removing the local linear trend are mostly from spatial scales less than approximately 30 km. We denote these anomalies as "small scale" and the linear trend as "large scale" in the following paragraph. It is worth emphasizing again that this operation is a crude way of separating small and large scales, given the limitation of the spatial coverage of the data.

The derived small-scale variability is significantly weaker than the large-scale variability (Fig. 15b). The RMS values of the total upper-500-m steric height for the three moorings are 1.9, 1.3, and 1.9 cm from north to south. The corresponding large scales defined by the linear trend have RMS values of 1.7, 1.2, and 1.9 cm. The small-scale (<~30 km) steric height is 0.4, 0.7, 0.2 cm for the northern, middle, and southern moorings, respectively. These values for small scales are smaller or close to the SWOT KaRIn noise values around 0.54 cm (section 2d). It indicates that the SSH signal at the Cal/Val site can be weaker than the SWOT KaRIn noise for spatial scales 20–30 km and smaller. This result is consistent with Wang et al. (2019).

Note that the sum of small-scale and large-scale temporal variances is larger than the variance of the total signal. This provides evidence that this spatial filtering does not separate the signal in the temporal space. However, removing the local linear trend effectively removes most of the low-frequency variability that is visually obvious in the time series (Fig. 15b) and also clearly shown in the frequency spectra in Fig. 15c, where the power spectra of the total and large-scale signals converge over periods longer than 10 days (blue and orange lines). Removing the linear trend also effectively removes most of the M_2 baroclinic tides in the steric height, which means that the baroclinic tides have spatial scales larger than about 30 km. Even though the large-scale signal is more energetic than the smaller spatial signal over almost all

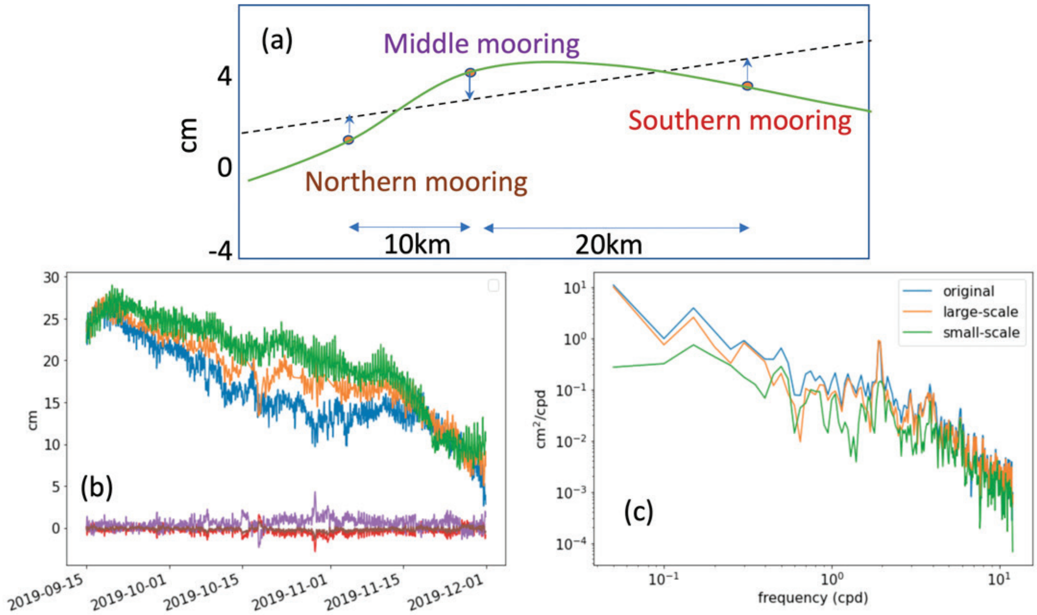

FIG. 15. (a) The schematic of deriving small-scale anomalies from three moorings. The linear trend (dashed line) was derived through the least squares method. The deviation of each mooring steric height from their linear trend is denoted as the small-scale component. Removing the linear trend over a 30 km segment is similar to high-pass filtering with a 20–30-km-wide Hanning window depending on the wavenumber slope of the signal. (b) The original steric height of each mooring (green, orange, and blue lines). The small-mesoscale signals defined in (a) are shown by purple, red, and brown lines for the three moorings. (c) The frequency spectra for the original steric height (blue), the linear trend representing the large-scale (orange), and the small-scale steric height (green) averaged over the spectra of the three moorings.

frequencies, the small-scale signal is particularly large over the period range of 2–5 days relative to the large scale. With a caveat of uncertain significance, we may tentatively associate <30 km spatial scales with 2–5-day temporal scales. This spatial–temporal-scale association may have a practical value for designing the optimal error covariance matrices in the data assimilation system with the multiscale approach, such as Li et al. (2019), D'Addezio et al. (2019), and Archer et al. (2022).

f. Comparison to Sentinel-3A *SSH*

The *Sentinel-3A* ground track was not a factor for the design of the SWOT Cal/Val orbit. It is rather fortunate that one of the *Sentinel-3A* (*S3A*) ground tracks is in the middle of a SWOT swath along the fast-repeating orbit. For this reason, the mooring array in the prelaunch field campaign was placed along the *S3A* ground track (Fig. 2). During the 2019/20 campaign period, *S3A* passed the mooring array five times (Fig. 16). The mooring steric heights (upper 500 m) match the *S3A* measurements within 2 cm RMS. There were two times when the steric heights and *S3A* values were different (the third and fifth rows). Despite the sizeable differences, the spatial structures in the mooring array steric heights resemble the spatial structures of the *S3A* SSH profiles. However, bias corrections of 2 and 6 cm were applied to 6 November 2019 and 2 January 2020 profiles, respectively. The nature of the bias is unknown at the time of writing and deferred to future investigations.

g. Bottom pressure

Bottom pressure recorders measure both the barotropic (due to additional water mass above the BPR) and baroclinic (due to interior temperature/salinity changes) signals on the ocean floor. The BPRs deployed in this campaign have enough precision to detect millimeter-level signals, but BPRs suffer from a large long-term drift that may be mistaken for a low-frequency signal in our ~90-day records. Ray (2013) analyzed a network of BPRs of this type, showing that the BPR-derived tide matches the altimetric tide model with about 5 mm RMS difference for the M_2 constituent. The BPRs used in the campaign should be accurate enough to detect deep baroclinic pressure signals even though separating them from much more energetic barotropic tides based on a single mooring is impossible (Ray 2013). The most prominent signal in the bottom pressure is the tide (Fig. 17a). We fit 53 tidal constituents to the measured bottom-pressure signal to produce a detided bottom pressure record (Fig. 17b) using the same tool from Ray (2013). The detided signals are relatively small (2.3–2.6 cm), but still potentially important. Unfortunately, we have little information about the spatial scale of the signals contributing to these residual bottom pressure signals. Taking the difference between the two detided bottom-pressure records can give us a vague sense of how small-scale signals

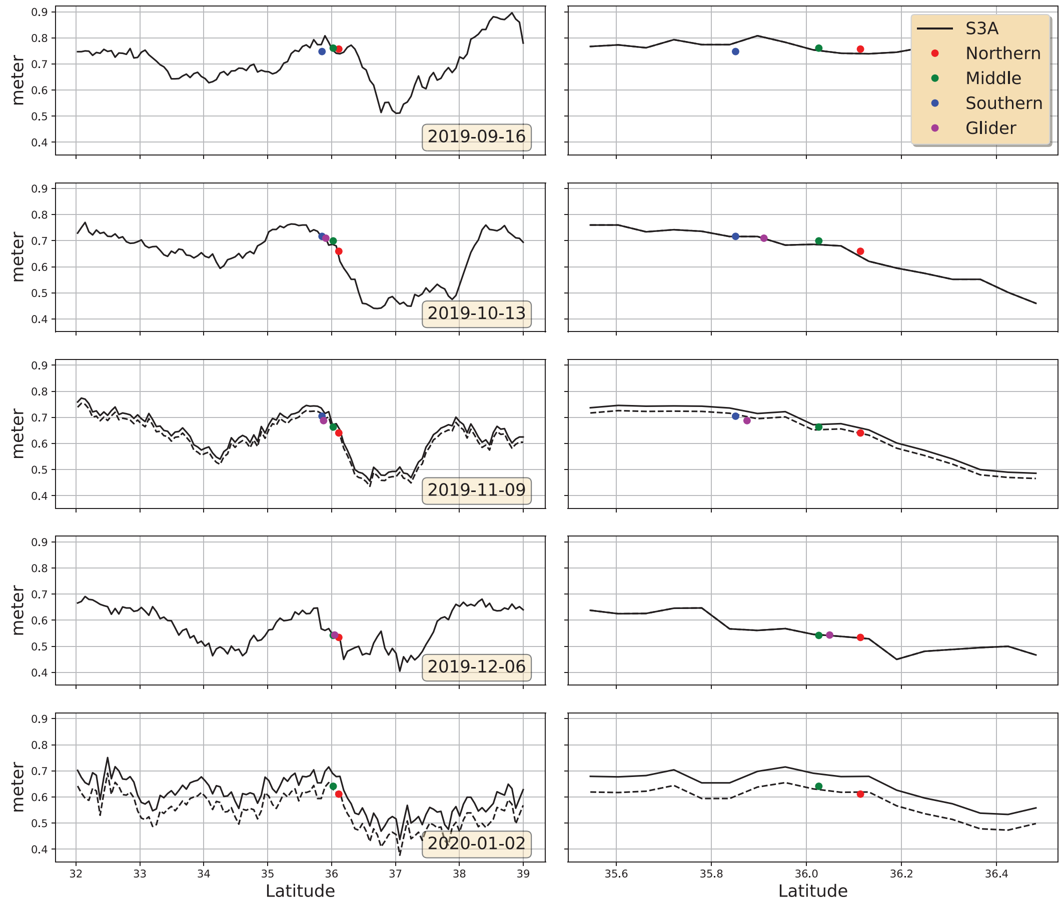

FIG. 16. The five *Sentinel-3A* SSH profiles during the 2019/20 campaign period that pass the mooring array (black lines). They are the L3 product with ocean (barotropic) tides, dynamic atmosphere correction (DAC), and long-wavelength-error (LWE) correction applied. The colored dots show the upper-500-m steric height from the northern (red), middle (green), and southern (blue) moorings and the glider (purple). (left) The 7° segment to show the large-scale context. (right) The same profile, but zooming in to focus on the mooring array within 100-km-wide segments. The dashed lines in the third and fifth rows are the black lines offset by 2 and 6 cm, respectively. The steric height is calculated from the original in situ density without removing the time mean, then offset by 496.385 m to match the *Sentinel-3A* profiles.

might contribute. This difference has an RMS amplitude of 0.6 cm based on the period of 1 October 2019–1 October 2020 when the bottom pressure drift becomes less obvious. It contains both barotropic and baroclinic signals, including several tidal frequencies and low-frequency variability, and the parabolic shape of the difference curve (Fig. 17b) suggests it may also be affected by differences in the low-frequency drift of the two bottom pressure recorders. Removing a quadratic fit to the difference between the two detided bottom-pressure records reduces the RMS difference to about 0.4 cm, which is below the SWOT KaRIn noise level derived in section 2d.

5. The design of a SWOT postlaunch campaign

The main purpose of the SWOT prelaunch campaign described in the paper is to provide information for the design of an effective yet affordable postlaunch SWOT ocean in situ observing system for the mission's calibration and validation. To validate the SWOT SSH, we need an array of observations for comparison with the nearly simultaneous measurement taken by the satellite in less than 23 s over 150 km. The resolution of SWOT in the California Cal/Val region is about 20 km in wavelength, below which the baroclinic SSH becomes less than KaRIn instrument noise (Wang et al. 2019). To meet the Nyquist wavelength requirement of 20 km, we need a measurement every 10 km. Although Wang and Fu (2019) indicated that the onboard nadir altimeter is able to validate SWOT at wavelengths longer than 120 km, we feel that, in order to reduce cost, it is acceptable to deploy an array of 11 moorings covering 100 km to meet the in situ Cal/Val objectives.

Based on the analysis presented in the paper, it is acceptable to sample only the upper 500 m for the low-frequency ocean variability. However, it is desirable to sample the ocean deeper than 500 m to capture the deep signals of internal tides and occasional deep eddies. Since the wavelengths of internal

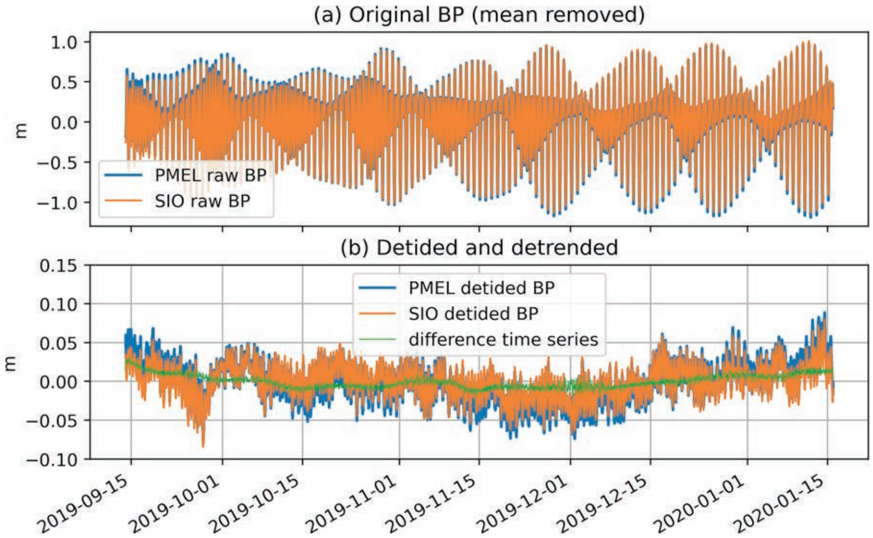

FIG. 17. (a) The original time series of the bottom pressure from the southern (orange) and the northern (blue) BPRs. (b) The residual after removing the fitted tides and linear trends. We fit 53 tidal constituents to the 4-month-long time series to reduce the residual. The remaining signal of each BPR still has 2.2–2.4 cm standard deviation.

tides are longer than 60 km (the two lowest modes of the M_2 tides; Zhao et al. 2019), the required Nyquist sampling interval for low-mode internal tides is 30 km. Shown in Fig. 18 is a baseline design of the postlaunch observing system. It contains 11 moorings with 4 of them (triangles) consisting of a Wirewalker and deep CTDs like the SIO system. The remaining 7 moorings are Prawler moorings like the PMEL system, sampling only the upper 500 m. These instruments will provide time series observations that allow the construction of the snapshots of steric height for comparison with the SWOT SSH measurement on a daily basis. The difference between the two observations will provide an assessment of the SWOT measurement errors for the small-wavelength range reconstructed by the in situ mooring array (20–100 km). Its wavenumber spectrum will be compared with the SWOT requirement (Fig. 1).

Based on the results from the prelaunch campaign, GPS buoys and BPRs are not critical for meeting the Cal/Val objectives. To make accurate IB correction for the SWOT SSH, one barometer at the center of the array is included in the design.

Two gliders are included to sample the cross-track ocean variability to aid the estimation of the two-dimensional state of the upper ocean for validating the science goals of the mission to determine the circulation of the upper ocean. If funding permits, more gliders would be highly desirable for achieving the science goals. As illustrated in the paper, the gliders, when operating in the station-keeping mode, will also serve as a contingency for any failed mooring.

Given the constraints of the mission's budget, this design presents a minimum system for meeting the mission's Cal/Val objectives. We look forward to opportunities of collaboration with other interested parties to expand this SWOT Cal/Val array into a larger-scope, submesoscale-focused experiment in this region.

6. Discussion and conclusions

It has been shown that observations from the moorings and the glider can be used to reconstruct a steric height field with accuracy at an RMS error below 1 cm at each location level. There are, however, remaining uncertainties in the accuracy of the horizontal wavenumber spectrum produced by an array of these moorings.

The moorings' large watch circles might be a source of uncertainty in making an SSH wavenumber calculation for the SWOT Cal/Val purpose. The watch circle can reach a 4 km radius. It may change the spacing between moorings and result in nonuniformly spaced mooring array. In addition, the deviation from the centerline of the mooring array (the middle of the SWOT swath) can also be as large as the watch circle radius. These along-track and cross-track drifts of the moorings will introduce errors and uncertainties, but we do not have a formal assessment of the error in this study. In any case, the size of the watch circle is less than the 15–20-km-wavelength resolution of SWOT in the Cal/Val region (Wang et al. 2019).

The deep-ocean steric height has variability and can contribute to the overall steric height signal. Based on the ~90 days of mooring observations collected during the 2019/20 campaign, the consequence of missing the deep-ocean steric height was about 0.6–0.8 cm standard deviation for each mooring, mostly arising from baroclinic tides (Fig. 10).

There is some evidence that eddies at and below 500 m occasionally occur in the Cal/Val region (Collins et al. 2013). Although Collins et al. (2013) do not report on the water

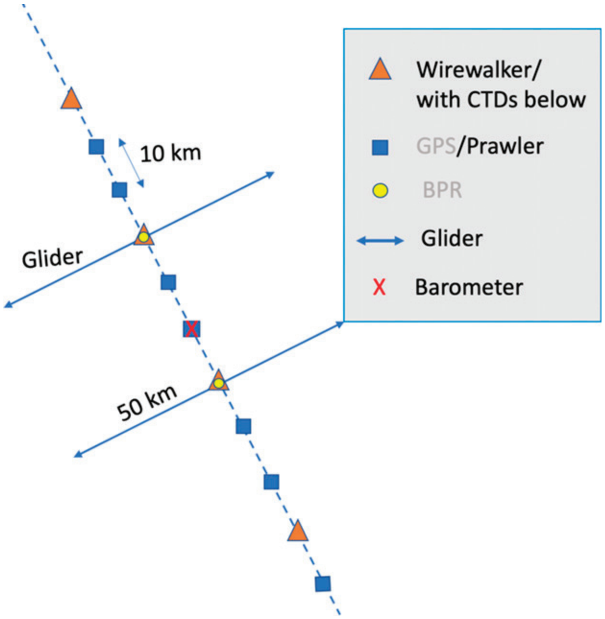

FIG. 18. A minimum baseline for the SWOT postlaunch ocean Cal/Val field campaign. The four hybrid moorings with full-depth *T*/*S* measurements can capture deep-reaching baroclinic tides with relatively longer wavelengths. The seven Prawlers will measure the upper-500-m steric height. Two gliders will sample the cross-swath direction and also serve as a contingency for failed moorings. The barometer will provide high-precision, high-frequency atmospheric pressure for IB correction. BPRs and GPS receivers are not part of the minimum baseline but will be a valuable upgrade.

column structure associated with the observed deep eddies, they could contribute to variability in steric height and to significant nonzero velocities at 500 m depth. For example, assuming a mode-1 structure, a 25-km-wide eddy at 1500 m with ~10 cm s^{-1} velocities as reported by Collins et al. (2013) would be associated with a ~1 cm change in steric height across its diameter. They also observed an eddy at 660 m depth with velocities that would correspond to 1.4 cm steric height signal across the eddy with a diameter of 54 km at that depth. However, deep eddies need not be associated with a mode-1 structure. For example, Gula et al. (2019) report on the presence of deep submesoscale coherent vortices (SCVs) in the Gulf Stream with diameters of 10–30 km. Those SCVs have a mode-2 like signature that would have little if any impact on steric height (e.g., Fig. 2d in Gula et al. 2019). Given the potential for deep eddies to contribute a small amount of steric height variability, a subset of moorings in the SWOT Cal/Val effort will monitor the deep ocean to account for these signals if they arise (Fig. 18).

Even though the error in GPS SSH from a single buoy (>1 cm RMS) is larger than SWOT mission requirements, much of this error is attributed to sea-state and water-line errors, and intrinsic GPS errors (e.g., from tropospheric refraction) that are spatially correlated over the campaign footprint. Significant cancellation of common mode errors can thus be expected from combined processing of observations of multiple buoys operating in the same campaign theater. This is supported by recent tandem buoy campaigns in the Bass Strait (Zhou et al. 2020) and near the Harvest platform (Haines et al. 2019), both of which suggest that errors (on ΔSSH between buoys in proximity) are reduced to less than 1 cm. Whether the accuracies achieved can approach the stringent requirements imposed by the validation of the SWOT wavenumber spectrum remains an open question (Zhou et al. 2020). Regardless, the GPS buoy technique has advanced significantly and already offers a powerful means of resolving discrepancies between steric height (as measured with hydrographic techniques) and geodetic SSH (as measured by SWOT).

We have shown that it is possible to measure the steric contribution to sea surface height to <1 cm RMS precision with several moorings and a glider. This allows confidence that an array of moorings and collocated glider lines (e.g., Fig. 18) will allow for a robust oceanographic calibration and validation of the KaRIn sensor on board the SWOT satellite during the planned 1-day fast-repeat period before the satellite is moved to its final orbit.

This is the first time when a combination of independent high-precision in situ instruments is used to analyze the SSH budget focusing on such small spatial scales (less than 30 km) and high frequencies (period less than monthly). The results shed light on the design of the SWOT postlaunch field campaign as well as the ocean physics over such small scales and high frequencies (periods ranging from hours to months).

We have shown that the ocean sea surface height measured by GPS, which is like altimeter/SWOT measurements, matches the steric height derived from the temperature and salinity measurements using CTDs after subtracting the bottom pressure and applying the inverted barometer correction. The consistency between the GPS-BPR and the mooring steric height validated the utility of the steric height as the ground truth for satellite calibration and validation. Even though the absolute RMS difference between GPS-BPR-derived steric height and CTD-derived steric height is larger than 1 cm, how much of the error is due to the large-scale common mode GPS error is unknown, but expected to be largely removable. The utility of GPS in the SWOT Cal/Val is still under investigation through the second GPS on the middle mooring. The major advantage of using steric height is the absence of the errors due to surface waves.

The variability in steric height is mostly due to the upper-ocean processes. For example, the deep-ocean ($z < -500$ m) steric height variability has a standard deviation of 0.6–0.8 cm, most of which comes from superinertial frequencies, especially around the semidiurnal M_2. If only subinertial variabilities with periods between 2 and 14 days are considered, missing deep ocean results in <2 mm uncertainty.

Small scales less than 30 km wavelength have very weak steric height variation, 0.2–0.7 cm standard deviation near the SWOT Cal/Val campaign region diagnosed from the 2019/20 campaign conducted in the wintertime. This small-scale variability is estimated based on the deviations of the three mooring steric heights from their spatial linear trend. This weak small-scale steric height signal underlines the challenge for

SWOT, but also highlights the opportunities provided by SWOT and the values of a full-scale array with a dozen CTD moorings in conducting the mission Cal/Val and studying the small-scale ocean circulation.

Acknowledgments. We are grateful to Anna Savage and R/V *Sally Ride* captain and crew for the unplanned recovery of the Wirewalker, and to Hong Zhang for providing ERA5 atmospheric pressure for the IB correction, Ed Zaron for the discussion on internal tides, and Marie Eble and George Mungov for the discussions on the tidal reconstruction from BP. The research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration (80NM0018D0004). All authors are supported by the SWOT project. J. T. Farrar was partially supported by NASA NNX16AH76G. The in-situ observations are available for download at https://podaac.jpl.nasa.gov/.

Abstract—— **The Mid-Atlantic Cold Pool is a seasonal mass of cold bottom water that extends throughout the Mid-Atlantic Bight (MAB). The Cold Pool forms from rapid surface warming in the spring and dissipates in the fall due to mixing events such as storms. The Cold Pool supports coastal ecosystems and economically valuable commercial and recreational fisheries along the MAB. Offshore wind energy has been rapidly developing within the MAB in recent years. Studies in Europe demonstrate that existing WEAs can impact seasonal stratification; however, there is limited information on how MAB wind development will affect the Cold Pool. Seasonal overlap between the Cold Pool and wind lease areas in the Southern New York Bight along coastal New Jersey was evaluated using a data assimilative ocean model. Results highlight overlap periods as well as a thermal gradient that persists after bottom temperatures warm above the threshold typically used to identify the Cold Pool. These results also support cross-shelf variability in Cold Pool evolution. This work highlights the need for more focused ocean modeling studies and observations of the Cold Pool and MAB wind lease area overlap.**

Keywords—Stratification, Bottom Temperature, Cold Pool, Offshore Wind, Mid-Atlantic Bight

I. Introduction

The Mid-Atlantic Cold Pool is a seasonal mass of cold bottom water extending throughout the Mid-Atlantic Bight (MAB) from Nantucket, MA to Cape Hatteras, NC, which results in one of the largest thermal gradients in the world (Fig.1). This stratification and the associated cold bottom temperatures and nutrient-rich environment support a diverse coastal ecosystem including economically important recreational and commercial fisheries [1]. Within the MAB, over 2.3 million acres of the MAB continental shelf has been leased for offshore wind energy projects that are under development, including sites that overlap with the seasonal Cold Pool [1,2]. Limited information exists about the extent of this overlap, as well as the impact of the turbines on the Cold Pool [1].

The Cold Pool develops in the winter as cold water from the Nantucket Shoals, north of the MAB, is transported southward to well-mixed MAB water [3,4]. In the spring, as surface water temperature increases and storm frequency decreases, a strong thermocline develops that isolates the cold, and relatively fresh bottom water, known as the Cold Pool [3, 5]. Stratification within the MAB is controlled and stabilized by salinity and temperature [6]. The strength of the thermocline, driven primarily by temperature, reaches a seasonal peak between July and August, when the Cold Pool also peaks [6]. As surface temperatures begin to decrease in the late summer and early fall, the thermocline weakens and fall storms eventually mix stratified surface waters to the bottom and the Cold Pool dissipates [3-8].

Seasonal Cold Pool evolution is integral to MAB ecosystem processes. Upwelling along the MAB occurs annually transporting Cold Pool waters further inshore and towards the coastal surface, which can drive phytoplankton blooms [9,10]. The presence of Cold Pool water allows species ranges to extend further south than would be anticipated by latitude, supporting many economically and culturally valuable finfish and shellfish fisheries [11–14].

The United States is anticipated to become one of the largest offshore energy markets by 2030 with an estimated 1.7 million acres under lease, and more than 2,100 turbine foundations to be installed [15]. The MAB region leads the nation in proposed offshore wind energy projects with regional offshore wind goals totaling more than 40,083 megawatts (MW) of energy within the next decade [2]. Offshore wind development in the United States is relatively new, while European offshore wind energy has been developed extensively and can provide insight into possible interactions between turbines, physical oceanographic processes, and biological systems despite key differences between the regions [16].

Funding provided by the National Science Foundation and the Science Center for Marine Fisheries

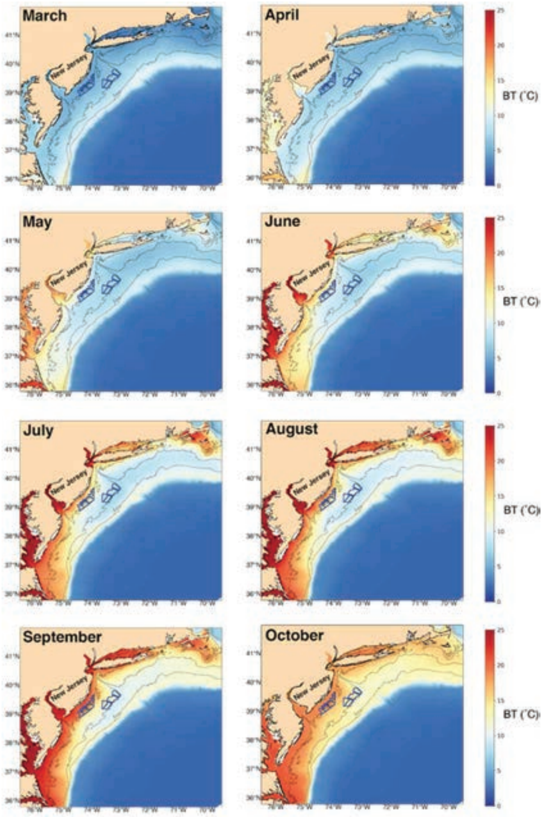

Fig.1. Monthly averaged bottom temperatures based on Doppio simulations spanning 2007 to 2020 within the MAB. Only peak Cold Pool months are included. The Cold Pool is highlighted with white and blue colors when the bottom temperature reaches below 10˚C. Wind lease areas included in this study are outlined in blue. The 25, 50 and 75m isobaths are shown in black.

While still applicable, results from European studies are more representative of conditions in the MAB during relatively weakly stratified periods, and do not represent Cold Pool conditions [1]. Likewise, many European lease areas use smaller turbines with different density and spacing, further adding to uncertainty about how relevant European research is to MAB conditions [16].

Wind turbines can directly impact the hydrodynamics within and around the site through their underwater infrastructure, and indirectly through changes in both the surface and atmospheric wind fields [17]. Structure-induced friction and blocking from flow past cylindrical structures often forms Von Kármán vortex streets, increasing the turbulence directly downstream of the turbine. In the context of the Cold Pool, this could lead to less stratified conditions [1]. It is unclear what the effects will be on the highly stratified system like the MAB Cold Pool if the area of increased turbulence is expanded [17-18]. Likewise, the extraction of atmospheric kinetic energy by turbines may be amplified by larger clusters of wind turbines in turn reducing shear-driven forcing at the sea surface and decreasing horizontal velocities, and turbulent mixing within several kilometers of the wind site [19]. This could potentially mean that within the MAB, offshore wind projects within the Cold Pool could strengthen stratification. The implications of offshore wind on the hydrodynamic features of the MAB require further study, however, because of the broader spatial extent of wind lease areas, the weaker tidal strength and increased storm frequency within the MAB versus Europe, as well as the technological differences in turbine design.

In this paper, we evaluate the extent and cross-shelf variability of spatial overlap between wind lease areas and the Cold Pool. We will focus on projects proposed in waters off the state of New Jersey to highlight trends in these differences. Specifically, we will evaluate the duration, strength, and variability of stratification where the Cold Pool overlaps with wind lease areas within the southern New York Bight, off of New Jersey (NJ) using output from a data assimilative regional ocean model known as Doppio [20].

II. Methods

Data used in this study was simulated by the Doppio model, a Regional Ocean Modeling System (ROMS) application of the MAB and the Gulf of Maine [20]. Doppio is computed using 4-Dimensional variational assimilation of satellites, HF-radar ocean surface currents and all available *in situ* observations from MARACOOS and NERACOOS regional associations of the U.S Integrated Ocean Observing System (IOOS). The model resolution is a uniform 7 km horizontal grid with 40 vertical layers. The output of Doppio used in this study is from a free-running regional model run with simulations spanning from 2007 to 2021. Data was accessed in March 2022 using the thredds link: (https://tds.marine.rutgers.edu/thredds/roms/doppio/catalog.html?dataset=DopAnV3R3-ini2007_da_monthly_averages).

The presence and location of the Cold Pool is defined as locations where the vertical temperature gradient is 0.2˚C/m or greater and the bottom temperature is 10˚C or less [1, 3, 7, 21–24]. The density stratification over the MAB region is primarily thermally controlled during the peak Cold Pool months, thus stratification is determined by calculating the temperature gradient:

$$0.2^\circ C/m \le \delta T/\delta z \ \& \ T \le 10^\circ C \qquad (1)$$

Seven wind lease areas (WLAs) were identified as the closest geographically to the New Jersey shoreline and were selected for this study (Fig. 2). Six study locations were selected approximately central within or at a boundary between the seven WLAs. Monthly averaged temperature values were obtained from Doppio simulations for each study location (Fig. 2). Using all 40 vertical layers of the monthly averaged temperature data, a monthly vertical temperature gradient was calculated for each location (n=180). The monthly average bottom temperature was also calculated for each location. Temporal trends and variability in Cold Pool evolution were determined using ensemble monthly averages (i.e the mean of all January temperature values from 2007-2021) and standard deviation calculated for both bottom temperature and temperature gradients for all 15 years at each study location.

III. RESULTS

Based on the temperature gradient and bottom temperature criteria, the Cold Pool was present at all six selected study locations within the seven wind lease areas (Fig. 3,Table I,Table II). Despite the fifteen-year temporal span of the ensemble monthly averages of bottom temperature and the temperature gradient, variability across the time series at each study point was limited. Bottom temperature during peak Cold Pool months varied by 0.13˚C (standard deviation) while temperature gradient varied by 0.02˚C/m (standard deviation) across all sites and years.

There were limited latitudinal differences in the duration or strength of the Cold Pool across the six study locations (Fig. 3,Table I,Table II). Four study points are offshore in 50m water depth, while two are relatively inshore at approximately 25m of depth. All four offshore study locations had bottom water temperature below 10˚C and a thermal gradient greater than 0.2˚C/m in the month of April signifying the presence of the Cold Pool (Fig. 3). The bottom temperature at these four offshore study points exceeded 10˚C in July meaning the Cold Pool duration there was approximately three months (Fig. 3,Table I). Despite the warming bottom temperatures in all four offshore sites, the thermal gradient value above 0.2˚C/m was maintained for two additional months dissipating in September (table I). In the four offshore sites, the minimum bottom water temperature occurred at approximately the same time as the temperature gradient exceeded 0.2˚C/m in either March or April (Fig. 3, Table I, Table II). The peak temperature gradient occurred simultaneously with bottom water warming above 10˚C (Fig. 3). The highest bottom temperatures occurred as stratification broke down around October or November (Fig. 3).

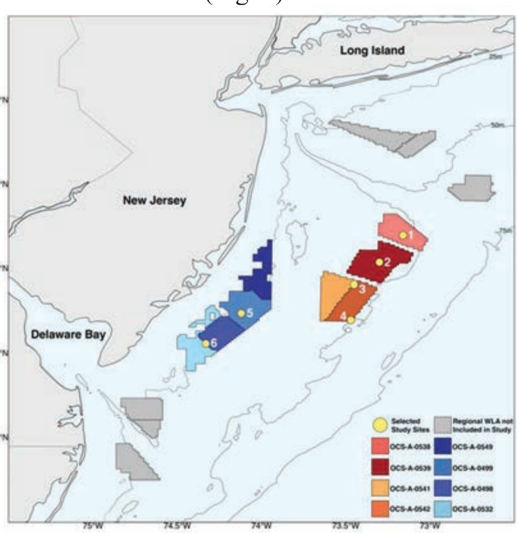

Fig. 2**.** Study locations are depicted with yellow circles and associated wind lease areas (WLA) are shown as colored blocks, with different colors for different lease blocks. Blue WLA correspond to nearshore study points while red WLA are offshore study points. Other WLA not included in this study are shown in gray. The 25, 50 and 75m isobaths are shown in black.

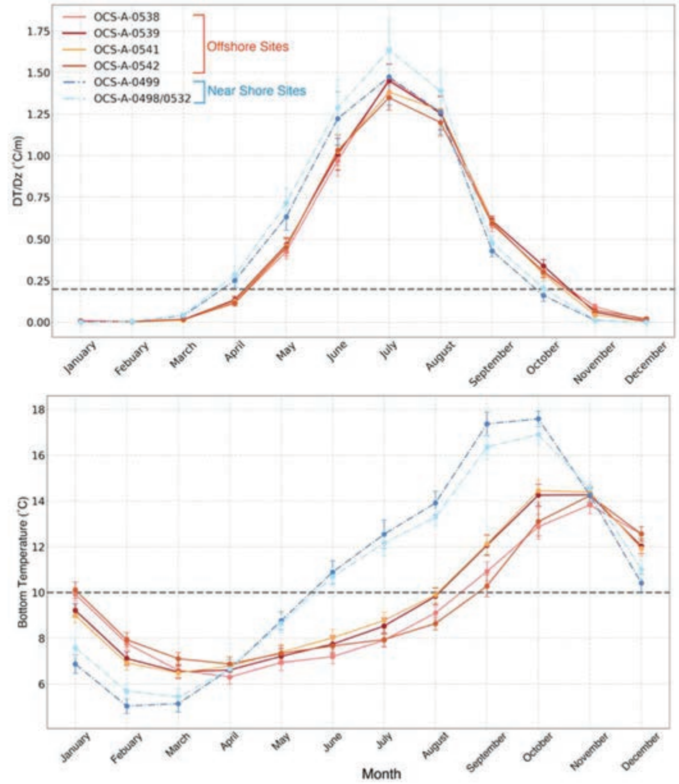

Fig.3. Monthly average bottom temperature (lower panel) and dt/dz values (upper panel) from 2007-2021 for study locations. Colors correspond to the specified wind lease area (Fig. 2). Blue colors represent nearshore sites while red colors symbolize offshore sites. The Cold Pool exists when bottom temperature values remain below the dashed grey line and when dt/dz values are above the above grey dashed line.

TABLE I. The duration of the Cold Pool based on ensemble averages from 2007-2021 according to the traditional definition as well as the duration of the thermal gradient above 0.2˚C/m for each study location. The Cold Pool start signifies the thermal gradient passing 0.2˚C/m and the Cold Pool end occurs when bottom temperatures surpass 10˚C. Wind lease area (WLA) names correspond to official lease call numbers.

Study Location	WLA Name (OCS-A-)	Cold Pool			dT/dz>0.2˚C/m	
		Start	*End*	*Length*	*End*	*Length*

5	0499	5.03	Feb.	1.47	Jul.
6	0498/0532	5.43	Mar.	1.64	Jul.

There are notable differences in the Cold Pool evolution between the nearshore and offshore points (Fig. 3, Table I,Table II). In the two nearshore study sites, the Cold Pool duration was shorter, spanning approximately one month, starting in March with increasing thermal gradient values and ending in April when the bottom temperature surpassed 10˚C (Fig. 3). Despite the short duration of the Cold Pool, the heightened thermal gradient values in these two nearshore sites lasted longer than at the four offshore sites (Fig. 3,Table I). In study sites five and six, the thermal gradient above the Cold Pool threshold extended for seven months (Fig. 3,Table I). Despite an earlier development in sites five and six, the thermal gradient dissipated at approximately the same time as the offshore sites (Fig. 3,Table I). In both nearshore sites, the minimum bottom temperature occurred at a similar time to the offshore sites but was more than 1˚C cooler than the offshore sites. Peak thermal gradients in both nearshore sites occurred in July, despite the bottom temperature warming above 10˚C in April. Bottom temperature and thermal gradients reached a greater maximum value at the nearshore sites.

IV. Discussion

Findings of regional Cold Pool trends offshore of New Jersey in this study are consistent with those of previous papers that discuss the spatial and temporal variability of the Cold Pool [3, 4, 6–8, 21, 23]. Nearshore bottom temperatures warmed more quickly (0.02˚C/day) than offshore bottom temperatures (0.06˚C/day) which is consistent with results from previous papers [7, 8]. Generally, the Cold Pool is shorter in duration at areas of relatively shallow depths [7,8]. Previous studies have defined the Cold Pool dissipation as the decrease in stratification strength in early fall [7,8]. While findings in this study support the strengthened thermal gradient extending into the early fall, bottom temperatures were consistently above the Cold Pool threshold after July. The thermal gradient in the southern New York Bight, where all six study sites are located, has been observed to be greater than in other areas of the MAB because of lower thermal diffusivity in the area [7,8]. Previous studies indicate the maximum temperature gradients to be around between 0.5 and 0.8 ˚C/m, while in both offshore and nearshore sites the values in this study exceeded 1˚C/m [7,8].

Cold Pool dissipation has previously been associated with bottom temperatures warming above 10˚C [3,7, 8]; however, we found that the thermal gradient remains above 0.2˚C/m well beyond when the bottom temperature warms. Even in the nearshore sites, stratification extends months after the bottom temperature warms and reaches higher maximum thermal gradient values than within the offshore sites. This finding is important as stratification is the buoyancy force that inhibits mixing by flow past structures such as wind turbines, and it maintains ecologically important habitat [1]Atlantic Surf clams, Ocean Quahogs and Sea Scallops are some of the most dominant and economically valuable fisheries within the larger MAB as well as within the state of New Jersey [1, 13, 25, 26]. These species are thermally sensitive and their distribution is often an indicator of changing bottom temperatures [13, 25].Thermal gradients and changes in bottom temperature could have direct impacts on these and other commercially and ecologically important species. Results indicate a larger spatial and temporal overlap between offshore NJ wind lease areas and the MAB Cold Pool versus near shore wind lease areas following traditional Cold Pool definition. It is still uncertain the extent to which impacts from WEA development will affect the Cold Pool. European studies have shown that wind lease areas do influence the hydrodynamic features of coastal environments [17–19]. These impacts, however, depend heavily on the spatial extent of the WEAs as well as the temporal and spatial variability of stratification and mixing [18-19]. The current wind lease areas within the German Bight occupy a significantly smaller area than those proposed along the MAB. The stratification within the German Bight is quantified as a 5-10˚C difference between surface and bottom water temperature and tidal currents in this region can reach near 1.0 m/s [18-19]. At the peak of thermal stratification in the German Bight during the year 2014, the bottom water temperature along the 25m isobath only reached 14˚C resulting in a maximum thermal gradient of 0.2˚C/m [18]. Local tidal forcing within the MAB is much weaker than the German Bight (>0.1 m/s) despite more frequent storms within the MAB [27]. The German Bight, therefore, has significantly weaker stratification than the MAB and stronger currents. Because of the spatial, technological, and environmental differences between the German Bight and the MAB, it is uncertain what the hydrodynamic impacts of offshore wind on the Cold Pool will be, however, the above characteristics of the MAB and findings of this study suggest that the impacts from turbines will be less than those found in the German Bight.

V. Conclusion

The MAB Cold Pool is an invaluable coastal ocean feature that supports some of the most economically and culturally valuable fisheries in the United States. The Cold Pool influences a variety of oceanographic processes, such as atmospheric and oceanic circulation, coastal primary productivity, and carbon sequestration. The development of offshore wind has been rapidly expanding off of coastal NJ. This study found that there is notable overlap between proposed offshore wind lease areas in NJ and the Cold Pool. In addition, it was found that thermal gradient values above the Cold Pool threshold extended past when bottom temperatures warmed above the Cold Pool criteria. Results also supported results from previous studies that nearshore bottom temperatures warm more rapidly than offshore, despite stronger thermal gradient values in nearshore sites. It is unclear from the technological, environmental, and spatial differences between the German Bight and the MAB what the impacts of the development of offshore wind on the Cold Pool will be. Future studies to determine the interdecadal trends of Cold Pool evolution is necessary to further evaluate the extent of overlap between the Cold Pool and the MAB wind lease areas are needed. Additional study is also necessary to determine the effects of newer turbine technology on the MAB seasonally stratified environment.

ACKNOWLEDGMENT

We thank the Rutgers University Department of Marine and Coastal Sciences, the Haskin Shellfish Research Lab at Rutgers University, and the Geology and Environmental Studies departments at Carleton College for their continued support. We also thank Julia Levin, John Wilkin and Alex Lòpez for their help with Doppio. Special thanks to Joe Gradone and Ailey Sheehan.

ABSTRACT

Lim, H.S.; Kim, D.; Lee, H.J.; Kim, M.; Jin, S.H.; Miles, T.N., and Glenn, S., 2021. Typhoon-induced full vertical mixing and subsequent intrusion of Yangtze fresh waters in the Southern Yellow Sea: Observation with an underwater glider and GOCI ocean color imagery. *In:* Lee, J.L.; Suh, K.-S.; Lee, B.; Shin, S., and Lee, J. (eds.), *Crisis and Integrated Management for Coastal and Marine Safety*. *Journal of Coastal Research*, Special Issue No. 114, pp. 171–175. Coconut Creek (Florida), ISSN 0749-0208.

Typhoons have been regarded as an important forcing to control oceanographic phenomena, particularly in the Yellow and East China Seas. The influences of typhoons have become increasingly severe due to global warming. An autonomous underwater glider was deployed west of Jeju Island for 10 days from 15th to 25th August, 2018 to observe changes in physical environments induced by Typhoon Soulik. The glider data show that the stratified water masses were destroyed by the typhoon into a fully mixed stage of the entire water column. This de-stratification is manifested by many environmental parameters including temperature, salinity, chlorophyll-a, and suspended sediment concentrations. Accordingly, calculated parameters, density, and Richardson number, indicate de-stratification. The water column displayed, however, a rapid return to the stratification stage immediately after the typhoon passage. In addition, the GOCI geostationary ocean color imagery was analyzed that were obtained during and after the passage of Soulik between 15-25 August, 2018. These satellite images suggest that the discharge of the Yangtze River fresh water so increased during the typhoon that the intensified freshwater plume could move toward Jeju Island. As a result, observations with an autonomous glider may provide a promising means in analyzing oceanographic processes occurring during the peak of typhoons.

ADDITIONAL INDEX WORDS: *Typhoon-ocean interaction, ocean de-stratification, Yangtze diluted water, underwater glider, GOGI observation.*

INTRODUCTION

Recently, the threat of typhoons on the coast of the Korean Peninsula has been gradually increasing because of rising of sea water temperature and sea level due to global warming. The number of typhoons that influenced South Korea sharply increased from 2.5 a year on average in the last 10 years (2001-2010) to 5 in 2018 and 7 in 2019 (KMA, 2020). Many of the typhoons entering the Yellow Sea moved toward the southern coast of the Korean Peninsula through the coastal waters of Jeju Island (Figure 1a).

In addition, typhoons caused the surface water temperature to be dramatically changed producing a strong surface cooling. In August 2012, the passing of Typhoon Bolaven resulted in the surface water temperature dropping from 27-28 °C to 16-20 °C according to satellite observations from near the west coast of Jeju Island (Kim *et al.*, 2014). The passing of Typhoon Soulik also resulted in the surface water temperature decreasing from 27.5 °C to 16.5 °C according to underwater glider observation from the west coast of Jeju Island (Lim *et al.*, 2020). Both typhoons passed through west Jeju Island from the East China Sea in August 2012 and 2018, respectively. The study area is a critical alley of typhoons that enter the East China Sea (Figure 1a). This area is characterized by the Yellow Sea Cold Bottom Water and is frequently influenced by a low-salinity plume of the Yangtze fresh water in summer (Kim *et al.*, 2004). Prior to the Typhoon Soulik passage, strong summer stratification was observed to form due to substantial differences in temperature (11 °C) between the surface and bottom layers (Lim *et al.*, 2020). Similarly, the rapid surface cooling by Hurricane Irene also observed over the stratified coastal waters of northeast United States in August 2011 (Glenn *et al.*, 2016).

This study updates the preliminary results (Lim *et al.*, 2020) from the underwater glider observations in the western coastal waters of Jeju Island of Korea (Figure 1b). The observations were performed vertically through the water column down to 100 m during a 10-day period including the passage of Typhoon Soulik. The major goal of the present study is to illuminate details of the oceanographic changes induced by Typhoon Soulik. To do this, the glider data were carefully re-analyzed, and the GOCI (Geostationary Ocean Color Imager) imagery was used to monitor how the typhoon influenced the distributions of suspended matter in the study area.

METHODS

Typhoon Soulik formed on August 16, 2018 in the western North Pacific and rapidly intensified to the level of typhoon in two days. The typhoon slowly passed west of Jeju Island around 12:00 KST (3:00 UTC) on 23 August. On the same day, though somewhat weakened, it made landfall over the southwestern coast of the Korean Peninsula around 23:00 KST.

Underwater Glider

An underwater glider (RU22) was deployed in an area west of Jeju Island (Figure 1b) from 15th to 25th August 2018 (Lim *et al.*, 2020). The RU22 glider was equipped with CTD and optical BBFL2 sensors to measure various oceanographic parameters including temperature, salinity, density, chlorophyll-a, dissolved organic matter, and optical backscatter, a proxy of suspended sediment concentrations. The glider moved through the almost entire water column from the surface down to 100 m. Details on operation and measurements can be seen elsewhere (Lim *et al.*, 2020).

Figure 1. (a) Track of Typhoon Rumbia (Red) and Soulik (Blue) in south Yellow Sea and (b) Track of glider observation for 10 days from 15th to 25th August 2018. Triangle = deployment site; circle = recovery site; star = Marado ocean buoy; square = Ieodo station.

GOCI Observation

GOCI obtains ocean color images every day during the daytime (Choi *et al.*, 2012). Some of GOCI images obtained during 21-26 August 2018 were chosen in this study to reveal distributional time-series of chlorophyll-a and suspended sediment concentration (SSC).

RESULTS

The vertical ocean mixing induced by Typhoon Soulik is evident in the distributions of temperature, salinity, and thus density (Figure 2). At the Soulik passage on 23 August, temperature dropped about 11 °C from 27.5 °C to 16.5 °C at the surface in contrast to the water depth of 100 m where it increased by 3 °C (from 11 °C to 14 °C) (Figure 2a). At the same time, salinity clearly shows a remarkable increase of about 1.8 psu at the surface, while it remained constant or barely increased (about 0.7 psu) at 100 m (Figure 2b). The Marado ocean buoy close to the glider area (Figure 1b) exhibits that significant wave heights measured 8 m during the typhoon; this buoy also measures tide. Immediately after the typhoon passage, however, salinity rapidly increase to about 34.3 psu in the bottom layer. Both the temperature and salinity display a thermocline and a halocline, respectively, around the water depths of 20-40 m before the typhoon (Figure 2a, b). Density follows well the patterns of temperature and salinity as the latter control density dominantly (Figure 2c). A pycnocline was therefore existent between 20 and 40 m. It is interesting that tidal fluctuations may affect the variations of these three parameters considerably, particularly in the mid-to-bottom water depths.

The typhoon effects on temperature, salinity, and density are more clearly shown in selected vertical profiles (Figure 3). All the profiles illustrate vertical mixing and hence the de-stratification of the entire water mass by Typhoon Soulik.

The degree of stratification can be evaluated using the Richardson number, *Ri* (Prandle, 2009):

$$Ri = \frac{g}{\rho} \frac{\partial \rho / \partial z}{\left(\partial u / \partial z \right)^2} \tag{1}$$

where, g is gravity, ρ is density of sea water, u is flow speed, and z is water depth. The condition, $Ri < 0.25$, was used to signal de-stratification. Flow speed was obtained on the assumption that the horizontal speeds of the glider and flows were identical to each other. Figure 4 shows full mixing at the typhoon passage and otherwise a consistent stratification in the water layer of 20-40 m.

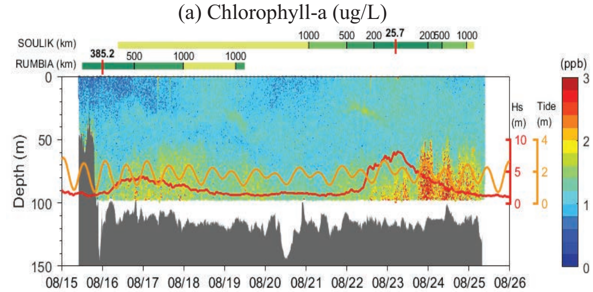
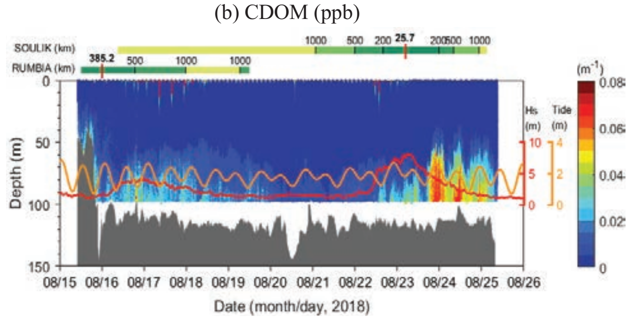
(a) Chlorophyll-a (ug/L)



(b) CDOM (ppb)



(c) Optical backscatter (b_b) at a wavelength of 880 nm (m^{-1})

Figure 5. Time-series of vertical variations of (a) chlorophyll-a (ug/L), (b) colored dissolved organic matter (ppb), and (c) optical backscatter at 880 nm (m^{-1}) for 10 days from 15th to 25th August, 2018. The significant wave height (red line) and tide elevation (brown line) were derived from the Marado ocean buoy.

Figure 5 shows time-series of chlorophyll-a, colored dissolved organic matter (CDOM) and optical backscatter. Chlorophyll-a also indicates vertical mixing processes by the typhoon (Figure 5a). Its concentrations were diluted in the surface layer but somewhat increased in the mid layer during the typhoon passage. The CDOM and optical backscatter display rapid increases by high waves of the typhoon in the bottom waters (Figure 5b, c). Such an increase continued after the typhoon waned. The concordant variations of these two parameters with tide suggest that tidal currents can resuspend seabed sediments in this area.

The GOCI ocean color images show the distribution of surface chlorophyll-a in the southern Yellow Sea before and after the Typhoon Soulik passage (Figure 6). A surface plume laden by chlorophyll-a came to move eastward from the Yangtze-river mouth to near Jeju Island as the Yangtze-river discharge greatly increased owing to heavy rainfall during the typhoon. The SSC distributions were quite similar to those of chlorophyll-a (Figure 7). Typhoon Soulik resulted in the Yangtz-river diluted fresh water extending to Jeju Island.

Figure 7. Distribution of surface suspended sediment concentrations from GOCI images on August (a) 21, (b) 24 and (c) 26, 2018. A surface plume of Yangtze-river fresh waters was shown to move toward Jeju Island during Typhoon Soulik.

DISCUSSION

Typhoon Soulik created an extensive vertical mixing of the order of 100 m. That mixing destructed pre-typhoon ocean stratification that had been characterized by a thermocline and a pycnocline well established between water depths of 20-40 m near west Jeju Island, Korea. As a result, the bottom-water layer received a great amount of heat energies (equivalent to an increase of 3 ℃), whereas the surface layer was cooled significantly (a drop of 11 ℃). In this exchange of water masses, organic matters abundant in the surface layer were also dispersed down to the bottom layer. Such a scale of vertical mixing observed by underwater glider has not been demonstrated in the study area. Kang, Jo, and Kim (2020) also reported vertical mixing and fluctuation of the thermocline by Typhoon Soulik from Argo floats near the coastal waters of southwestern Korean Peninsula. However, the thermocline layer, where temperature range is 15-20 °C, was deepened from 20-30 m to 40-50 m by the typhoon.

The seabed sediments appear to be resuspended by tidal currents. The time-series data (Figure 5c) show that during spring tide the resuspension occurred in tidal modulation. However, Typhoon Soulik most probably agitated the seabed sediments in that optical-backscatter signals began to be recorded abruptly when waves heights rapidly increased (Figure 5c). Those data suggest that the threshold of the seabed sediments may be exceeded by typhoon- or storm-induced, 5-m-high waves. This finding may reflect that typhoon and storms play an important role in the mud flux and distribution in the Yellow Sea and adjacent seas (Lee and Chough, 1987). It is interesting that the optical backscatter further increased during the diminishing waves under the same tidal conditions unchanged. More detailed physical data from the near-bottom layer should be needed to resolve these resuspension processes.

The satellite data (Figures 6 and 7) have illuminated that the Yangtze fresh waters can reach the coastal zone of Jeju Island, not only during the summertime flooding seasons but also during a short period of heavy rainfalls by typhoons. Previous studies were mostly focused on the movements of a Yangtze diluted freshwater plume associated with the summer flooding (Bai *et al*., 2014). The present study clearly shows that the Yangtze fresh waters extended to near Jeju Island by Typhoon Soulik, although the summer flooding seasons of that year (2018) had already ended. The appearance of the Yangtze plume near Jeju Island is a critical issue to fishery industries of that region. Therefore, typhoons should be requisite to forecasting the plume formation and behavior accurately.

CONCLUSIONS

The vertical ocean mixing by the Typhoon Soulik over the highly stratified waters of west Jeju Island was re-analyzed with the oceanographic parameters including temperature, salinity, and density from CTD sensor and chlorophyll-a, dissolved organic matter, and optical backscatter from optical BBFL2 sensor equipped with the underwater glider. The change of surface distribution of chlorophyll-a and suspended sediment concentration which was derived from GOCI ocean color imagery was also analyzed for the Typhoon Soulik influence.

The ocean stratification in the water depth of 20-40 m before the typhoon was vertically fully mixed by the strong typhoon effect and tidal fluctuations. The typhoon-driven vertical ocean mixing also could affected the suspended sediment transport concentration in the mid-to-bottom water depths enhanced by the tidal effect. The Yangtze-river fresh water affected significantly not only the surface temperature and salinity but also the surface concentrations of chlorophyll-a, CDOM, and SSC during the typhoon passage.

ACKNOWLEDGMENTS

The authors thank to Dr. Young Baek Son and Dr. Jae-Seol Shim, Korea Institute of Ocean Science and Technology (KIOST), for supporting and facilitating the glider observation. This research was fully supported by the Ministry of Trade, Industry and Energy (MOTIE), Korea for its financial support of the project titled “The establishment of advanced marine industry open laboratory and development of realistic convergence content.” The authors are also grateful to the Ministry of Oceans and Fisheries (MOF), Korea for its administrative support of the project titled “Construction of ocean research stations and their application studies” with NOAA-MOF Joint Project Agreement.

ABSTRACT

The Southern Ocean serves as the primary gateway through which the intermediate, deep, and bottom waters of the ocean interact with the surface ocean (and thus the atmosphere), and it has a profound influence on the oceanic uptake of anthropogenic carbon and heat as well as nutrient resupply from the abyss to the surface. Yet it has been the least observed and understood region of the world ocean. The Southern Ocean Carbon and Climate Observations and Modeling (SOCCOM) project was implemented in 2014 with a goal to help remedy this deficit in observations and understanding. The SOCCOM project is based on two major advances that have the potential to transform understanding of the Southern Ocean. The first is the development of new biogeochemical sensors mounted on autonomous profiling floats that allow sampling of ocean biogeochemistry in 3-dimensional space. Floats may detect processes with a temporal resolution that ranges from hours to years. The second is that the climate modeling community finally has the computational resources and physical understanding to develop fully coupled climate models that can represent crucial, mesoscale processes in the Southern Ocean, as well as corresponding models that assimilate observations to produce a state estimate. The observational component, based on deployment of profiling floats with oxygen, nitrate, pH and bio-optical sensors, is generating vast amounts of new biogeochemical data that provide a year-round view of the Southern Ocean from the surface to 2000 m. The modeling effort is applying these observations and enhancing our understanding of the current ocean, and reducing uncertainty in projections of future carbon and nutrient cycles and climate. After nine years of operation, including a project renewal in the sixth year, the SOCCOM project has deployed more than 260 profiling floats. These floats have collected over 27,000 vertical profiles throughout the Southern Ocean. A data-assimilating biogeochemical state estimate model has been implemented. Here, the design of the SOCCOM project is reviewed and the scientific results that have been obtained are described. The project's capability to help meet the observing system priorities outlined for a notional UN Decade for Ocean Sciences Southern Ocean observing system is assessed.

1. Introduction

In 2014, the Southern Ocean Carbon and Climate Observations and Modeling (SOCCOM) project was initiated with a vision to enable a transformative shift in scientific and public understanding of the role of the Southern Ocean in global carbon biogeochemistry and the associated effects on climate. A strategic mix of innovative and sustained observations of the physical and biogeochemical elements of the carbon cycle, as well as mesoscale eddying model simulations linked to the observations formed the nucleus of the project. The project focused on the Southern Ocean because of its outsized role in regulating the global cycles of carbon and heat and the climate of the earth. Prior results suggested that:

- the Southern Ocean south of 44°S accounts for up to half of the annual oceanic uptake of anthropogenic carbon dioxide (CO_2) from the atmosphere (cf., Gruber et al., 2009);
- vertical exchange in the Southern Ocean south of about 40°S supplies nutrients that fertilize up to three-quarters of the biological production in the global ocean north of 30°S (Sarmiento et al., 2004; Marinov et al., 2006);
- the Southern Ocean is warming rapidly (Gille, 2002; Levitus et al., 2012) and recent work suggests that the region south of 30°S accounts for about 75%±22% of the excess heat that is transferred from the atmosphere into the ocean each year (Frölicher et al., 2015); and
- Southern Ocean winds and buoyancy fluxes are the principal source of energy for driving the global large-scale deep meridional overturning circulation (e.g., Toggweiler and Samuels, 1998; Marshall and Speer, 2012).

Model studies also projected that changes in the Southern Ocean would have a profound influence on future climate trends, with corresponding alteration of the ocean carbon cycle, heat uptake, and ecosystems. Projections included:

- due to acidification, the Southern Ocean south of ~ 60°S will become undersaturated in aragonitic calcium carbonate by ~ 2030 (McNeil and Matear, 2008; Feely et al., 2009), with potentially large impacts on calcifying organisms and Antarctic ecosystems (Bednaršek et al., 2012); and.
- The vertical exchange of deep and surface waters may either increase or decrease. Projected increases in winds over the Southern Ocean will decrease stratification and increase vertical exchange, whereas projected increases in rainfall and meltwater input will increase stratification and decrease vertical exchange. More vertical exchange would be expected to result in more anthropogenic carbon uptake from the atmosphere, but less storage of carbon through biological cycling (cf. Sarmiento et al., 1988), while its impact on heat uptake depends on whether it brings anomalously warm or cold waters to the ocean surface.

The two overarching goals of SOCCOM were:

- Goal 1: Quantify and understand the role of all regions of the Southern Ocean in carbon cycling, acidification, nutrient cycling including oxygen, and heat uptake, on seasonal, interannual, and longer time scales.
- Goal 2: Develop the scientific basis for projecting the contribution of the Southern Ocean to the future trajectory of carbon, acidification, nutrient cycling, and heat uptake.

To achieve these ends, we proposed a three-pronged approach, consisting of:

- a novel autonomous biogeochemical observing system for the Southern Ocean;
- high-resolution state estimation that would incorporate biogeochemical processes and assimilate the new data sets; and
- Earth System Model analyses, data/model assessment metrics, and development of a Southern Ocean Model Intercomparison Project.

The proposed observing system was to span all sectors of the Southern Ocean and extend from the surface to depths of two kilometers (Fig. 1). It was to be capable of measuring the processes outlined in Goal 1 with the skill needed for internally consistent observations spanning decades.

The modeling and state estimation components leveraged large external resources. The most expensive part of SOCCOM by far has been the observing system simply because of the cost of instrumentation, deployment, and data management. This observing system was necessary because, despite the significance of the Southern Ocean in the carbon cycle and climate-related processes (Martin et al., 1990), it has been one of the least observed basins of the global ocean (Bakker et al., 2016, Johnson et al., 2017b). To remedy this deficiency, the SOCCOM project proposed to deploy an array consisting of roughly 180 Biogeochemical-Argo (BGC-Argo) profiling floats (Johnson, 2017; Riser et al., 2018; Claustre et al., 2020) throughout the Southern Ocean over a 6-year interval beginning in 2014. The size of the array was based on several assessments described in Section 2.2. As floats are lost due to system failures or battery exhaustion, additional floats must be deployed to sustain the array. A subsequent renewal of the program funded an additional 120 floats over 4 years to maintain the array. This renewal began in 2020 and ends in 2024. Finally, the project aspired to educate a new generation of ocean scientists trained in both ocean observation and simulation, and to develop a sophisticated outreach effort to disseminate results to the broadest possible community.

As SOCCOM was developing, planning also began in 2017 for the United Nations Decade of Ocean Science, with the theme "the science we need for the ocean we want". In conjunction with the UN Decade, it was argued (Pendleton et al., 2020) that scientific research in the ocean has not kept pace with changing social and environmental conditions. Pendleton et al. (2020) called for fundamental changes in ocean science and ocean observing to equip society with the necessary information to manage marine systems. A UN Decade working group for the Southern Ocean (Hofmann et al., 2020) defined a series of priorities for an observing system in the Southern Ocean that would enable the UN goals to be achieved (Table 1). Many of the observing system priorities outlined in the UN report align closely with the design and objectives of the SOCCOM program. Given the significance of the UN Decade of Ocean Science effort, this review will incorporate the observing system priorities identified in the UN Decade Southern Ocean Workshop Report (Hofmann et al., 2020; hereafter UN Southern Ocean Report). This enables a comparison that serves, in part, as an assessment of the capability to build and operate an observing system compatible with UN Decade of Ocean Science goals and that would also achieve the goals outlined in the SOCCOM proposal.

The first part of this paper describes the SOCCOM observation and modeling implementation strategy followed by our major biogeochemical and modeling results, and then assessment of public outreach. This structure reflects the design of the SOCCOM project. SOCCOM operated with teams focused on observations, modeling, and broader impacts, rather than teams that might focus on a specific science topic, such as carbon cycling. This structure ensured that communications between groups always covered a broad range of topics, rather than permitting smaller groups with a single focus to become isolated. In each section that addresses a priority in the UN Southern Ocean Report (Table 1), those priorities are reiterated to emphasize the coherence between SOCCOM and the desired observing system. In a "SOCCOM in the Future" section, new applications of SOCCOM data are described.

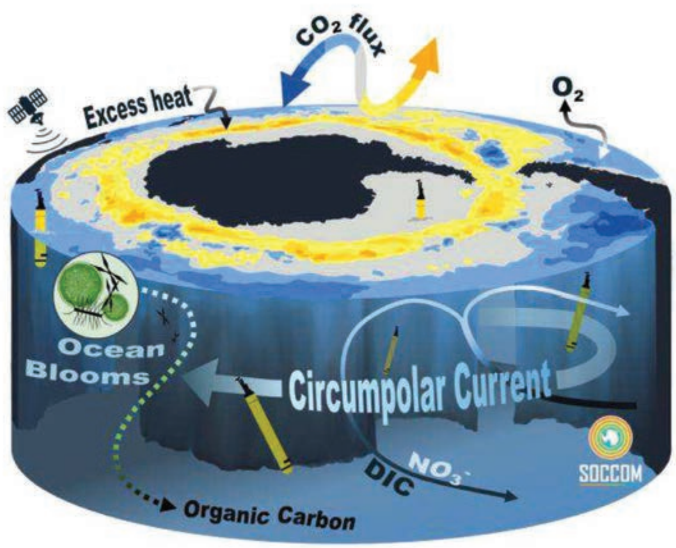

Fig. 1. The SOCCOM observing system concept. An array of profiling floats spanning all sectors of the Southern Ocean. The profiling floats would carry sensors that enable fluxes and stocks of carbon, oxygen, and nitrate to be assessed, along with the major biological and physical processes that contribute to the fluxes. Data would be delivered in real time, via satellite, for assimilation in state estimates and scientific analysis. Surface shading represents the air-sea CO_2 flux in August 2017 (Bushinsky et al. 2019a,b). Graphic by Emily Clark, MBARI.

Table 1
Priorities of the UN Decade of Ocean Science Southern Ocean Report (Hofmann et al., 2020) addressed by the SOCCOM project design.

Theme 1: Healthy and Resilient Ocean
Priority 1: Improve understanding of key drivers of change and their impacts on Southern Ocean species and food webs.
Priority 2: Improve understanding of sea ice, including its role in ecological processes of the Southern Ocean.
Priority 3: Improve understanding of Southern Ocean biogeochemical cycling. The Southern Ocean plays a key role in biogeochemical cycling, particularly in regulating air-sea exchange of carbon dioxide in the global carbon cycle.
Priority 4: Improve societal understanding of Southern Ocean issues and appreciation of the Southern Ocean for its global value in Earth systems and unique environment.
Theme 2: Predicted Ocean
Priority 1: Enhance and expand observational capability to support predictions.
Priority 2: Improve and enhance Southern Ocean modeling capability.
Theme 3: Sustainable Productive Ocean
Priority 1: Increase the suite, types and reliability of measurements, including those focused on ecosystem change, needed to inform management and policy.
Priority 3: Ensure science-based and effective MPAs and uphold sustainable fisheries management.
Cross Cutting Themes
Priority 3: Implement a coordinated, international, circumpolar observational program to elucidate processes that 1) allow life histories of key species in the Southern Ocean ecosystem to be quantified, 2) allow a total carbon budget to be developed, 3) provide coverage of the annual cycle, and 4) quantify the role of sea ice in regulating ecosystem productivity.
Priority 5: Enhance predictive skill across climate, circulation, cryosphere, and ecosystems. The Southern Ocean community can add scenarios, such as freshwater inputs in the Southern Ocean, to understand climate sensitivity. End-to-end integration across ecosystems is needed to improve estimations of carbon fluxes, understand the effects of multiple stressor on ecosystems, identify biological hotspots, and evaluate the effects of living resource extraction on biological productivity. This requires working across disciplines, comprehensive observational systems, community engagement, and resources.

2. SOCCOM implementation strategy

2.1. Observational strategy

The SOCCOM observational program was designed to provide circumpolar biogeochemical observations throughout the year, within the Southern Ocean (Talley et al., 2019), by deployment of a large array of BGC-Argo profiling floats (Fig. 2). The BGC-Argo program is described in Claustre et al. (2020). The quality controlled data would be served in real time (Maurer et al., 2021). The SOCCOM float array was also designed to provide crucial year-round profile data in the large seasonal sea ice zone south of 60°S. Argo-type profiling floats are free drifting, battery-powered platforms that cycle between 2000 m depth and the surface (Johnson, 2017; Riser et al., 2016, 2018; Roemmich et al., 2019). A typical profile cycle is shown in Fig. 3. Floats ascend from depths near 2000 m to the surface at defined time intervals (typically 10.08 days). Physical and chemical measurements are made during the ascent at programmed depth intervals (typically 70 depths for chemical measurements and every 2 m for physical measurements in SOCCOM floats). Once at the surface, the float position is determined by GPS, and the observed data are then transmitted via the Iridium communication system to a shore-based server. The data are immediately processed. This includes any necessary corrections for sensor calibration offsets or sensor drift (Maurer et al., 2021). Data suitable for scientific analysis are then made available through publicly accessible databases on the Internet (https://soccom.princeton.edu/content/data-access) and the Argo data system (Wong et al., 2020) within 24 h. The float then returns to a parking depth at 1000 m before repeating the cycle.

The current status of the SOCCOM BGC-Argo float array is shown in Fig. 4a. SOCCOM has achieved circumpolar coverage, with many floats operating in the Antarctic sea ice zone. SOCCOM also sought from the start to achieve sampling in all dynamical and BGC regimes of the Southern Ocean (Talley et al., 2019). The Antarctic Circumpolar Current (ACC) fronts are shown for context in Fig. 4a; SOCCOM has also achieved this regime-defined coverage which has enabled studies of the zonal and meridional dependence of carbon, productivity and air-sea fluxes. After 9 years of deployments, floats in the earliest years of SOCCOM have become inactive due to battery lifetime, such that about half of the floats deployed are active at this time (Fig. 4b).

The observing system implemented for the SOCCOM project aligns closely with the UN Southern Ocean Workshop Report priorities:

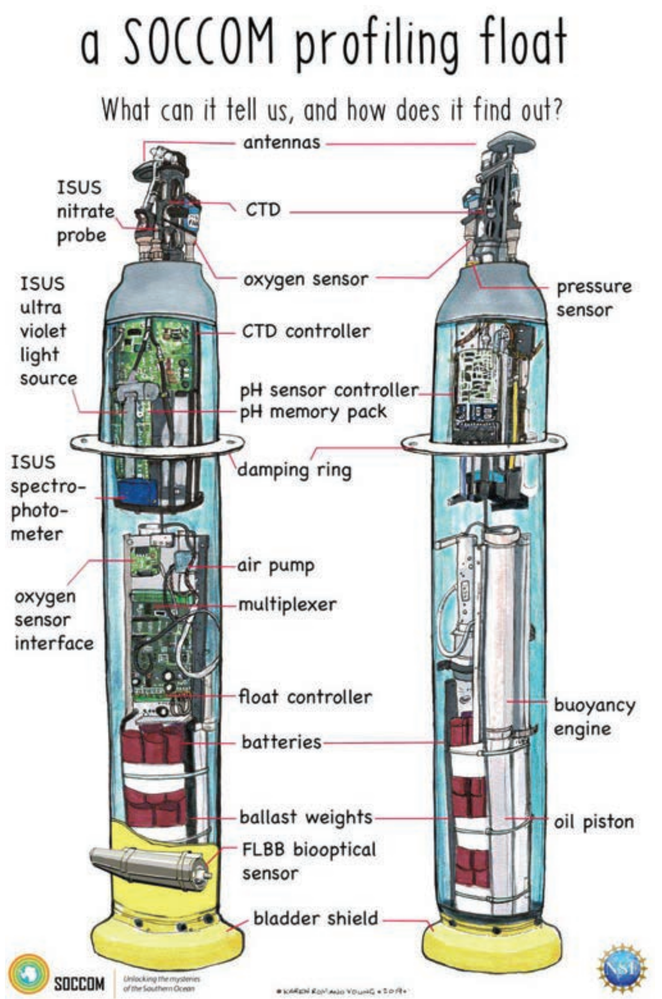

Fig. 2. Schematic of a SOCCOM profiling float showing component views of the float (left) and rotated by 180° (right). This sketch, created by Karen Romano Young, is widely used in SOCCOM's K-12 outreach program. The original drawing, with additional detail, was designed for a poster size and is available on the SOCCOM website (https://soccom.princeton.edu).

- *Enhance and expand observational capability to support predictions.*
- *Increase the suite, types and reliability of measurements, including those focused on ecosystem change, needed to inform management and policy.*

2.2. Array size

A variety of methods have been applied to assess the optimum number of floats in the SOCCOM array. One of the primary tools has been Observing System Simulation Experiments (OSSE). Majkut et al. (2014) sampled CO_2 fluxes in the GFDL-ESM2M 'historical' simulation (years 1995–2000) with synthetic floats. This OSSE found that a large uncertainty reduction in reconstruction of the air-sea CO_2 flux in the Southern Ocean (south of 30°S) was obtained with approximately 200 floats. Kamenkovich et al. (2017) subsampled oxygen in CM2.6 to assess observing system design and also identified 200 floats as being an optimal choice. Taking a different approach, Mazloff et al. (2018) estimated the correlation scales in the Southern Ocean for carbon flux and content on seasonal time-scales and longer using an ocean model. These findings suggest that, ideally, approximately 100 floats would be deployed with one every 20° longitude by 6° latitude. In practice, however, this deployment spacing is impossible to achieve due to advection that aggregates floats in some regions and removes them from others, making the required float number greater than 100. An additional caveat for all these studies is that constraining the higher frequency signals (i.e. subseasonal) may require far more than 200 floats. For example, Prend et al. (2022c) found that much of the Southern Ocean chlorophyll variability occurs at sub-seasonal time scales that would require a much larger float array to characterize. Chlorophyll has a very short turnover time that leads to a patchier distribution than tracers such as DIC (Mahadevan and Campbell, 2002). A float array cannot resolve the short length scales that characterize ocean chlorophyll. But the analysis of Mazloff et al (2018) shows that a float array can resolve the DIC length scales. This implies that a float array can quantify processes such as net community production from DIC (or nitrate) drawdown. Further, we have shown (Johnson and Bif, 2021) that float arrays can resolve primary productivity signals quantitatively, but at low spatial and temporal resolution.

The goal in the initial SOCCOM proposal was to deploy 180 floats south of 30°, based on Majkut et al.'s (2014) results. It was presumed that international partners would supply the remainder. A uniform distribution of floats was desired to meet the goals outlined in the BGC-Argo Science and Implementation Plan (Biogeochemical-Argo Planning Group, 2016) with floats in all basins of the Southern Ocean. Fig. 4b shows the number of SOCCOM floats that were operating in each year and the cumulative number deployed by the project. The highest population of active floats was achieved in year 6 of the project (2020) with 152 floats. This number fell short of the 180 float goal due a fault in APEX float (the primary float-type deployed) power management that led to premature failure of the float batteries at around 150 vertical profiles. The fault was not recognized until floats had been in the water nearly 4 years. The power management fault has since been resolved and APEX floats deployed since 2020 are capable of making $\sim$ 275 vertical profiles before battery depletion. The resolution of this problem was followed immediately by the Covid-19 pandemic, which limited production and deployment capabilities. The array population then fell to $\sim$ 120 floats operating each year. The number of operating floats, now at 137, will gradually increase at planned deployment rates of 30 floats per year.

Observing system design work continues with similar and expanded approaches, including the use of transition matrices to project information forward in time (Chamberlain et al., 2023). The prospect of utilizing covariance information from other observables to reduce observational demands is also being explored (Giglio et al., 2018; Liang et al., 2018). Finally, other groups have been applying OSSEs for other BGC variables. For example, Valsala et al. (2021) considered observing system design for pCO_2 in the Indian Ocean. Ford (2021) assessed the effect of assimilation for chlorophyll, oxygen, pH and nitrate in the global ocean. These studies all find significant reduction in error through use of a large array of biogeochemical floats.

2.3. SOCCOM float sensors

Major advances in sensor technology have enabled SOCCOM floats to measure nitrate and oxygen concentrations and bio-optical properties from profiling floats (Riser and Johnson, 2008; Johnson, 2017; Johnson et al., 2013, 2017b; Körtzinger et al., 2005; Boss et al., 2008; and Bittig et al., 2018a). Newly developed pH sensors have now been successfully integrated onto the profiling float platform with measurements to 2000 m depth (Johnson et al., 2016, 2017b; Williams et al., 2017).

Oxygen is measured with optode sensors that determine concentration from the effect of oxygen partial pressure on luminescence lifetime of an embedded fluorophore (Bittig et al., 2018a). The large number of deployments in SOCCOM have enabled a robust demonstration of the capability to recalibrate the optode sensors with air oxygen measurements (Johnson et al., 2015). Nitrate is measured using direct UV spectrophotometry (Johnson et al., 2013). pH is measured with an Ion Sensitive Field Effect Transistor (Johnson et al., 2016). Both the nitrate and pH sensor output must be corrected for offsets in the initial calibration that may arise during the many months between laboratory

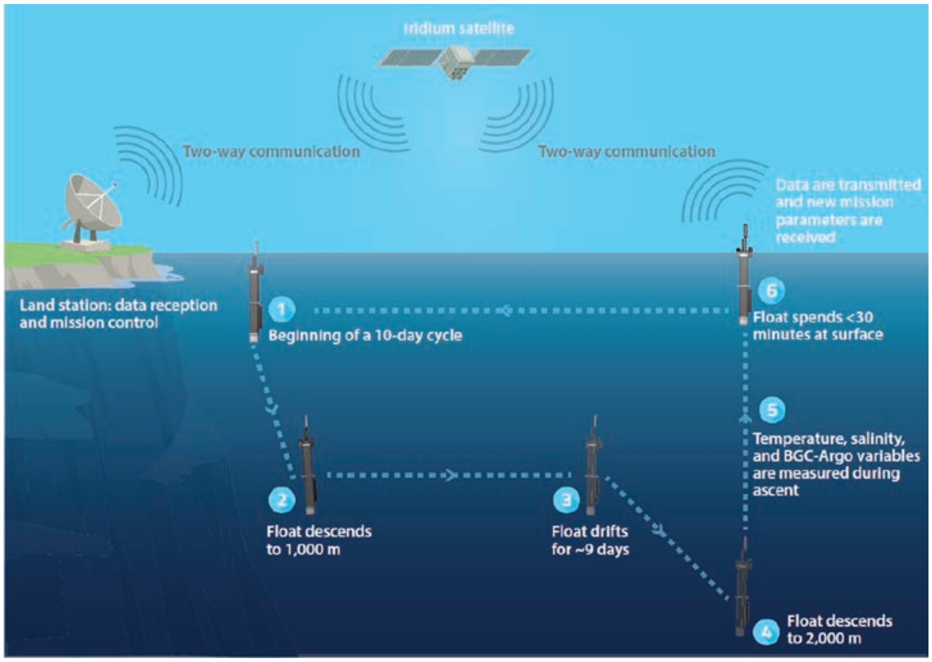

Fig. 3. Typical profile cycle for a SOCCOM Argo float. From Claustre et al. (2020).

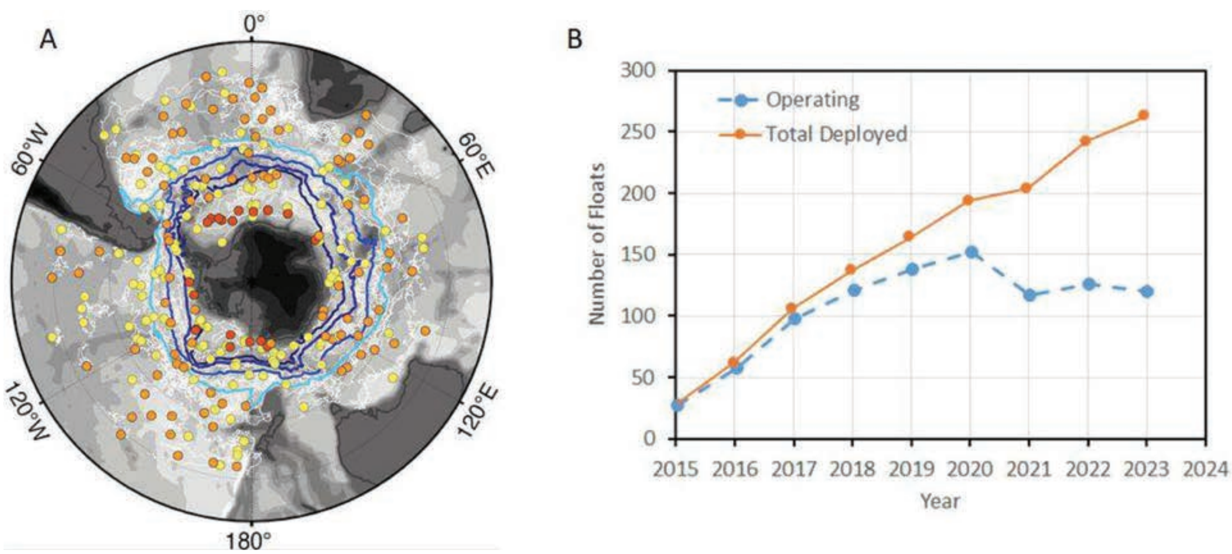

Fig. 4. A) SOCCOM float locations as of December 2022. Active floats: orange. Under-ice floats: dark orange. Inactive floats: yellow. Trajectories of all floats shown as white lines. Antarctic Circumpolar Current frontal positions are shown as solid lines: Subantarctic Front (light blue), Polar Front (medium blue), Southern ACC Front (dark blue), Southern Boundary of the ACC (black), from north to south (positions from Kim and Orsi, 2014). B) Number of floats operating in each year of the SOCCOM project and total number of floats deployed.

calibration and deployment, as well as correction for offsets or drifts that occur after deployment. Protocols were developed for these corrections (Johnson et al., 2017b; Maurer et al., 2021) and these are described further in Section 2.6.1. Particle abundance (primarily phytoplankton and their detritus in the open ocean; Graff et al., 2015) is measured using optical backscatter. Chlorophyll fluorescence is measured by in situ fluorometry (Roesler et al., 2017). These sensors are all capable of operating for years through the pressure and temperature extremes experienced by Argo floats (Johnson et al. 2017b). Fig. 5 shows one example of the data records in the upper 300 m from all of these sensors. This record spans four years on a SOCCOM float (WMO 5904468) operating in the seasonal ice zone of the Weddell Sea (Claustre et al., 2020).

2.4. Float performance

The SOCCOM project utilizes both APEX and Navis profiling floats. The APEX floats used in SOCCOM are constructed at the University of Washington from components purchased from Teledyne/Webb Corporation. They carry batteries capable of powering the floats for about 250 profiles to 2000 m. However, due to a power management fault in early floats used by the project, the batteries failed shortly after 150 cycles. This fault was corrected in floats that were built after 2019. The mortality of the floats used in SOCCOM is somewhat higher than analogous floats used throughout the world ocean in Argo and other programs (Riser et al., 2018). About 50% of the SOCCOM floats have survived about 4 years, or 150 profiles. For longer times, the survivability

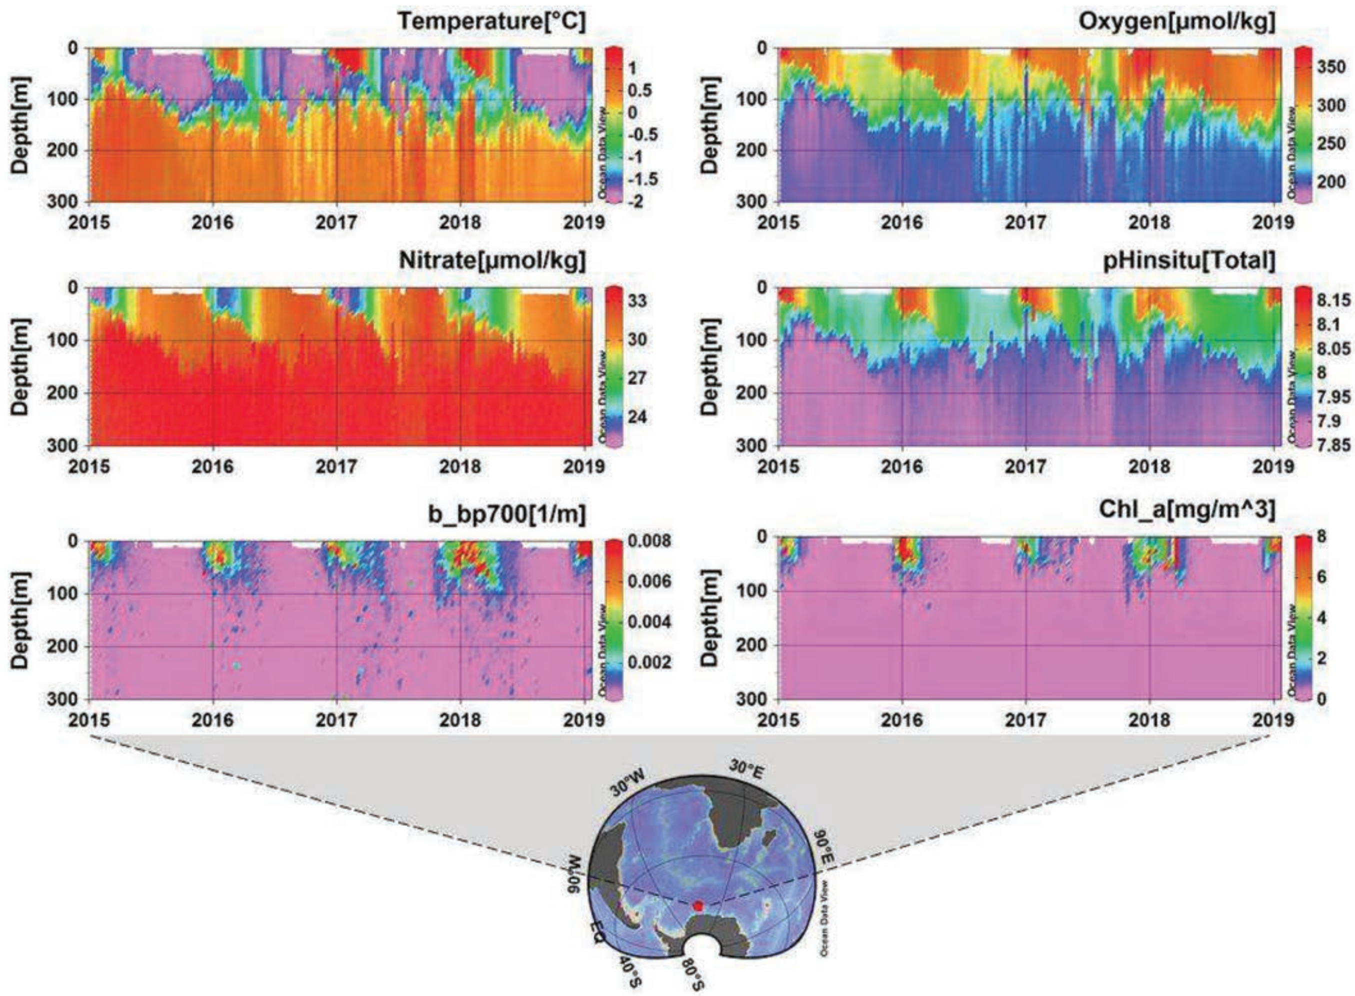

Fig. 5. Sensor data gathered by World Meteorological Organization (WMO) float number 5904468 in the upper 300 m of the Atlantic sector of the Southern Ocean. Note that the float acquired data under ice (during the periods identified by white sectors in the surface layer) and then transmitted them when the ocean surface became ice free (adapted from Claustre et al., 2020).

decreases, largely due to the power management fault, and only about 30% of the floats continue to operate for 250 profiles. The technical details and performance characteristics of the floats used in SOCCOM are discussed in Riser et al. (2018). The Navis floats are acquired in completed form from Sea-Bird Scientific and used after a thorough inspection that now includes disassembly of complete floats to check internal components.

Argo floats, including the BGC-Argo floats deployed by the SOCCOM project, are regularly operating under ice-covered water (Wong and Riser, 2011; Riser et al., 2018; Chamberlain et al., 2018). Sixty-six SOCCOM floats have operated under seasonal sea ice and collected over 2600 vertical BGC profiles in the seasonal ice zone. The survival rate for APEX floats operating in ice is moderately lower (93% survival/year) versus floats outside the seasonal ice zone (96%/year).

Like all Argo floats, SOCCOM floats cannot determine position from GPS when operating under ice. The Argo default is linear interpolation between available profiles with GPS fixes. Acoustic receivers have been added to limited sets of Argo floats for under-ice tracking in the insonified Weddell Sea (Klatt et al., 2007). However, the rough sea ice bottom interferes with acoustic range. As part of SOCCOM, Chamberlain et al. (2022a) developed a Kalman smoothing method for improved acoustic tracking and applied it to the Weddell Sea floats. While this work is promising, expansion of the existing Weddell array of moored sound sources to the full Southern Ocean is prohibitively expensive at present. Chamberlain et al. (2018) used a set of acoustically-tracked Argo floats to quantify the uncertainty in the linear interpolation of float locations. The location error is approximately 100 km for a 9-month sojourn under the ice. This is of comparable size to other sources of representation error (e.g. "eddy noise"). As a result, acoustic receivers have not been incorporated on SOCCOM floats.

2.5. Float deployments

SOCCOM has operated with essentially no dedicated ship time (Talley et al., 2019). Float deployments have occurred from ships of opportunity in nearly all cases. The primary exception has been the assignment of several days of ship time to SOCCOM for float deployments on US research vessels making transits between ports. At this time, floats have been deployed from 19 different ships. Fifteen of these ships have been from other nations, including Australia, Germany, Japan, Korea, New Zealand, Russia (on a Swiss charter), South Africa, Spain, and the United Kingdom. This international collaboration has been essential to the development of the SOCCOM array by providing access to all regions of the Southern Ocean.

Although SOCCOM has not used dedicated ships for the most part, the deployment platforms have played a key role in the success of the project. A SOCCOM policy was to collect a hydrocast with high quality measurements of oxygen, nitrate, carbonate parameters (pH, titration alkalinity, dissolved inorganic carbon), HPLC measurements of photosynthetic pigments, and particulate organic carbon whenever possible

(Talley et al., 2019). The shipboard chemical measurements are used to validate the data obtained from float sensors. Nearly all deployments have occurred from research vessels, as a result. Nearly 50% of the deployments have been on GO-SHIP cruises (Talley et al., 2016) to take advantage of the high quality data generated by this program. The data from these hydrographic stations taken at float deployment sites has provided convincing evidence of the quality of the float observations (Section 2.6.1). The validation data was also a key contribution to the development of the quality control methods by providing a quantitative metric for improvements to data processing. As sensors evolve, continued collection of validation data will be essential to demonstrate their improvement. The SOCCOM project encourages the collection of this type of supporting data whenever possible.

As batteries in a profiling float are depleted, the float is lost at depths near 2000 m when the external bladder can no longer be inflated to change its buoyancy. Each profiling float, with a mass near 30 kg, thus contributes to marine waste. However, when compared to the impacts from operation of an ocean going research vessel that may burn five tons of fuel each day, a 30 kg profiling float that operates 4 to 6 years is an extremely low impact observing system. A further assessment of the environmental impacts of Argo floats can be found in Riser and Wijffels (2020).

2.6. Data system

Parameters observed by SOCCOM floats (temperature, salinity, dissolved oxygen, nitrate, pH, chlorophyll and particulate backscatter) are Essential Ocean Variables (EOVs) and contribute to our understanding of the Southern Ocean and its response to a changing climate. Profiling float data are provided in real-time (<24 h) to the community with equal access to all. The SOCCOM website (https://soccom.princeton.edu) provides a direct link to these data resources. Although the SOCCOM data system was developed before the FAIR concept for data accessibility was published (Wilkinson et al., 2016), it adheres closely to the principles of findability, accessibility, interoperability, and reusability. The success of the SOCCOM system in achieving the FAIR principles can be assessed through the number of external publications that use the observations and model output, as described in Section 3.6. SOCCOM data are provided to users through multiple format options, including both NetCDF files and human-readable text files that contain estimates of derived carbon parameters (dissolved inorganic carbon (DIC), total alkalinity (TAlk), partial pressure of carbon dioxide (pCO2) and particulate organic carbon (POC)). The provision of such value-added products, calculated in a standardized way, facilitates analysis across a broad user base. A key objective of the SOCCOM program has been to supply the data in a way that fosters direct and efficient ingestion by users. SOCCOM scientists have collaborated with the sister Global Ocean Biogeochemistry Array (GO-BGC) to make toolboxes available in a variety of computer languages (Matlab, Python, R; https://go-bgc.org) to further facilitate data access. These toolboxes include instructional videos and examples.

SOCCOM is integrated into the larger One Argo program framework, a program that serves as the backbone to both the Global Ocean Observing System (GOOS) and Global Climate Observing System (GCOS) (Roemmich et al, 2019; Owens et al., 2022). SOCCOM deployments represent up to 15 percent of annual Argo deployments in the ocean south of 30°S and, on average, close to 70 percent of total BGC-Argo floats deployed in this region annually. This has established SOCCOM as an integral part of the Core Argo program to observe ocean temperature and salinity and of the BGC-Argo global networks. All SOCCOM data are delivered to Argo Global Data Assembly Centers via the US Argo Data Assembly Center within 24 h of successful transmission to shore. SOCCOM has become the dominant source of in situ biogeochemical observations in the Southern Ocean (Table 2). SOCCOM and partner international programs that comprise BGC-Argo have become essential for observing biogeochemical changes in the ocean interior as the amount of such data collected from ships has declined precipitously in recent decades (Fig. 6). The expanded ocean coverage in space and in time is enabling a transformation in ocean observing similar to the transformation Argo has provided for physical measurements (Wong et al., 2020). This was especially true during the COVID-19 pandemic when ship activity was constrained but deployed floats continued to collect data (Boyer et al., 2023).

Table 2
Number of profiles to at least 900 m depth over an 8-year span reported by SOCCOM floats or by ships. The float data includes only profiles with data quality marked good. Ship data was obtained from World Ocean Database (https://www.ncei.noaa.gov/products/world-ocean-database).

Property	SOCCOM 2015–2022	Ships South of 30°S 2010–2017	Ships North of 30°S 2010–2017
Oxygen	21,420	1,764	3,032
Nitrate	20,564	1,651	2,840
pH	12,603	1,054	1,976

2.6.1. Data quality

The goal of the SOCCOM float program is to produce a climate-quality data record for carbon, oxygen, and nitrate cycling. This is a "time series of measurements of sufficient length, consistency and continuity to determine climate variability and change" (National Research Council, 2004). Such a record requires sensors that are well characterized and calibrated to the property of interest before deployment, and whose calibration is assessed at deployment with high quality hydrographic measurements, or in which post-deployment calibration is possible. Meeting project goals requires continuous reviews to ensure that the profiling float data are of high quality and consistency. Further, as SOCCOM is one element of the BGC-Argo array, these efforts should be well documented and capable of implementation at all Argo Data Assembly Centers (DACs). To meet these sensor goals, novel methods were developed to ensure sensors were accurate and could be corrected for post-deployment drift in calibration (Maurer et al., 2021).

Körtzinger et al. (2005) and Bittig and Körtzinger (2015) demonstrated the potential for optical oxygen sensors to be calibrated in air when floats surface. This work was limited to a small number of floats. Using nearly 50 SOCCOM and Argo Canada floats, the SOCCOM project built on this work to establish that air oxygen calibration could reduce oxygen concentration errors below 1% of surface saturation values for large arrays (Johnson et al., 2015). These capabilities were built into a software package, the SOCCOM Assessment and Graphical Evaluation (SAGE-O2) tool, which is now in widespread use at Argo DACs (Maurer et al., 2021). The air oxygen measurements enable assessment of sensor calibration and calibration drift in time.

Errors arising in nitrate and pH sensor calibrations are corrected using methods that build on the techniques developed in the Core Argo program to assess change in salinity sensor calibration (Owens and Wong, 2009). Sensor measurements at depths between 1000 and 2000 dbar, where conditions change only slowly in time, are compared to high quality shipboard observations. Differences are assigned to sensor offsets or drifts. In the case of salinity, there are sufficient ship-based observations to use objective mapping to predict salinity values at float profile locations. There are too few ship-based observations of nitrate and pH to allow direct mapping of these observations to float profile locations. Instead, software was developed to interpolate shipboard observations using the well-known relationship between oxygen and nitrate or pH that is encapsulated in the Redfield Ratio (Anderson and Sarmiento, 1994). Initially, locally interpolated regressions (LIR) were built using the GLODAPv2 dataset (Carter et al., 2018). The LIRs allow nitrate and pH to be predicted at depth using profiling float oxygen, date, and position data with biases less than 0.00 ± 0.47 (1 SD) μmol kg^{-1} and 0.001 ± 0.006 pH at depths near 2000 m. Subsequent work using neural networks has provided improved spatial resolution in fitted

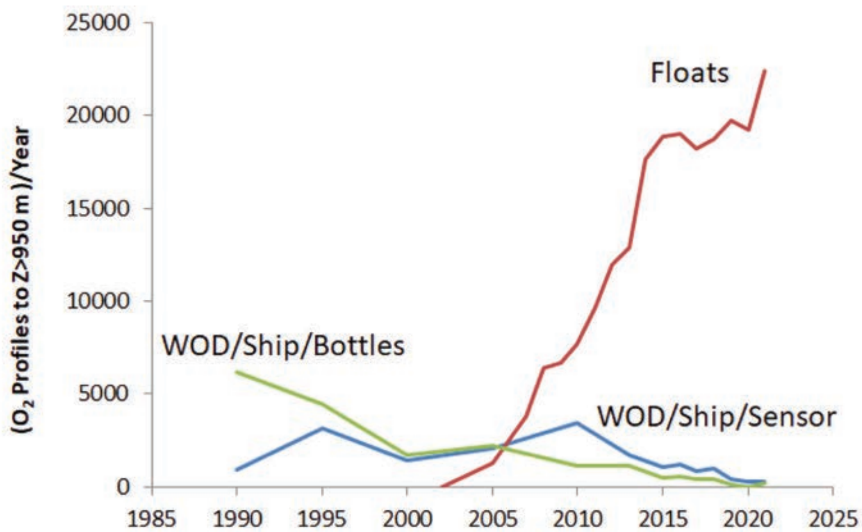

Fig. 6. Oxygen profiles in the global ocean to a depth of at least 950 m per year. Values for analyses of water collected on bottle casts (green) and for oxygen sensors on CTD casts from ships (blue) are from the NOAA/NCEI World Ocean Database. Values for Argo profiling floats are from the Argo Global Data Assembly Center and are for all BGC-Argo floats.

deep reference data (Bittig et al., 2018a,b; Carter et al., 2021). These tools are used in the SAGE software application to quality control and adjust nitrate and pH sensor data (Maurer et al., 2021).

The accuracy of the adjusted and quality-controlled data collected by SOCCOM floats has been assessed by comparing sensor values from the first float profile with data from standard laboratory analysis methods applied to water samples collected during a conventional hydrocast coincident with the float deployment. Such shipboard measurements of oxygen, nitrate, pH, HPLC pigments and particulate organic carbon (POC) have been made alongside nearly all SOCCOM float deployments. Note that SOCCOM sensor calibrations are made independently of the accompanying shipboard measurements. Oxygen sensors use air oxygen measured by the floats for the final sensor calibration (Johnson et al., 2015). pH and nitrate data are adjusted by applying an offset based on a deep, stable reference field (Johnson et al., 2013; 2016; 2017a, 2017b; Maurer et al., 2021) predicted with global algorithms fitted to high quality ship data (Carter et al., 2018; Bittig et al., 2018b). Both the raw and adjusted sensor data are always reported.

Statistical comparison of float sensor data with shipboard data (Fig. 7) yields the overall accuracies quoted for SOCCOM float BGC sensors (Maurer et al., 2021). Some of the statistical uncertainty in the validation comparisons is due to hydrographic differences between float and shipboard sampling times and locations. Validation matchups across the array are an average of 23 h and 8 km apart in time and space. Assuming that half of the standard deviation in the bottle minus float differences (Fig. 7) is from natural ocean variability, float data uncertainties are 3 μmol kg^{-1}, 0.5 μmol kg^{-1}, and 0.007 for oxygen, nitrate, and pH, respectively. These uncertainties correspond to coefficients of variation near 1.5% for oxygen and nitrate concentrations near their mean values. The assumption that half of the error is due to oceanographic processes is consistent with alternate assessments of data quality, such as a comparison of sensor nitrate concentrations in surface water with temperature >24 °C, excluding equatorial regions. The expected nitrate concentration in these conditions is near 0. The observed surface nitrate concentration for all profiles that meet these conditions from floats supported by the UW/MBARI group is 0.2 ± 0.5 μmol kg^{-1}. This standard deviation is similar to one half of the value for nitrate in Fig. 7. These uncertainties meet or exceed targets for sensor performance set in the original proposal.

Note that when chemical concentrations are near zero, both the oxygen and nitrate sensors will report negative values. A negative concentration is physically impossible. However, the values returned by a sensor are an estimate of concentration and estimates can be negative (Thompson, 1988). At concentrations near zero, half the estimates of concentration will be negative. The SOCCOM project has elected to retain these negative values in the dataset with a quality flag of good to

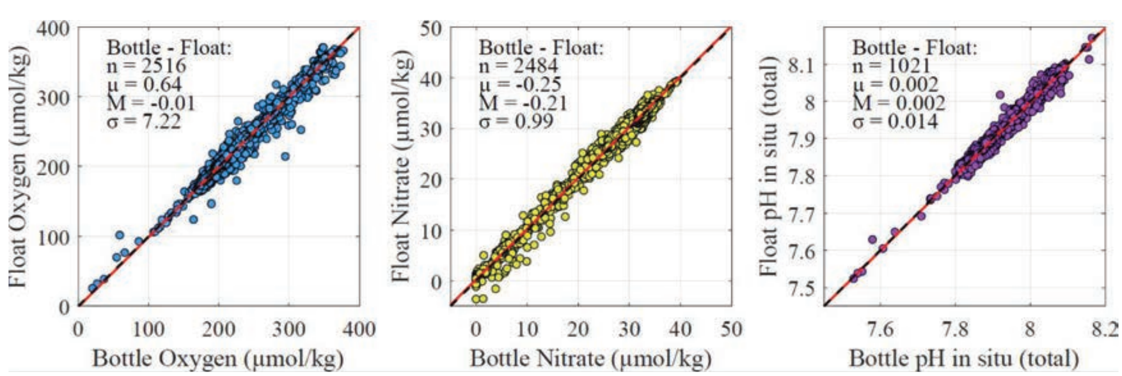

Fig. 7. Comparison of profiling float oxygen, nitrate, and pH sensor values versus values measured on board ship in samples collected from a hydrocast made near the time of float deployment. Statistics for number of comparisons (n), mean difference (μ), median difference (M), and standard deviation (σ) are shown for each property. Adapted from Maurer et al. (2021) after updating to all data available through 2022.

avoid a bias known as "left censoring" of the data (Newman et al., 1989). Left censoring results in unrealistic estimates of error near zero concentration. The user must make their own decision on how to utilize these negative values.

The long term stability of the adjusted sensor data has been assessed by comparing the quality controlled sensor values to shipboard profile measurements when floats pass within 20 km of a station in the GLODAPv2 database (Johnson et al., 2017b; Maurer et al., 2021). Offsets in the comparisons change with the age of the shipboard observations. The rate of change for both pH and oxygen are consistent with known ocean acidification or deoxygenation rates (Johnson et al., 2017b; Maurer et al., 2021). The nitrate comparisons are invariant with the age of the shipboard observations. These results indicate that the quality controlled float data are stable in time.

These statistical adjustments relative to deep ocean data that may slowly change in time require a continuous update of the deep, ship-based reference data. In essence, the float measurements provide a record of the large, seasonal changes in upper ocean chemistry (Fig. 5) relative to a deep, ship-based observational product. As such, projects such as SOCCOM require a decadal scale set of repeated hydrographic section measurements, such as those conducted in the GO-SHIP program (Talley et al., 2016), to produce a climate quality dataset.

In addition to the chemical sensor measurements, SOCCOM floats have also collected chlorophyll fluorescence and optical backscatter data. The conversion of chlorophyll fluorescence to chlorophyll concentration is fraught with uncertainty (Roesler et al., 2017). Measurements of chlorophyll pigments by High Performance Liquid Chromatography in samples collected at float deployment show large variability in the relationship between chlorophyll fluorescence and chlorophyll (Johnson et al., 2017b). Despite this uncertainty the chlorophyll fluorescence data have proven to be extremely useful in a variety of SOCCOM studies (e.g., Carranza et al., 2018; Haëntjens et al., 2017; Von Berg et al., 2020). The optical backscatter data show a robust relationship with Particulate Organic Carbon (POC) concentration in samples collected at float deployment (Johnson et al., 2017b). This has enabled estimates of POC throughout the Southern Ocean (Haëntjens et al., 2017; Johnson et al., 2017a; Arteaga et al., 2020).

2.7. Biogeochemical-Southern Ocean state estimate

An integral strategy in the SOCCOM design was to assimilate the observational data into a state estimate model. Data assimilating models are computationally expensive, especially for biogeochemistry. Ample and sustained data constraints are required in order to justify the task of operating a large-scale ocean model that assimilates data. The SOCCOM array has provided this data source. The Biogeochemical Southern Ocean State Estimate (B-SOSE; Verdy and Mazloff, 2017) assimilates physical and biogeochemical data into the MIT ocean general circulation model using an adjoint method developed by the consortium for Estimating the Climate and Circulation of the Ocean (ECCO; Stammer et al., 2002; Forget et al., 2015). The biogeochemical model in B-SOSE is the nitrogen version of the Biogeochemistry with LIght, Nutrients and Gases model (NBLING; evolved from Galbraith et al., 2010). B-SOSE provides a complete, budget-closing analysis of Southern Ocean biogeochemical and physical processes. Similar data assimilation efforts are now appearing elsewhere (Fennel et al., 2019).

The B-SOSE objective is to yield a baseline estimate of the large-scale Southern Ocean biogeochemical, sea ice, and physical properties, and a framework to understand this baseline. Nudging (i.e. reinitializing) models allows one to fit eddy signals, but the B-SOSE aim is to have closed budgets, and thus there is no nudging included. The gridded model solution aims to capture the seasonally varying properties by adjusting the atmospheric state and initial conditions, with eddies represented in a statistical sense. The first state estimate produced was a 1/3° resolution solution for the period 2008–2012. Validation, analysis, model inputs, code, and comprehensive diagnostics have been published. This demonstrates the maturity of BGC state estimation (Verdy and Mazloff, 2017). A subsequent 2013–2021 SOCCOM era state estimate was produced at higher-resolution (1/6°).

B-SOSE offers a gridded product consistent with model physics and constrained to the large-scale signals observed by the SOCCOM array. A first study with B-SOSE was an intensive analysis of the dissolved inorganic carbon budget (Rosso et al., 2017). B-SOSE has also had smaller regional models nested inside to inform the impact of resolution on the carbon cycle (e.g. Jersild et al., 2021; Swierczek et al., 2021a) and its predictability (Swierczek et al., 2021b). The B-SOSE resource has been used as an essential component of numerous studies, which are noted throughout the remainder of this review.

2.8. Earth system models

The Southern Ocean is notoriously difficult to simulate consistently. At every stage of the Coupled Model Intercomparison Project (CMIP), sponsored by the Intergovernmental Panel on Climate Change (IPCC), there have been significant inter-model differences as well as a lack of observationally-based metrics on which to discern the overall quality of each model (Russell et al. 2006a, 2006b, 2018; Meijers et al., 2012; Beadling et al. 2019, 2020; Kajtar et al., 2021; Bourgeois et al., 2022). To address this issue, a climate and biogeochemistry modeling component, including the Geophysical Fluid Dynamics Laboratory (GFDL) mesoscale eddying coupled climate models (e.g. "CM4") and Earth System Models (e.g., "ESM4"), has been a core SOCCOM element. This enables the program to translate our evolving understanding of the current ocean into a greatly improved projection of the future with an emphasis on the role of the Southern Ocean in the global climate. The benefits of the SOCCOM joint observation and modeling approach are clear, as important spatially- and temporally-resolved data have been assimilated into our state estimates and metrics of biogeochemical and physical ocean properties that provide consistent benchmarks have been established (Beadling et al., 2020).

The state estimation and global modeling components address the UN Southern Ocean Report priority:

- *Improve and enhance Southern Ocean modeling capability.*

3. Major SOCCOM biogeochemical results

Here we review SOCCOM results that improve our understanding of biogeochemical cycles in the Southern Ocean. These results advance the UN Southern Ocean Report priorities:

- *Improve understanding of Southern Ocean biogeochemical cycling. The Southern Ocean plays a key role in biogeochemical cycling, particularly in regulating air-sea exchange of carbon dioxide in the global carbon cycle.*
- *Implement a coordinated, international, circumpolar observational program to elucidate processes that 1) allow life histories of key species in the Southern Ocean ecosystem to be quantified, 2) allow a total carbon budget to be developed, 3) provide coverage of the annual cycle, and 4) quantify the role of sea ice in regulating ecosystem productivity.*

3.1. Southern Ocean air-sea gas fluxes

Autonomous profiling floats have enabled year-round observations of biogeochemical parameters such as oxygen, nitrate, pH, and bio-optics in large regions of the ocean that previously were under-sampled (Hennon et al. 2016; Briggs et al. 2018; Arteaga et al. 2019, 2020; Johnson and Bif 2021). In sufficient numbers, profiling floats can provide the quasi-continuous data needed to calculate air-sea gas exchange over broad regions through full annual cycles.

3.1.1. Oxygen fluxes

Bushinsky et al. (2017) demonstrated the capability to resolve basin-scale gas exchange processes by calculating air-sea oxygen fluxes in the major zones of the Southern Ocean using the data in Fig. 8. They found a Southern Ocean oxygen sink of -221 ± 57 Tmol O_2 yr^{-1} south of 30°S, nearly double prior estimates (Gruber et al., 2001). The increased sink is due, in part, to strong uptake in partially ice covered waters of the Seasonal Ice Zone.

3.1.2. CO_2 fluxes

Few autonomous vehicles have been deployed that are capable of constraining the carbonate system through the full water column (Bushinsky et al. 2019b). The deployment of autonomous profiling floats equipped with pH sensors requires one other carbon parameter to enable determination of the complete carbon system. Fortunately, titration alkalinity can be estimated with reasonable accuracy using a variety of models fitted to shipboard data sets such as GLODAPv2 (Olsen et al., 2020). pCO_2 values determined using pH are not particularly sensitive to the titration alkalinity estimate (Williams et al., 2017). Estimates of pCO_2 and Dissolved Inorganic Carbon (DIC) using measured pH and estimated alkalinity have the potential to greatly increase our understanding of the wintertime carbon cycle (Williams et al., 2018), spatial patterns of carbon uptake (Johnson et al., 2022), and the influence of sub-surface processes on gas fluxes (Prend et al., 2022b; Chen et al., 2022).

The first Southern Ocean study using float-based estimates of carbonate system parameters to explore the seasonal drivers of carbonate changes (Williams et al., 2018) found variable agreement with prior studies based on shipboard observations (Takahashi et al., 2014). There is reasonable agreement between float-based estimates of pCO_2 and DIC in the more northerly Subtropical and Subantarctic zones (Fig. 9; Williams et al. 2018). However, in the poorly sampled Polar Frontal Zone and Antarctic Southern Zone there are large offsets in pCO_2 (Fig. 9). These offsets were suspected to result from undersampling in the ship-based data. Fay et al. (2018) compared pCO_2 estimates from SOCCOM floats going through the Drake Passage with nearby, shipboard observations from the Drake Passage Time-series (Munro et al., 2015). They found that the float estimates of pCO_2 agreed, within their estimated relative error of 2.7%, with the shipboard observations.

Estimates of the air-sea CO_2 flux using data from the first 3 years of SOCCOM float observations led to a calculated Southern Ocean net annual flux south of 35°S of only -0.08 ± 0.55 Pg C yr^{-1} (negative into the ocean), relative to the ship-based estimate of approximately -1.1 Pg C yr^{-1} (Gray et al. 2018). To obtain a more comprehensive assessment, these float data were combined with Surface Ocean CO_2 Atlas (Bakker et al., 2016) observations and gridded using previously established mapping and interpolation methods. The merged data (Fig. 10a) yields a contemporary Southern Ocean flux of -0.75 ± 0.22 Pg C yr^{-1} (Bushinsky et al. 2019a). This represents an approximately 0.4 Pg C yr^{-1} reduction in the contemporary Southern Ocean sink, relative to estimates based only on SOCAT data. Independent estimates of the Southern Ocean anthropogenic carbon sink from observations of ocean interior carbon concentrations coupled with inverse modeling approaches indicate that the anthropogenic flux is -1.1 Pg C yr^{-1} (DeVries 2014; Mikaloff Fletcher et al. 2006; Gruber et al. 2019). A contemporary flux of -0.75 Pg C yr^{-1} implies that the Southern Ocean natural outgassing flux is likely positive and on the order of several tenths of a Pg yr^{-1}, changing the prior understanding of a neutral natural carbon flux with uptake in the subtropical north balancing upwelling-driven outgassing South of the Antarctic Circumpolar Current (ACC; Gruber et al. 2019).

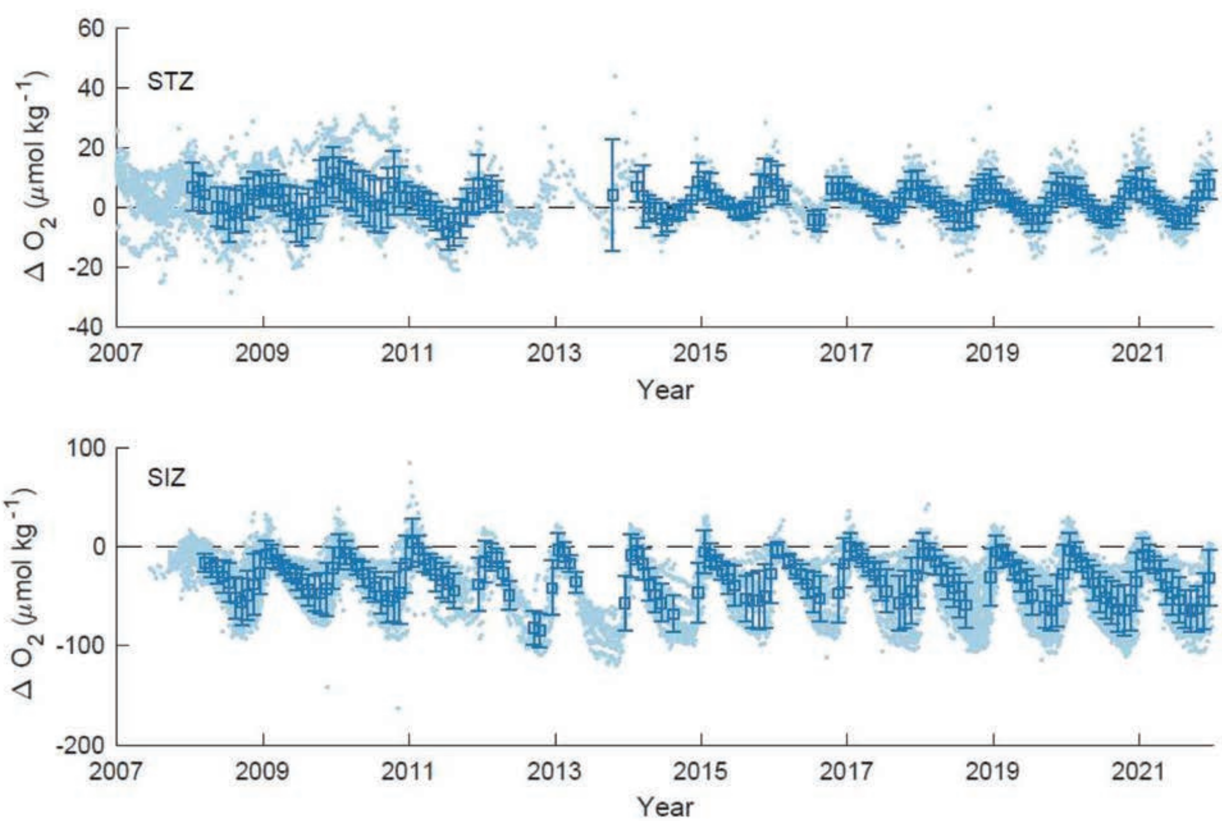

Fig. 8. Oxygen concentration difference from saturation ($\Delta O_2 = [O_2]_{measured} - [O_2]_{saturation}$) for the Subtropical Zone (STZ) and Sea ice Zone (SIZ). Updated from Bushinsky et al. (2017) with data through 2022. Light blue points indicate mixed layer concentrations from individual profile averages. Blue squares and error bars are monthly means ± 1 SD when average float temperature agreed with the NOAA Optimal Interpolation Sea Surface Temperature product as a check on data coverage.

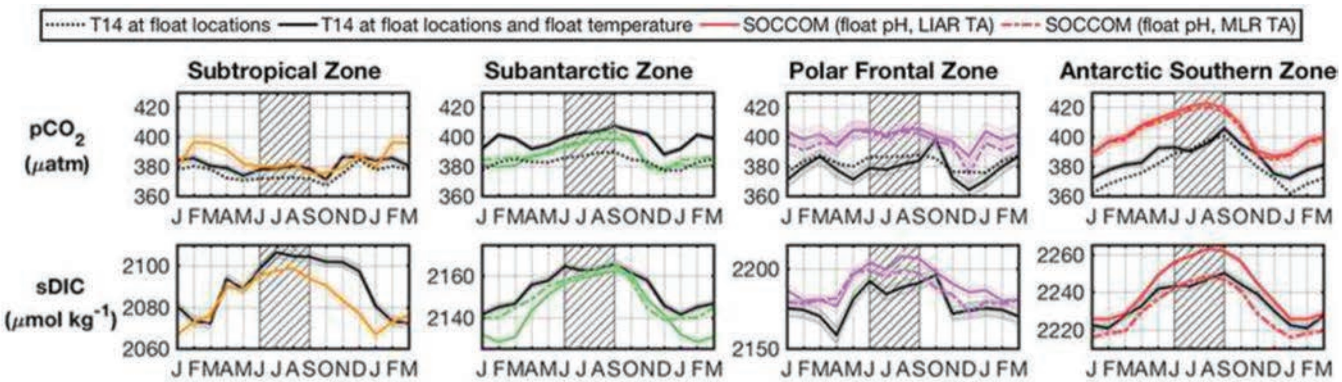

Fig. 9. Seasonal cycles of pCO_2 and salinity normalized DIC (sDIC) in the Subtropical, Subantarctic, Polar Frontal, and Antarctic Southern Zones. Float data are shown as solid, colored lines. The climatological values reported by Takahashi et al. (2014) for the year 2005 (T14 on figure), were adjusted to the present. The mean of all Takahashi et al. (2014) data at each float location are shown as black dotted lines and a filtered data set, with values selected only when float and climatology temperatures were similar, are shown as solid black lines.

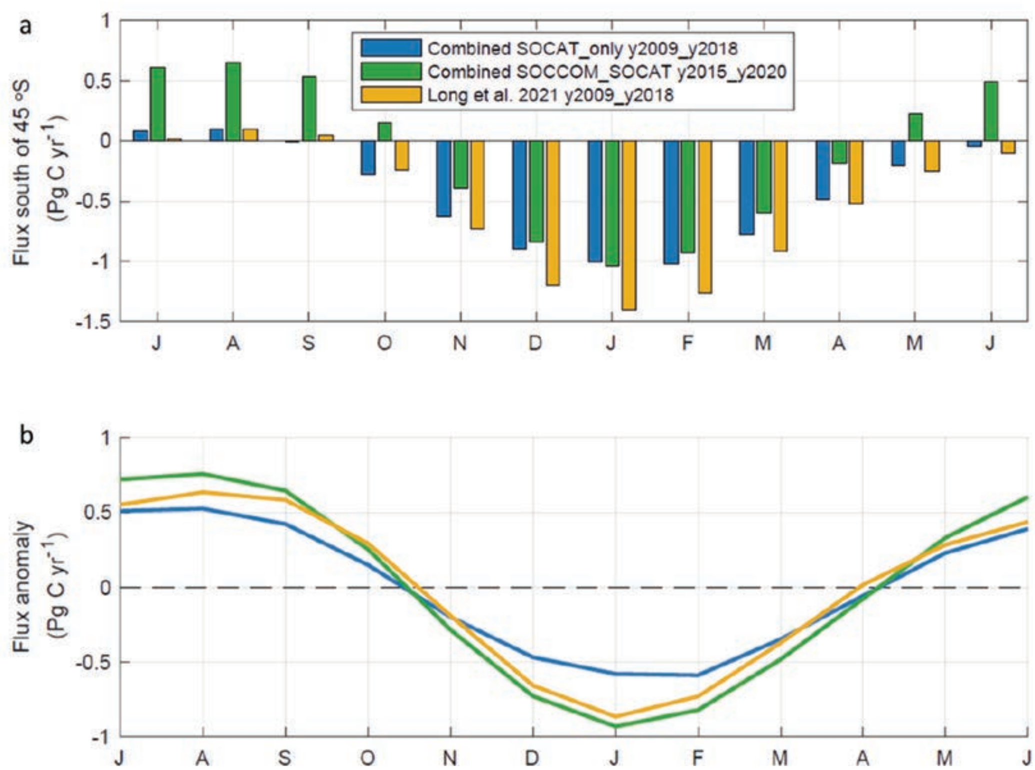

Fig. 10. Monthly mean sea to air CO_2 fluxes south of 45°S (positive values for flux from sea to air). (a) Values reported by Long et al. (2021) for 2009 to 2018 are shown as yellow bars. Values determined from the MPI SOM-FFN method (Landschützer et al., 2017) fitted to SOCAT shipboard data only for 2009 to 2018 are shown as blue bars. Values from the MPI SOM-FFN method fitted to the combined SOCAT and SOCCOM profiling float datasets (Bushinsky et al. 2019a,b) for 2015 to 2020 are shown as green bars. (b) The same data from panel a) are shown as monthly anomalies from the overall mean of each data set.

A recent study used aircraft and ground station measurements of atmospheric pCO_2 with atmospheric inversion models to develop a new constraint on air-sea CO_2 fluxes south of 45°S (Long et al. 2021). These fluxes, derived primarily from vertical gradients in atmospheric pCO_2 observations, agree more closely in annual magnitude with prior ship-only estimates. This may suggest a systematic bias in float based pCO_2 fluxes that would arise if float pH were consistently low around 0.005 to 0.010 pH. However, it is also clear that the flux based on the merged float and SOCAT data yield a seasonal cycle much closer to the values derived from atmospheric measurements than do the SOCAT only fluxes. This is shown by a plot of the anomaly from the annual mean in seasonal cycles from the atmospheric data, the shipboard only data and the shipboard plus float data (Fig. 10b). The SOCCOM float data appear to add significant information regarding the timing and amplitude of the seasonal cycle, relative to the SOCAT only dataset. The merged SOCCOM and SOCAT data yield a seasonal flux cycle that agrees closely with the aircraft data in seasonal amplitude and timing (Fig. 10b). The seasonal cycle would be difficult to obtain from sparse, shipboard observations in the Southern Ocean that are heavily biased to observations in summer (Bushinsky et al., 2019a).

Independent studies such as Long et al. (2021), Wu et al. (2022), and MacKay and Watson (2021) suggest that there may be a systematic offset in pCO_2 values that are derived from profiling floats of 5 to 10 μatm. It should be possible to identify and correct such a systematic error. Possible sources of systematic error include biases in carbon system thermodynamics (Fong and Dickson, 2019) or a systematic error in calibration protocols (Johnson et al., 2016). Resolving a potential bias will clearly lead to more precise and accurate air-sea CO_2 fluxes. The potential need for improvements in the profiling float pH and derived pCO_2 accuracy are reminiscent of the work required to make shipboard pCO_2 observations from different research groups consistent with each other (Körtzinger et al., 2000).

As the SOCCOM array has grown to cover the Southern Ocean in all of its most distinctive regimes, it has become possible to document regional differences within circumpolar regimes (Williams et al., 2018). These spatial and temporal variations can then be related to physical and biological processes. Chen et al. (2022) documented the connection of the deep water reservoirs of high carbon to the near-surface in the southern part of the Antarctic Circumpolar Current, using both SOCCOM float and historical hydrographic data (Olsen et al., 2020) and the property potential pCO_2 (PCO_2). The PCO_2 is the pCO_2 a parcel of water would have if raised to the sea surface (Broecker and Peng, 1982), and better characterizes the potential for air-sea exchange than the DIC concentration. Prend et al. (2022b) connected this high subsurface PCO_2 to the sea surface. Using SOCCOM air-sea carbon fluxes, they showed preferential outgassing in the Indian and Pacific sectors of the Southern Ocean compared with the Atlantic (Fig. 11). The initial hypothesis for the asymmetry was the lower PCO_2 observed for Atlantic deep water compared with Indo-Pacific Deep Water. However, Prend et al. (2022b) showed that stronger winter entrainment of high PCO_2 waters into the mixed layer is the proximate cause. Thus, a future with strengthening westerly winds and deepening mixed layers (e.g. Sallée et al., 2021)

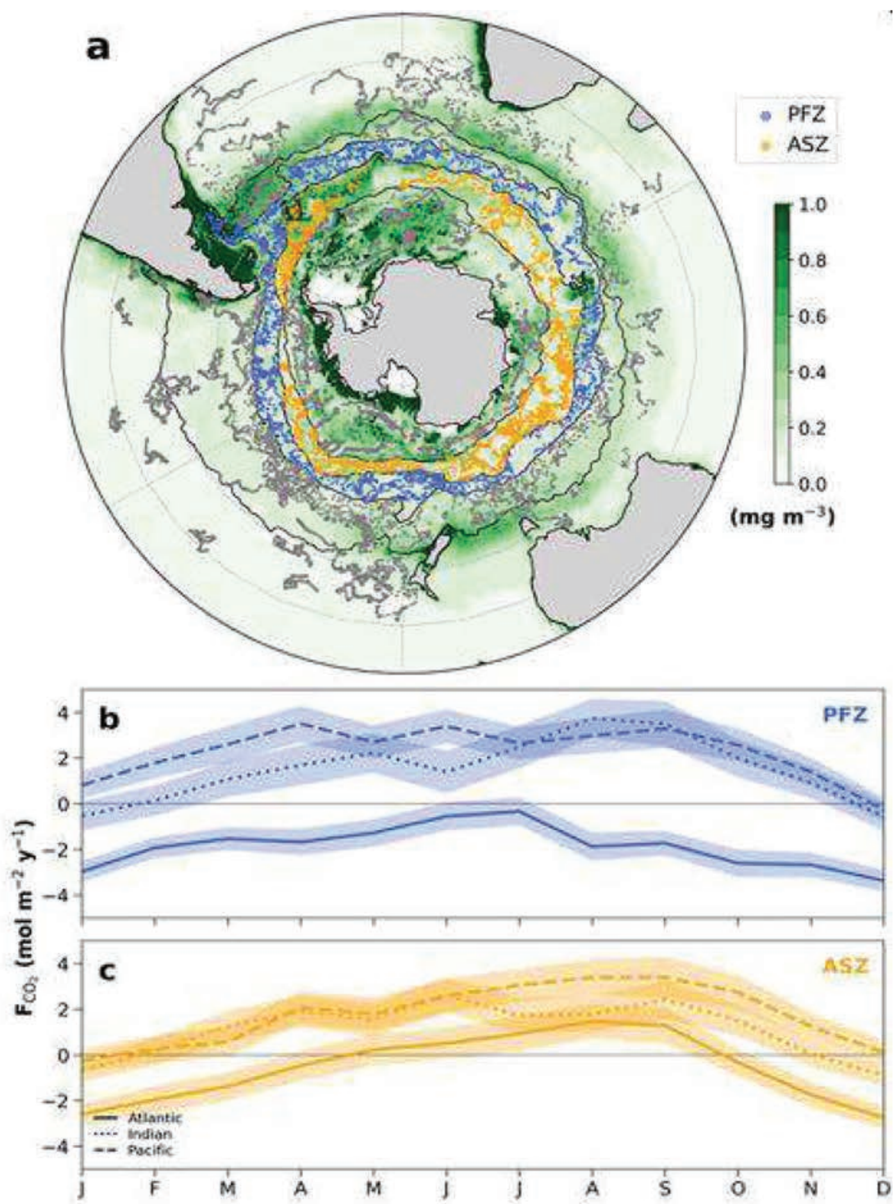

Fig. 11. (a) SOCCOM float profile locations sorted by frontal zone (PFZ: Polar Frontal Zone; ASZ: Antarctic Southern Zone). The color shading shows austral summer surface chlorophyll (mg/m3) from a 2002 to 2019 satellite ocean color climatology (NASA Goddard Space Flight Center, Ocean Ecology Laboratory, Ocean Biology Processing Group, 2018). (b) Monthly climatology of air-sea CO2 flux (mol C/m2/yr) in the PFZ from float profiles in the Atlantic, 65°W–25°E (solid line), Indian, 25°E – 150°E (dotted line), and Pacific, 150°E – 65°W (dashed line) sectors. Float profiles were made between 2014 and 2020. Panel (c) same as panel (b), but for the ASZ. Adapted from Prend et al. (2022b).

would lead to greater carbon outgassing.

Prend et al. (2022a) demonstrate the capability of SOCCOM profiling float pH observations to assess the processes that drive pCO_2 seasonal cycles. There is a change from a summer maximum of pCO_2 in the subtropics to a winter maximum in the polar regions. They find this shift is driven by a reduction in the amplitude of the seasonal temperature change at high latitudes, rather than biological processes.

3.2. Primary production and seasonal biomass cycles

3.2.1. Primary productivity

The transformation of dissolved inorganic to organic carbon during photosynthesis in the ocean, i.e., primary productivity, fuels marine ecosystems and plays an essential role in the global carbon cycle. Global marine net primary productivity (NPP) (defined as gross carbon fixation minus autotrophic respiration) is commonly inferred from ocean color remote sensing observations. Satellite observations provide information on water optical constituents and the available light field to infer phytoplankton biomass and division rates (Behrenfeld and Falkowski, 1997). The calibration of these satellite productivity models relies on scarce in situ observations of productivity determined from incubations of seawater samples with added $H^{14}CO_3^-$. The in situ observations are mostly constrained to low latitude regions (Buitenhuis et al., 2013; Marra et al., 2021).

Alternatively, primary productivity can be quantified by tracking the production of oxygen through photosynthesis. BGC-floats with oxygen sensors, including all floats within the SOCCOM array, permit the direct measurement of in situ gross oxygen production (GOP), albeit at coarse spatial scales. Although profiling floats cycle at ~ 10 day intervals, the diel cycle of oxygen can be detected by a float array if the individual floats surface at different times of the day (Fig. 12; Johnson and Bif, 2021). In this case, the set of profiling floats act as a dispersed chemical sensor array. The GOP computed from the diel cycle in oxygen concentration can then be converted to NPP, yielding a globally integrated value of 53 ± 7 (1 standard error) Pg C yr^{-1}. This value is consistent with the previous mean estimate of 50.7 Pg C yr^{-1} obtained from multiple ocean color and general circulation models (Carr et al., 2006). The diel oxygen method developed in SOCCOM has been extended to include diel cycles of particulate organic carbon in a study using SOCCOM data (Stoer and Fennel, 2022).

In addition to chemical sensors, SOCCOM floats have been equipped with bio-optical instruments that allow the estimation of phytoplankton chlorophyll and carbon biomass from measurements of fluorescence and particle backscattering that are combined with the models used to calculate productivity from remote sensing observations. These bio-optical observations are used to constrain phytoplankton physiology in response to nutrient and light limitation and to extend the computation of NPP beyond the mixed ocean surface and past the first optical depth (Arteaga et al., 2022), where most satellite sensors are unable to retrieve bio-optical information. Within the surface ocean observed by satellites, the increasing availability of float bio-optical observations is enabling the evaluation of ocean color remote sensing products (Bisson et al., 2019, 2021). For example, an assessment of estimates of chlorophyll and particulate organic carbon from NASA's Ocean Color Index (OCI) algorithm based on retrievals from the Moderate Resolution Imaging Spectroradiometer (MODIS) and (VIIRS) showed a good agreement with float-based estimates of these variables in the Southern Ocean (Haëntjens et al., 2017).

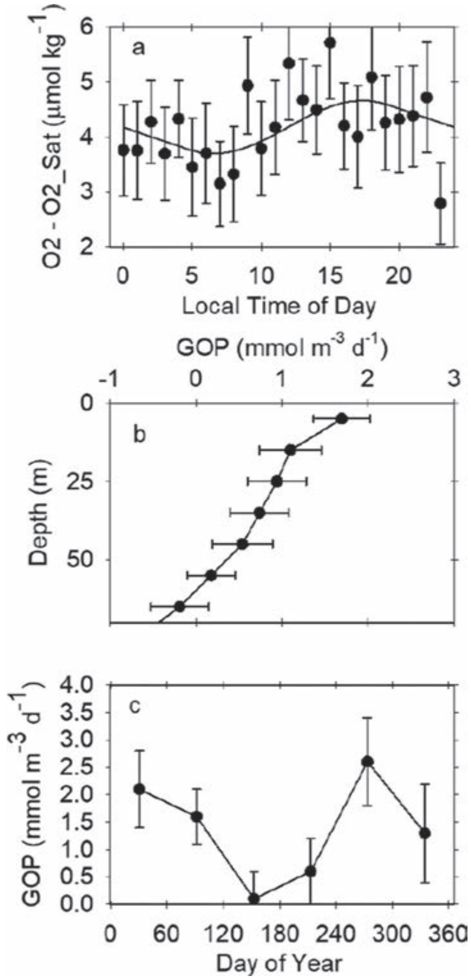

Fig. 12. Diel oxygen productivity from 30°S to 60°S following Johnson and Bif (2021). (a) Diel cycle of oxygen in the upper 20 m for all SOCCOM floats on days 0 to 61. (b) Vertical profile of Gross Oxygen Production (GOP). (c) Seasonal cycle of GOP in the upper 10 m. Error bars are 90% confidence intervals.

3.2.2. Bloom dynamics

The incorporation of bio-optical sensors together with the float's biogeochemical measurements has increased our capacity to assess the role of ocean physics in setting the necessary nutrient and light preconditions needed for phytoplankton to grow and blooms to develop. Prend et al. (2019) coupled float data with the B-SOSE model to show that the large bloom in the Scotia Sea is linked to an unusually shallow mixed layer. This is due to a Taylor column over a topographic feature supporting early bloom formation. von Berg et al. (2020) show that the initiation and magnitude of blooms in the seasonal ice zone are linked to the timing of sea ice retreat. Uchida et al. (2019) and Arteaga et al. (2020) examined the phenology of phytoplankton blooms from the in situ observations of SOCCOM floats, a complementary approach to prior satellite-based assessments. Over the last ten years, studies based on satellite information have suggested that the temporal evolution of phytoplankton blooms cannot be fully understood from abiotic environmental properties controlling phytoplankton division rates (Behrenfeld and Boss, 2018). In situ observations of phytoplankton biomass from SOCCOM float bio-optical sensors have revealed a temporal gap between the seasonal cycle of phytoplankton division rates and actual biomass accumulation, which highlights the role of biomass-loss processes (e.g., grazing, viruses, sinking) as important drivers of bloom initiation and termination (Arteaga et al., 2020).

3.2.3. Linking to elements of the global ocean observing system

Profiling floats operate in synergy with all elements of the global ocean observing system. They are dependent on ships for deployments, sensor validation, and mapped products for sensor adjustment (Maurer et al., 2021). They complement earth observing satellites such as ocean color sensors and altimeters by providing observations with vertical resolution under clouds and ice, and during dark winter periods. Satellite-based communication systems are required to transmit data.

These synergies are illustrated in Fig. 13. The figure emphasizes the role that floats add to the observing system. They extend ship-based observations in time. They extend satellite observations in depth. They provide a consistent set of in situ observations that can effectively link these systems. For example, Haëntjens et al. (2017) have demonstrated consistency between SOCCOM profiling float chlorophyll values and the concentrations determined from ocean color satellites. Arteaga et al. (2022) used SOCCOM profiling float bio-optical data to extend NPP values computed with the Carbon-Based Productivity Model (Westberry et al., 2008), developed to support ocean color satellites, into waters deeper than can be resolved by ocean color satellites. They find that the vertical extrapolations necessary with ocean color satellite data have systematic biases in the Southern Ocean that affect vertical integrals of NPP.

The spatial density of profiling float observations cannot approach that obtained by ocean color satellites. However, processes that operate at higher temporal and spatial scales than those that floats sample at are aliased into the float data. In many cases, these signals can be recovered from the analysis of large numbers of float profiles. In addition to the above example of diel oxygen production by phytoplankton (Johnson and Bif, 2021), Carranza et al. (2018) used SOCCOM profiling float bio-optical sensors and satellite wind sensors to examine the effects of Southern Ocean storms on the vertical structure of plankton communities and their ability to develop vertical structure during quiescent wind periods.

3.3. Biological carbon pump

The biological influence on air-sea carbon flux is controlled by the downward flux of organic matter produced by phytoplankton in the surface ocean. This export and transfer of carbon from the surface to depth is termed the biological carbon pump. It is one of the main regulators of global atmospheric CO_2 levels (Volk and Hoffert, 1985). In most cases, the amount of carbon exported by the biological carbon pump will equal the annually integrated net community production (NCP), where NCP is the amount of primary production minus respiration at all trophic levels. SOCCOM floats have observed NCP from the seasonal drawdown of nitrate (Johnson et al., 2017a; Arteaga et al., 2019) and DIC (Briggs et al., 2018) in all regions of the Southern Ocean, providing comprehensive assessments of the net carbon production that is subsequently exported. This work allows the first, systemwide rate observations with the potential for annual resolution.

These analyses of NCP and the biological carbon pump generally make simplifying assumptions regarding potential biases due to ocean physics. As the number of floats increase, more effective use of the observational data may be made by incorporating the results with data assimilating models such as B-SOSE. Such an approach was used to study the mismatches in NCP rates determined from DIC and nitrate that may occur in oligotrophic systems. Elevated rates of DIC uptake may occur without corresponding nitrate uptake (Johnson et al., 2022) in oligotrophic systems. This study, which merged observations of 234 seasonal cycles of nitrate and DIC from floats with the corresponding results in B-SOSE, implies that much of the DIC uptake north of about 40°S is due to the production of dissolved organic matter containing little or no nitrogen. Seasonal declines in oxygen concentration observed by SOCCOM floats in the mesopelagic zone (depths between 100 and 1000 m) have been used to determine consumption rates of exported carbon (Arteaga et al., 2018, 2019; Hennon et al., 2016). The decreases in oxygen are driven by respiration of sinking organic carbon.

The ocean near the Polar Front (~50° S), a region of extremely low iron concentrations, appears to be an area of elevated biogenic carbon export relative to the rest of the Southern Ocean (Arteaga et al., 2019; Johnson et al., 2017a; Fig. 14). Prior studies have suggested differences in the remineralization and grazing efficiency by bacteria and zooplankton as a potential driving mechanism (Cavan et al., 2015; Laurenceau-Cornec et al., 2015; Le Moigne et al., 2016). An alternative hypothesis derived from the analysis of SOCCOM float-based export estimates and satellite productivity algorithms is that iron limitation promotes silicification in diatoms, which is evidenced by the low silicate to nitrate ratio of surface waters around the Antarctic Polar Front

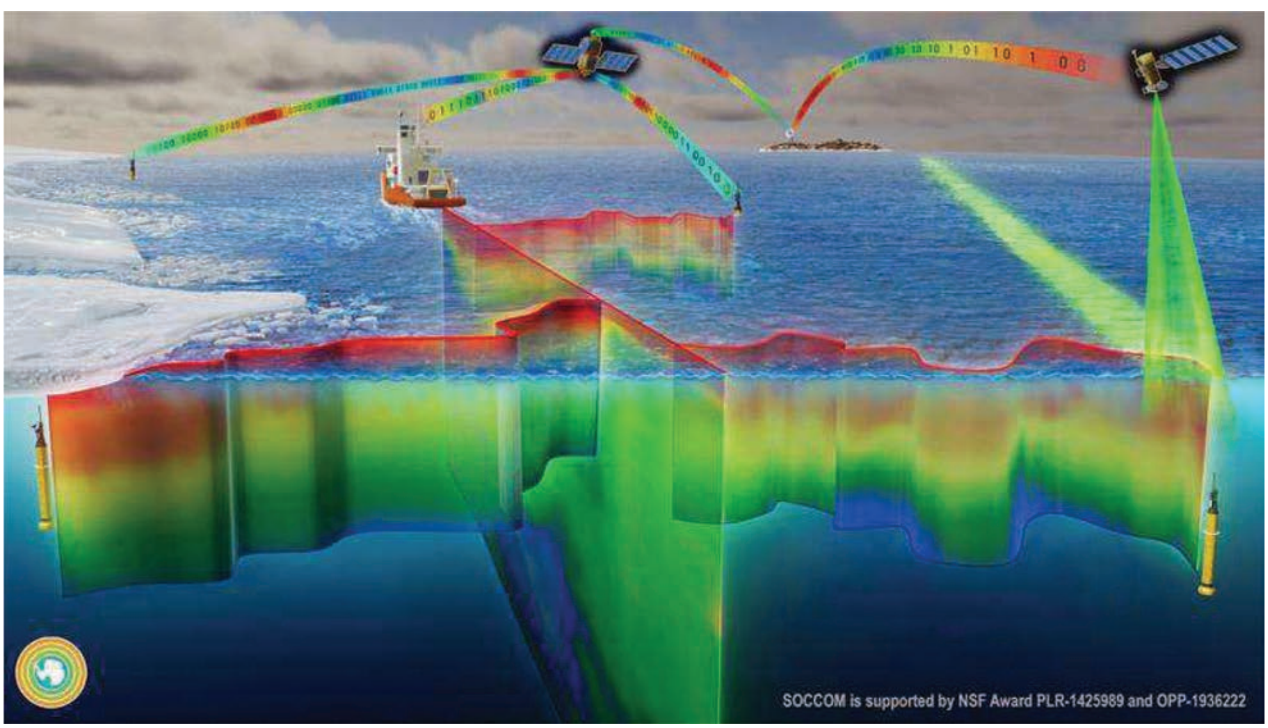

Fig. 13. Illustration of the SOCCOM float observing system embedded within the framework of ship-based observations and satellite remote sensing and communications. Floats deployed from the ship extend elements of the diverse laboratory data out in time. Floats extend the high spatial resolution of ocean color data in the first optical depth of the ocean down in the vertical, while depending on satellites for data communications. Credit: SOCCOM Project, Princeton University.

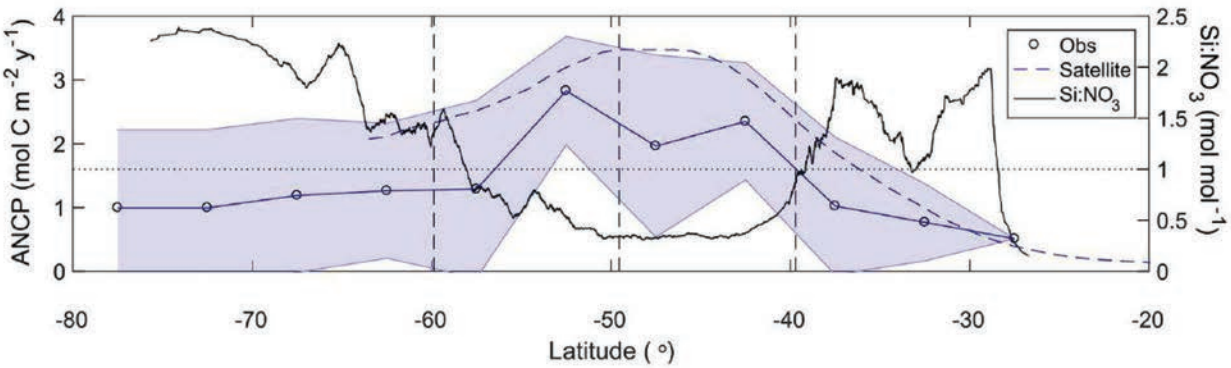

Fig. 14. Meridional pattern in export production (inferred from annual net community production - ANCP). Export production inferred from float oxygen and nitrate profiles (open blue circles and blue solid line), and satellite observations (blue dashed line). The Silicate to nitrate ratio (black solid line) was obtained from float nitrate observations and the World Ocean Atlas (2013) silicate climatology (Garcia et al., 2014).
Adapted from Arteaga et al. (2019)

(Arteaga et al., 2019). High diatom silicification increases the ballasting effect of particulate organic carbon and overall annual net community production in this region (Arteaga et al., 2019).

3.4. Floats in the seasonal ice zone

A hallmark of the Southern Ocean is the presence of seasonal sea ice south of about 60° S. Biogeochemical observations under sea ice have been rare, particularly during winter. SOCCOM has greatly improved sampling of both biogeochemistry and temperature/salinity in the sea-ice zone around the Antarctic continent with thousands of vertical profiles through all times of the year. These observations have allowed for unprecedented views of the under-ice water column properties in winter and the evolution of biogeochemical properties throughout an annual cycle (Briggs et al., 2018).

The SOCCOM floats operating in the seasonal ice zone enable a number of the observing system priorities identified in the UN Southern Ocean Report to be advanced. These include:

- *Improve understanding of sea ice, including its role in ecological processes of the Southern Ocean.*
- *Enhance predictive skill across climate, circulation, cryosphere, and ecosystems.*

3.4.1. Ice-ocean interactions

While SOCCOM was designed as a circumpolar observing system, its unprecedented year-round coverage has led to important contributions to more regional studies in the sea-ice zone as well (Wilson et al., 2019). In 2016 and again in 2017, a relatively large, open-ocean polynya appeared in the Weddell Sea region around Maud Rise (Campbell et al., 2019). This was in the same area occupied by the very large Weddell polynya of the mid-1970s. The 2016–17 polynya events were the largest since those observed in the mid-1970s (e.g. Gordon, 1978). SOCCOM floats over Maud Rise showed that the upper ocean in this region was only marginally statically stable during the events, with a mixed layer salinity approaching the limit for deep convection in late summer of both 2016 and 2017. The polynyas in both years were triggered by the passage of strong atmospheric storms, initiating mixing and heat loss from the subsurface ocean. Analysis of the stratification and climate forcing between the 1970s and 2016 indicated that this combination of weak stratification and strong climate forcing in the intervening years was rare (hence no polynya formation). The BGC sensors on the Maud Rise floats and in the northern Weddell Sea provided a comparison of productivity in the two regions, showing much higher productivity in the circulation trapped over Maud Rise, suggesting greatly enhanced vertical mixing that transports nutrients to the mixed layer.

Haumann et al. (2020) used a combination of under-ice profiles from both Core Argo floats and SOCCOM BGC-Argo floats, as well as ship-based and animal borne profiles, to investigate the details of temperature anomalies under and near sea ice. Surprisingly, a number of cases were found of water at temperatures below the in situ freezing point, termed supercooled, and water that would have been below the freezing point if it were raised to the sea surface, termed potential supercooled. Haumann et al. showed that nearly 6% of the profiles under the ice appeared to be supercooled, especially close to the Antarctic continent. The cause was attributed to melting of ice shelves and the existence of convective plumes during the formation of sea ice in winter. Such plumes might have important implications in the vertical transport of properties such as nutrients and carbon. An idealized modeling study nested in B-SOSE demonstrated the importance of ice shelf melt rates on spatial patterns of productivity (Twelves et al., 2021). These works suggest a need for a more focused observational study in these regions near the ice shelves.

3.4.2. Climatologies of BGC properties

The under-ice observations (from both Core Argo floats, with temperature and salinity data; and SOCCOM floats, with temperature, salinity, and BGC data) have been combined to produce a climatology of the wintertime under-ice regime around the continent, as can be seen in Fig. 15. Here we show the climatology in the wintertime surface mixed layer ($\sigma_\theta = 27.4$ and ~ 50 m deep in summer; $\sigma_\theta = 27.7$ and 100–120 deep in winter). The climatologies shown in this figure were formed by averaging and gridding the float data in an equal-area, scalable Earth projection, in order to avoid problems with convergence of meridians near the pole.

Mazloff et al. (2023) used the profiling float pH profiles and the B-SOSE model to create a monthly, mapped pH product for the Southern Ocean from 30°S to 70°S. The pH product was then compared to pH measurements made from ships prior to 2014. The differences in the climatology and shipboard measurements show that pH is decreasing most rapidly near the surface at a rate of -0.02 pH decade^{-1}, consistent with the rate of atmospheric CO_2 increase. The rate of decrease is not uniform horizontally, with some regions showing little change. The observed pattern of pH rate of change is consistent with the overturning circulation. Regions with low acidification rates are areas where Southern Ocean winds drive upwelling, which brings older, less acidified water to the surface and this decreases the rate at which pH declines.

3.4.3. Sea ice and phytoplankton

Sea ice plays a central role in structuring the productivity and

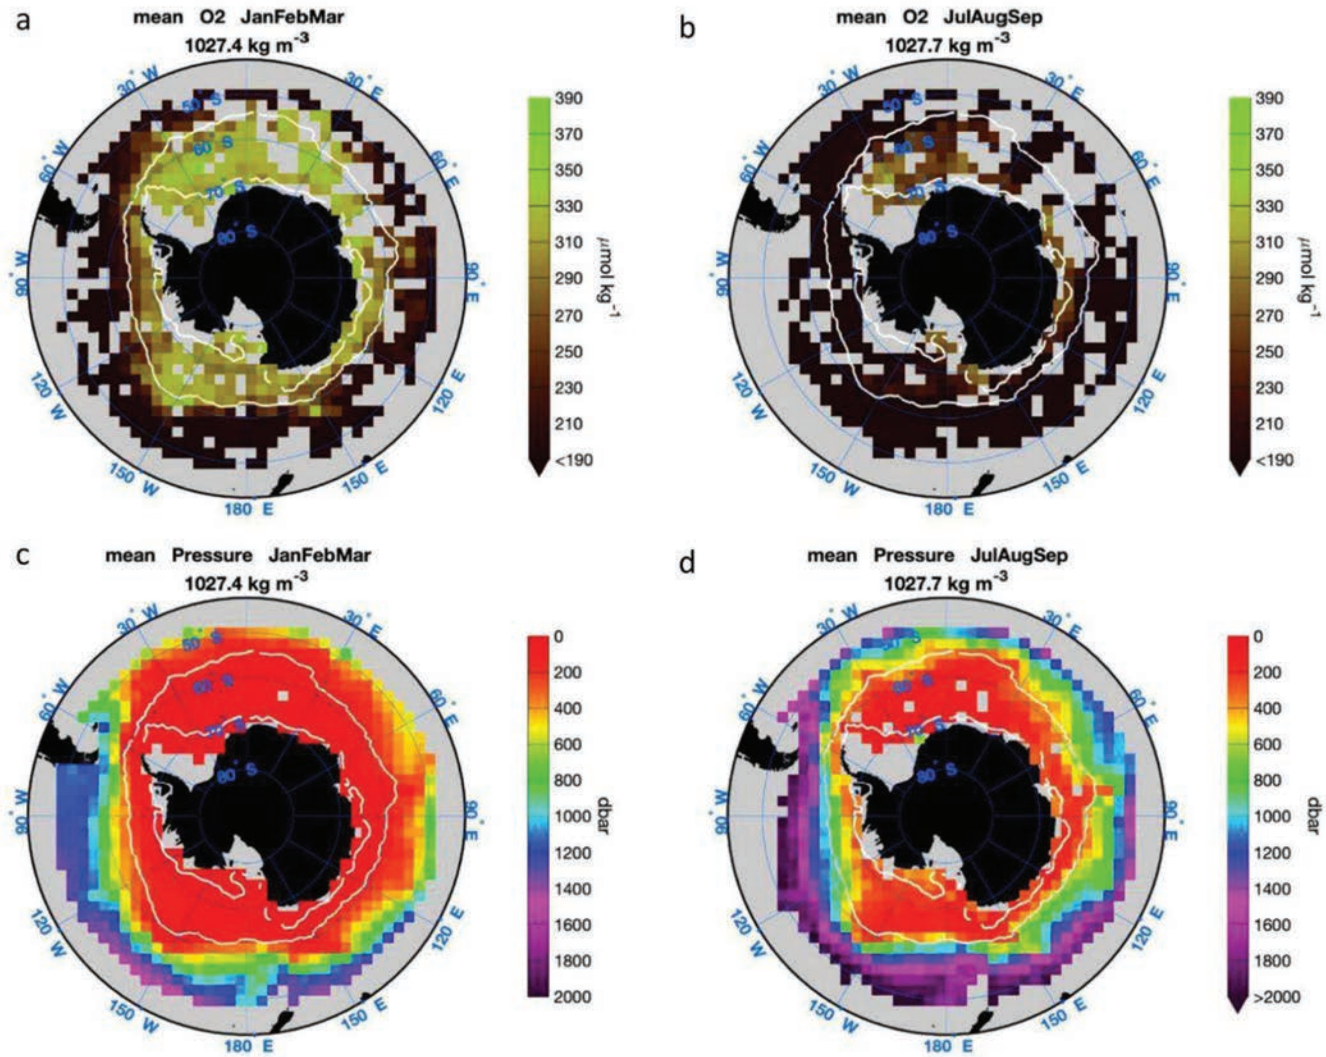

Fig. 15. Under ice climatology for oxygen. Dissolved O_2 (μmol kg^{-1}) determined from SOCCOM float data in summer (panel a) and winter (panel b) on the pressure (decibars) surfaces shown in panels c ($\sigma_\theta = 27.4$) and d ($\sigma_\theta = 27.7$). These pressure surface lie at the base of the mixed layer in summer and winter and the O_2 concentrations represent values in the surface mixed layer. The inner and outer white contours represent the summer and winter limits of the sea ice zone. The climatologies are gridded using an equal area scalable Earth projection that preserves the gridding in cells near the pole.

ecology of marine polar ecosystems. Observations in the Southern Ocean have long shown that sea ice communities are highly productive and diverse (Garrison 1991; Smith and Garrison, 1990). It has also been hypothesized that sea ice plays a critical role in adjacent pelagic communities (Smith and Nelson 1986), which represent a significant proportion of the annual primary productivity, and underpins trophic dynamics and biogeochemical cycles of the Southern Ocean (Arrigo et al. 2008).

Under-ice observations from SOCCOM floats revealed that Antarctic phytoplankton in ice covered regions begin to bloom (net increase in biomass accumulation) in early winter (Prend et al., 2019; von Berg et al., 2020; Arteaga et al., 2020), well before sea ice starts to retreat (Fig. 16). Under-ice blooming has been observed at local scales in the Arctic (Arrigo et al., 2012) and near Antarctica (Gibson and Trull, 1999; Arrigo et al., 2017), but the SOCCOM float dataset demonstrates that this phenomenon is a common feature of the seasonal ice zone. This is a remarkable event given the low light levels at which the bloom appears to begin (less than1 E m^{-2} d^{-1}). Biomass loss must be very low to permit phytoplankton to accumulate despite very low cellular division rates (Arteaga et al., 2020). These blooms deplete nitrate and DIC and, as light increases, they rapidly produce oxygen (Briggs et al., 2018). These observations show that respiration in winter nearly balances summer production with little net carbon export.

3.5. Circumpolar circulation

SOCCOM investigators worked on describing and understanding the pathways of the deep waters to the sea surface in the Southern Ocean (Morrison et al., 2015). This work was inspired by the findings of unexpectedly large carbon outgassing in the southern Antarctic Circumpolar Current (Section 3.1) that are driven by upwelling of high carbon deep waters. To explore the upwelling deep waters, Lagrangian tracking in multiple computer simulations revealed a southward and upward spiraling pathway (Tamsitt et al., 2017, 2018; Drake et al., 2019). Deep waters exiting the Atlantic, Pacific, and Indian Oceans were shown to be localized to the western and eastern boundaries and to mid-ocean ridges. These waters enter the eastward-flowing ACC, and mingle with each other and with ventilated waters from south of the ACC. While the net upward pathway is related to Ekman suction, most of the actual upwelling occurs in eddy fields at topographic features that are encountered by the ACC. This topographically-facilitated upwelling is active up to near the base of the surface mixed layers. The last step of

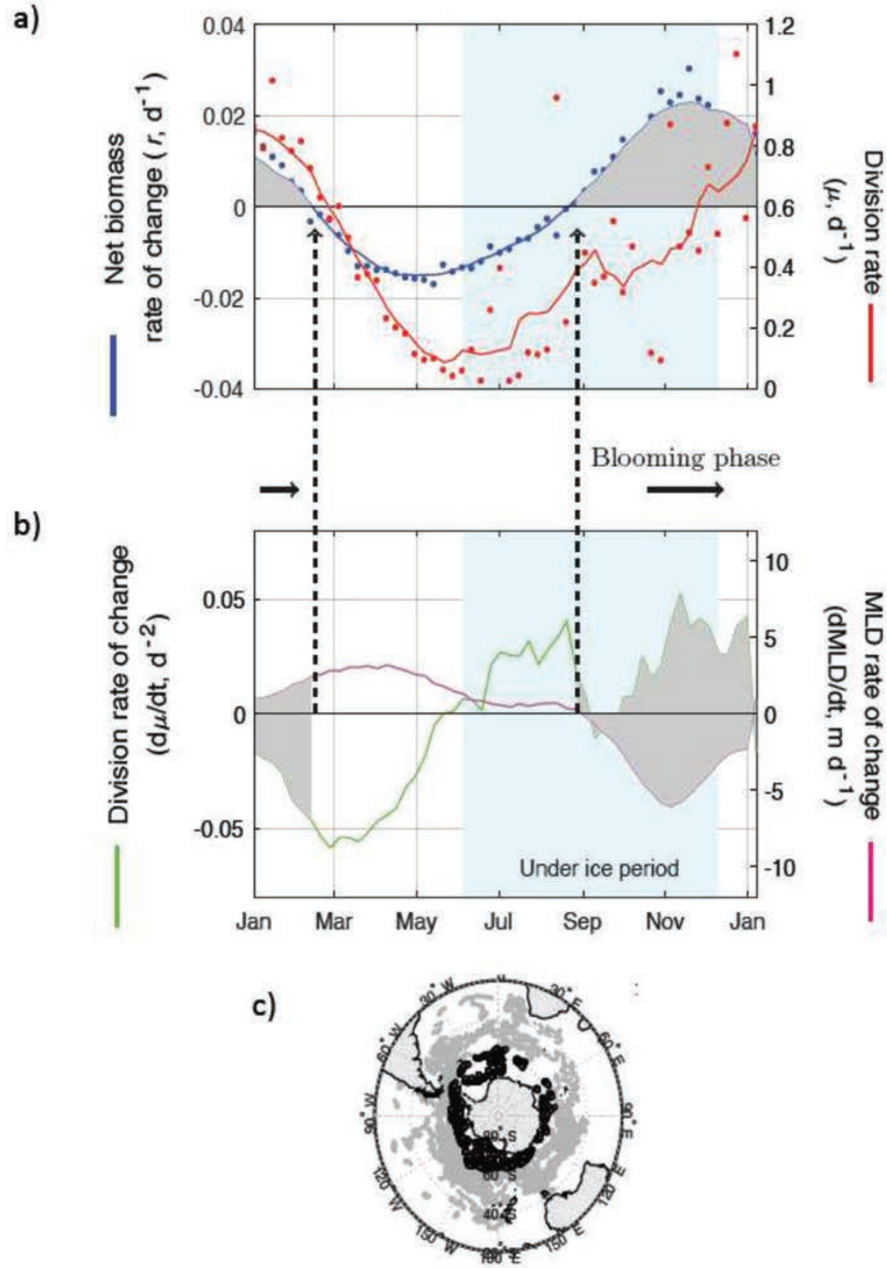

Fig. 16. Climatological phytoplankton bloom cycle in the Antarctic seasonal ice zone (SIZ). (a) Annual cycle of net phytoplankton biomass rate of change (r, blue line) and division rates (μ, red line). Individual points are weekly averaged observations and the continuous line is the result of a smoothing temporal filter. (b) Averaged time series of the temporal derivative of μ (dμ/dt, green line) and of the mixed layer depth (MLD) (dMLD/dt, magenta line). The blooming phase (r greater than 0) is highlighted by the gray shaded periods. The light blue shaded section indicates the period where 50% or more profiles were under ice. (c) Location of float profiles in the STZ and SIZ.
Adapted from Arteaga et al. (2020)

incorporation into the mixed layer is decoupled from these topographic features, and instead is dominated by surface-forced mixed layer entrainment. This process is most vigorous where winter mixed layers are deep, in the Indian and Pacific sectors of the ACC (Prend et al., 2022b).

Thus carbon outgassing in the southern ACC is driven by the conjunction of two processes – upwelling of high-carbon, northern deep waters to just below the surface layer, and vigorous winter entrainment that incorporates this water. There are many steps of this process that remain to be detailed, but the framework is now clear. After the northern deep waters upwell to near the sea surface, they split into the lower and upper limbs of the Southern Ocean's overturning circulation. The lower limb is fed by the densified surface layer, fueled by brine rejection from sea ice formation. In the upper limb, surface waters and sea ice are exported northward through Ekman transport. Freshwater from melted sea ice provides enough buoyancy to allow the upwelled water to move northward and warm, eventually reaching the northern ACC where it subducts into the thermocline (Haumann et al., 2016). This upper limb water carries high nutrients and carbon which become the source of nutrients for the thermocline (Sarmiento et al., 2004, Verdy and Mazloff 2017). This split between the upper and lower limbs has been quantified and localized in SOCCOM studies utilizing the B-SOSE output (Abernathey et al. 2016; Masich et al. 2018). Abernathey et al. 2016 showed the importance of freshwater transport via sea-ice in setting the structure of this overturning circulation (Fig. 17).

3.6. SOCCOM biogeochemical data as a community resource

A major focus of the SOCCOM program was to provide open access data to the community that was easily accessible outside of the program participants to ensure maximum influence. There are numerous publications by scientists outside the SOCCOM program who have used these data. Here we focus on just three topical examples; the effect of eddies on biogeochemical processes, studies of carbon export, and studies of plankton blooms under sea ice.

The open access SOCCOM dataset has played a seminal role in studies that illustrate the role of eddies on biogeochemical processes. This work has been performed completely by scientists outside of the project (Su et al., 2021; Cornec et al., 2021), illustrating both the Findability and Accessibility principles of a FAIR dataset (Wilkinson et al., 2016). These authors used the large SOCCOM dataset, as well as other floats in the BGC-Argo system, to assign float profiles to their location in cyclonic and anticyclonic mesoscale eddies that were mapped with satellite altimeters (an illustration of the FAIR Interoperability principle). This allowed them to test hypotheses regarding the role of eddy circulation in sustaining enhanced chlorophyll in these systems. Chlorophyll fluorescence in the deep chlorophyll maximum of eddies may increase due to biomass accumulation or photo-adaptation. Cornec et al. (2021) find, in a study with a global span, that in cyclonic eddies the fluorescence increase is primarily due to biomass accumulation, while in anti-cyclonic eddies it results primarily from photo-adaptation. Su et al. (2021) focused on the Indian Ocean sector of the Southern Ocean, where they found fluorescence increases generally resulted from both biomass accumulation and photo-adaptation. They show the importance of eddy pumping for sustaining elevated biomass in cyclonic eddies, as expected from prior studies. Supporting studies at the scale of eddies was not one of the original goals of SOCCOM, illustrating the FAIR principle of data Reusability.

SOCCOM floats have also played a significant role as a data source for studies of carbon export (Dall'Olmo et al., 2016; Stukel and Ducklow, 2017; Llort et al., 2018; Su et al., 2022). There is a growing appreciation that transport of organic carbon into the deep sea may occur by a variety of mechanisms (Boyd et al., 2019) in addition to the gravitational sinking of particles (the biological carbon pump; Ducklow et al., 2001). The broad distribution of SOCCOM floats allowed carbon export processes observed at the Long Term Ecological Research Station on the Palmer Peninsula to be extrapolated across the Southern Ocean (Stukel and Ducklow, 2017). Vertical mixing appeared to contribute one quarter of the biological carbon pump. In a global study, using many SOCCOM floats, Dall'Olmo et al. (2016) demonstrated that deep winter mixing is an important transport mechanism that detrains particles from surface waters to the deep-sea, a process labeled the seasonal mixed-layer pump. Llort et al. (2018) used SOCCOM floats to demonstrate that vertical motions along mesoscale eddies can further transport particulate carbon into the deep-sea, a process they termed the carbon eddy-pump. Su et al. (2022) used all of the available Southern Ocean oxygen profiles to compute oxygen consumption rates between the euphotic zone and 1000 m throughout the Southern Ocean. They obtained Annual Net Community Production rates by presuming the vertically integrated respiration rates are balanced by surface production and export. Their values are 1.1 to 2.8 times higher than found in prior studies.

The ability of the SOCCOM profiling floats to collect year-round data under sea ice has become a novel data resource that is being well utilized by the broader community. Jena and Pillai (2020) used SOCCOM floats, which fortuitously surfaced in the Weddell Polyna (Campbell et al., 2019), to examine the processes controlling plankton blooms in ice free regions of the seasonal ice zone. Hague and Vichi (2021) used SOCCOM float data to test the hypothesis that blooms in the seasonal ice zone form when meltwater stabilizes the water column. They found that significant growth occurred under ice and before there was a large salinity decrease. Bisson and Cael (2021) examined the relationship between phytoplankton abundance detected by SOCCOM floats and remotely sensed sea-ice properties to assess the role of ice in plankton growth. Horvat et al. (2022) used the SOCCOM data to demonstrate that under-

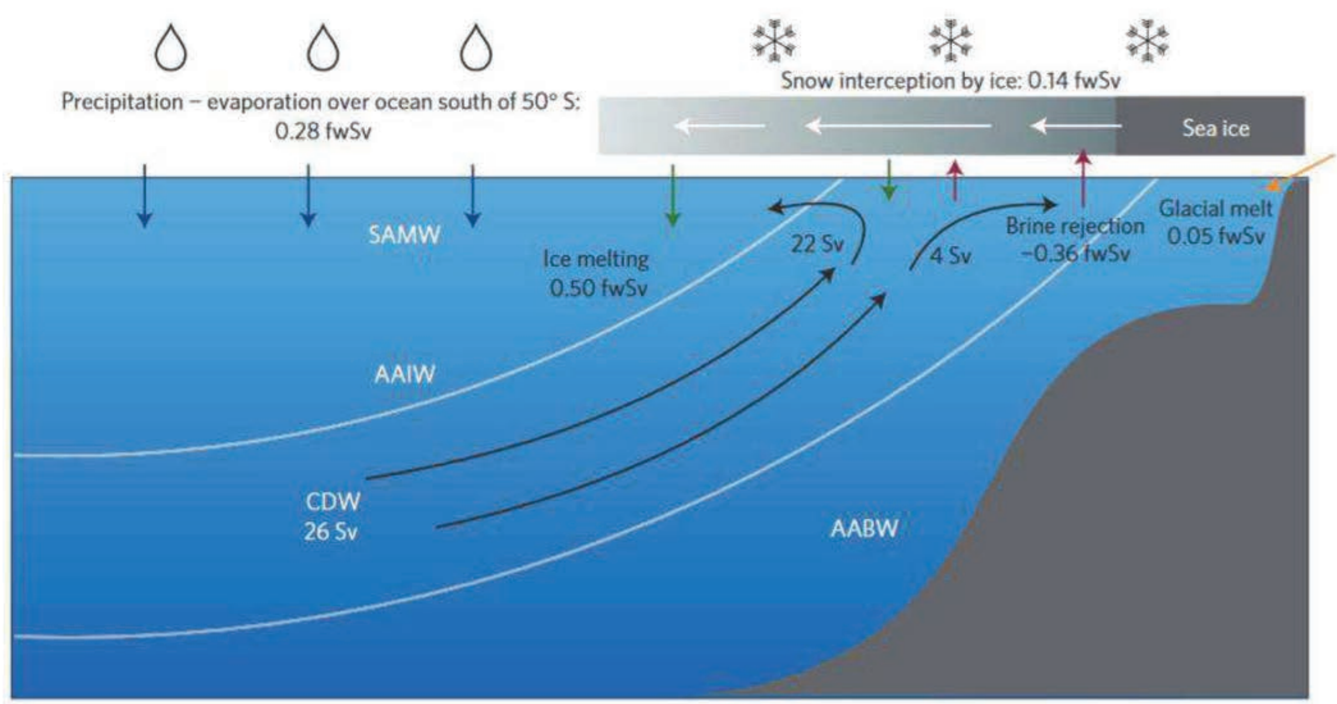

Fig. 17. Schematic depicting the various bulk contributions to the freshwater exchange at the ocean surface south of 50° S (positive downward). Net fluxes are given in units of freshwater sverdrups: 1 fwSv = 10^6 m^{-3} freshwater s^{-1} = 3.15 × 10^4 Gt freshwater per year. For reference, 1 fwSv = 1.9 mm d^{-1} of rainfall distributed over the region. From (Abernathey et al., 2016).

ice phytoplankton blooms are widespread in the Southern Ocean. Nearly all profiles under compact ice (80–100% coverage) showed large blooms during austral spring. Moreau et al. (2020) examined the fate of the carbon produced in ice-edge and under-ice blooms. Herbivory accounts for 90% of the losses and downward POC export is less than 10%.

These papers are just a subset of the analyses now produced by members of the ocean science community that are not directly associated with the program, but who are using the SOCCOM float data and B-SOSE output. They illustrate the role that SOCCOM is playing in becoming a major data resource that will enable both process studies and long-term assessments of the Southern Ocean response to climate forcing.

The SOCCOM observing system also fulfills a broader role through its synergism with other Southern Ocean observing systems and research programs. Examples of synergism with other programs include use of data from marine mammals that have been instrumented by the Marine Mammals Exploring the Oceans Pole to Pole (MEOP) program. The B-SOSE data assimilation system uses MEOP data as a constraint, which is particularly valuable in waters that are shallower than the 2000 m limit at which most floats are deployed. A SOCCOM study of the effect of storm driven mixing on bio-optical gradients used both profiling float and MEOP data (Carranza et al., 2018). Another SOCCOM study of the distribution of supercooled water used profiling float, MEOP, and ship-based measurements from the NOAA World Ocean Database (Haumann et al., 2020). Other major programs use the SOCCOM data in a variety of applications. For example, the Palmer Long Term Ecological Research (LTER) project is using SOCCOM float to provide an open ocean end member to assess the changes in shelf productivity driven by the precipitous declines in sea ice. Close interaction with focused programs such as Ocean Regulation of Climate by Heat and Carbon Sequestration and Transports (ORCHESTRA) resulted in benefit to both programs through float deployments and data exchange (Meredith et al., 2017). SOCCOM profiling float data have been used in Marine Ecosystem Assessment of the Southern Ocean (MEASO) to understand the ecological significance of subsurface chlorophyll maxima (Baldry et al., 2020). Of course, the SOCCOM program is closely intertwined with the international GO-SHIP program, which has deployed many of the SOCCOM floats and which is an irreplaceable source of validatation data for float sensors. These programs have formed an essential base for the success of the SOCCOM project.

4. Modeling the current and future state of the Southern Ocean and climate

Initial work with Earth System Models has focused on improving understanding of several important drivers of ocean change (Shi et al., 2018). This work addresses the UN Southern Ocean Report priority:

- *Improve understanding of key drivers of change and their impacts on Southern Ocean species and food webs.*

A critical component of SOCCOM modeling and the associated observations has been assessing the impacts of known model deficiencies and biases related to freshwater forcing, in addition to wind effects. Meltwater from the Antarctic Ice Sheet is projected to cause up to one meter of sea-level rise by 2100 under the highest greenhouse gas concentration trajectory (RCP8.5) considered by the Intergovernmental Panel on Climate Change (Oppenheimer et al., 2019). However, the effects of meltwater from the ice sheets and ice shelves of Antarctica are not included in the widely used CMIP5 or CMIP6 climate models, which may introduce bias into IPCC climate projections. Work using B-SOSE (Abernathey et al., 2016) highlights the importance of understanding and incorporating the effects of freshwater inputs on Southern Ocean circulation.

The Southern Hemisphere surface westerly winds are the main driver of the Southern Ocean circulation, mixing and air-sea exchanges. These strong westerly winds drive vertical mixing between surface and deep waters. An increase and poleward shift in these westerly winds, due to both the cooling of the stratosphere and the warming of the troposphere, has been inferred from reanalyses since 1980 (Swart and Fyfe 2012). The effects of meltwater provide a significant positive feedback on these changes. Models from both CMIP5 and CMIP6 still underestimate these historical trends (Beadling et al., 2020). The SOCCOM-led Southern Ocean Model Intercomparison Project (SOMIP) addresses this wind issue directly by imposing a “corrective perturbation” to the wind stress felt by the ocean.

4.1. Meltwater and wind

Antarctic Ice Sheet meltwater discharge into the Southern Ocean is generally neglected in most CMIP simulations (Pauling et al., 2016). Bronselaer et al. (2018), however, found that accounting for this discharge substantially affected the rest of the climate system. Including meltwater discharge slows the rate of global atmospheric warming, delaying the realization of both 1.5 °C and 2 °C warming by more than ten years. Ice sheet meltwater into the Southern Ocean during future simulations also drives a northward shift of the Inter-Tropical Convergence Zone (ITCZ), which results in reduced drying over Northern Hemisphere landmasses and enhanced drying in the Southern Hemisphere, relative to future simulations that neglect the meltwater. These SOCCOM results suggest that a feedback mechanism is in operation, whereby the meltwater added at the surface induces subsurface warming. That in turn leads to enhanced melting underneath ice shelves, potentially causing further meltwater-related climate effects (Fig. 18). The results demonstrate that meltwater discharge from the Antarctic Ice Sheet not only contributes to sea-level rise but also influences the global climate throughout most of the twenty-first century, emphasizing the importance of ocean and ice-sheet feedbacks on the climate system.

Wind increases and meltwater increases have opposing effects on Southern Ocean biogeochemistry. Additional meltwater causes a local reduction in ventilation that decreases subsurface oxygen levels. On the other hand, reduced ventilation increases subsurface nitrate concentrations along the continent through the accumulation of nutrients in more poorly ventilated waters and reduces nitrate export out of the Southern Ocean in newly formed intermediate water. The reduction in nitrate concentrations therefore propagates to low latitudes. In opposition, the wind-induced increase in ventilation causes an increase in oxygen concentrations throughout the upper 1,000 m of the Southern Ocean, while at the same time increasing surface nutrients and nutrient export through increased upwelling of deep, nutrient-rich waters. The balance between competing effects of wind and meltwater on ventilation will therefore influence future projections of ocean biogeochemistry.

Future climate change beyond 2100 is expected to cause nutrient trapping in the Southern Ocean through increases in surface stratification and poleward-shifting westerlies, starving the world-wide ocean of nutrients. Bronselaer et al. (2020) find that adding meltwater at the surface strongly amplifies Southern Ocean nutrient accumulation south of 60°S (Fig. 19). Previously, Pauling et al. (2016) concluded that adding meltwater at the surface or at ice shelves had little difference. Bronselaer et al. (2020) also find that increasing both wind and meltwater leads to significantly decreased nutrients north of 60°S as well (Fig. 19). While Southern Ocean nutrient trapping is found to be important in the twenty-second century, our results suggest that accounting for Antarctic meltwater and wind can cause similar effects in the twenty-first century, suppressing global biological productivity sooner than otherwise expected.

4.2. Buoyancy forcing, wind, and circulation changes

Strong westerly winds are a hallmark of the Southern Ocean and the primary driver of the ACC (Munk and Wunsch, 1998; Paparella and

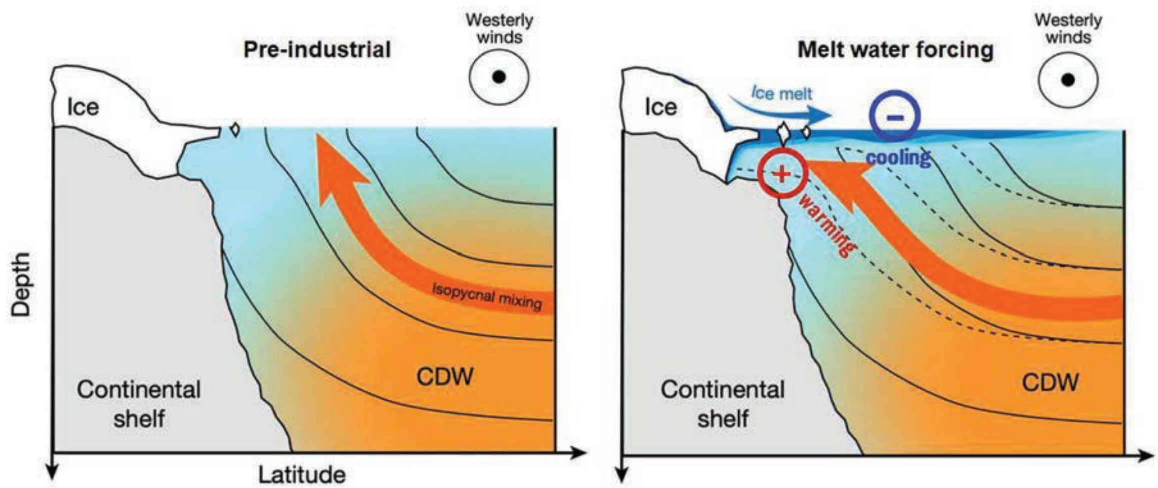

Fig. 18. Schematic showing subsurface warming in response to increased melt water is added to the surface of the Southern Ocean in an earth system model. After Bronselaer et al. (2018).

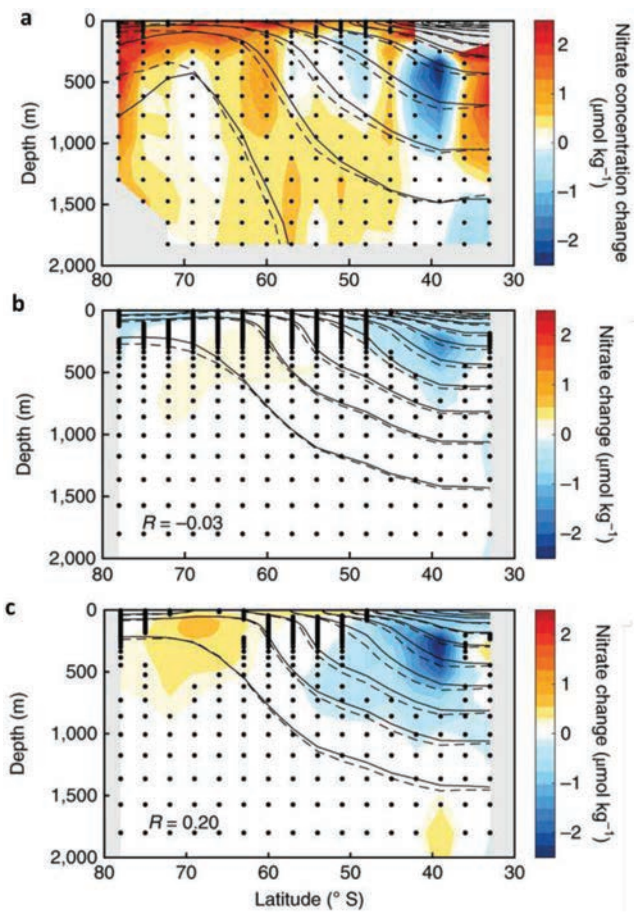

Fig. 19. Zonal-mean change in nitrate concentration. a) Observed nitrate change, SOCCOM float data 2014 to 2019 minus Ship data pre-2005. b) The decadal change of nitrate in the RCP 8.5 ESM2M simulation (2014 to 2019 mean minus 1985 to 2005 mean). c) The decadal change of nitrate in a SOMIP simulation with altered wind and meltwater (2005 to 2025 mean) minus the RCP 8.5 ESM2M simulation mean for 1985 to 2005. After Bronselaer et al. (2020).

Young, 2002). These winds are intensifying and shifting poleward, which may sustain an important feedback mechanism on the global carbon cycle (Russell et al., 2006b) and ocean warming (Armour et al., 2016). Much of the increased wind energy on the ocean appears in the mesoscale eddy field at locations determined by topographic interactions (Cai et al., 2022). Increased wind did not seem to appear in the mean flow. The weak effect on mean flow led to a concept known as eddy saturation (Straub, 1993; Munday et al., 2013).

In a SOCCOM supported study, Shi et al. (2020) used the Community Earth System Model (CESM) to examine climate driven controls on the ACC flow. They demonstrated that a changing buoyancy flux across the ACC was an important process regulating the ACC. To the north of the ACC, increasing ocean temperature produces a large buoyancy flux that has increased in time. Strong upwelling to the south of the ACC limits warming there. In a combined observational and modeling study, Shi et al. (2021) examined this process further. They used profiling floats, shipboard hydrography, and satellite altimetry with a careful statistical analysis to conclude that the zonally averaged ACC flow is accelerating, rather than remaining static. The increased baroclinicity due to the asymmetric buoyancy flux is a major driver of the increased flow, while strengthened wind stress is of secondary importance.

5. Broader impacts

SOCCOM's Broader Impacts vision is to transform training of oceanographers, expand public understanding of the Southern Ocean and its impact on climate change and living conditions on the planet, and enable broad access to the technology and findings of the SOCCOM initiative. The SOCCOM website, https://soccom.princeton.edu, was developed to enable much of this vision to be communicated to the public. The website includes access to profiling float data, model output, and a variety of multimedia resources including videos, photos, and graphics. Resources for an Adopt-A-Float program, including lesson plans for teachers are available. Some of these programs and resources are described in more detail below.

5.1. Public understanding

SOCCOM has a mission to drive a transformative shift in the scientific and public understanding of the outsized role of the ocean–and the Southern Ocean in particular–within our global climate system. In addition to deepening public understanding of the ocean's key role as a climate change buffer, the real-time monitoring of ocean health being done by SOCCOM provides critical information to policy makers, providing an ongoing assessment of carbon uptake and an independent way to effectively track progress on emission targets. This SOCCOM mission aligns with the UN Southern Ocean Report priority:

- *Improve societal understanding of Southern Ocean issues and appreciation of the Southern Ocean for its global value in Earth systems and unique environment.*

SOCCOM's Broader Impacts activities include use of social media, an Adopt-a-Float program, an array of multimedia content (lesson plans, videos, animations, and fact sheets), and capacity-building workshops to help researchers effectively apply float data (Matsumoto et al., 2022). The Adopt-a-Float program (Fig. 20) partners with teachers and classrooms around the world by enabling classes to adopt a profiling float with a goal to inspire and educate students about the Southern Ocean and climate change. Elementary- to college-level classes have the opportunity to give a soon-to-be-deployed float a name, and follow its progress at sea through online data visualizations and, sometimes, blogs written by their paired SOCCOM scientists. Students can find their float on the adopted floats table and explore data collected via a special Adopt-a-Float visualization application. Beginning with just one classroom in 2015, the program now has 180 adopted floats in classrooms across 42 states and seven countries (Chile, Canada, Australia, UK, Saudi Arabia, Japan, and Poland). Multimedia content is available through the SOCCOM YouTube channel that is linked on the SOCCOM website.

Outreach to communicate these key points has been part of the SOCCOM program since its inception and has helped scientists, teachers, students, and the public better understand the ocean's role in climate change while shining a light on the Southern Ocean.

5.2. Educating the next generation of Southern Ocean scientists

The SOCCOM project has contributed directly to the training and education of 19 postdocs, 22 graduate students, and 50 undergraduate students who have been actively engaged in our research program at SOCCOM institutions. Over half (59%) of these junior researchers have been female and nearly 9% have been participants from under-represented groups, with highest participation of under-represented groups at the undergraduate level. These students and postdocs are an integral part of the program. Many of the publications cited above are the direct result of research by postdocs, graduate students and undergraduates. As part of their training, SOCCOM early career personnel participate in regular research webinars as well as the SOCCOM annual meeting, where they present their research and take part in professional development activities. Ten SOCCOM-supported Ph.D. students have successfully defended their dissertations and have moved on to post-doctoral and faculty positions.

In addition to our program alumni, SOCCOM has established connections with dozens of ocean BGC researchers affiliated with the project partners through associate researcher and early career scientist groups. The program has also helped expand the community of BGC float and model data users through public training workshops on biogeochemical float and sensor technology, BGC data processing and QC, climate model data analysis and verification, and use and applications of the B-SOSE model.

5.3. SOCCOM in public policy

The SOCCOM program has been influential in shaping national

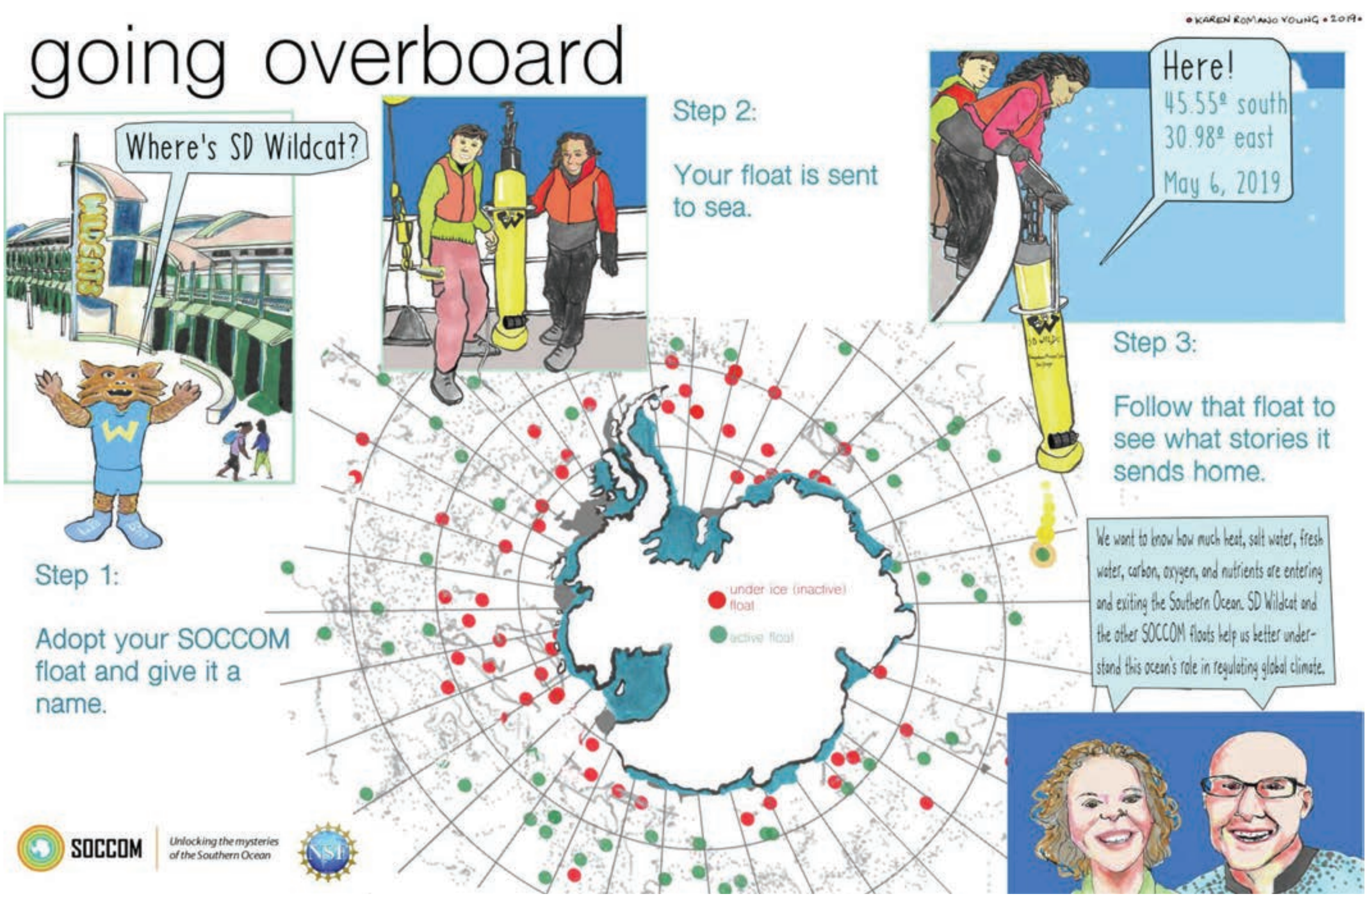

Fig. 20. The SOCCOM team partners with teachers and classrooms across the country to inspire and educate students about global ocean biogeochemistry and climate change through the "Adopt-A-Float" initiative. This illustration provides step-by-step instructions for adopting a float. Credit: Karen Romano Young for SOCCOM. The original drawing, with additional detail, was designed for a poster size and is available on the SOCCOM website (https://soccom.princeton.edu).

research policy. The second decadal plan for US ocean science, "Science and Technology for America's Oceans: A Decadal Vision" (NSTC, 2018), prominently features the SOCCOM project in the discussion on modernizing R&D infrastructure. The "Mid-Term Assessment of Progress on the 2015 Strategic Vision for Antarctic and Southern Ocean Research" (NAS, 2021) describes the role of SOCCOM in providing year-round observations of the Southern Ocean and the discoveries that have resulted. The role of SOCCOM in an international ocean carbon observing system has been discussed (IOC-R, 2021). Results from SOCCOM have been frequently included in the Bulletin of the American Meteorological Society Annual State of the Climate Assessment (Meredith et al., 2017; Swart et al., 2018; Meijers et al, 2019; Tamsitt et al., 2021).

6. SOCCOM in the future

The science performed in the SOCCOM program has evolved in scale as the profiling float array has grown. Initial studies were focused on one or a few floats (e.g., Williams et al., 2017; Briggs et al., 2018). The rapid growth of the array then enabled studies that encompassed the entire Southern Ocean, but without zonal resolution (e.g., Johnson et al., 2017a, 2017b; Bushinsky et al., 2017; Gray et al., 2018; Arteaga et al., 2019). As the array has progressed to more than 200 floats, studies with zonal resolution that reveal differences between processes in the Atlantic, Pacific, and Indian basins of the Southern Ocean are now possible (Prend et al., 2022b; Chen et al., 2022). Contrasting regional variability is also now possible. For example, Rosso et al. (2020) used machine learning techniques to classify profiles from the Indian Ocean sector of the Southern Ocean based on the vertical distribution of properties. The classification was then used to sort profiles into common groups. The grouping reproduced the expected frontal zone structure, but also showed significant differences with position relative to the Kerguelen Plateau. Such machine learning techniques will play an increasing role in studies of the growing SOCCOM dataset.

An immediate challenge for the SOCCOM system is sustaining the observations long enough to detect the effects of climate variability on biogeochemical processes. The time scales for detection of climate driven changes in biogeochemical cycles are typically greater than 15 years and often multiple decades (Henson et al., 2010; 2016; Schlunegger et al., 2020). The SOCCOM project has clearly established the capability to observe major elements of ocean biogeochemical cycles and their spatial variability over seasonal and internannual time scales (Bushinsky et al., 2017, 2019a; Johnson et al., 2017a, 2022; Gray et al., 2018; Arteaga et al., 2019; Prend et al., 2022a,b; Mazloff et al., 2023). However, with records that are typically less than 10 years in length, it is not yet reasonable to expect climate driven change to be detected unless float data is merged with prior, ship-based observations (Bronselaer et al., 2020; Mazloff et al., 2023). As the SOCCOM array operations are extended it will be critical to demonstrate that the data collected from profiling floats retain long-term consistency and can be used to directly detect climate driven change. Sustaining such a record will be a major challenge.

As the ocean warms (Roemmich et al., 2015, Cheng et al, 2022), it is likely that changes in primary productivity will result (Boyd et al., 2014) with significant effects throughout the ecosystem (IPCC, 2019). "Greening" of the Southern Ocean, quantified as an increase in chlorophyll detected by remote sensing (Del Castillo et al., 2019), has been suggested to result from warming. An enhanced focus on ecosystem properties, through bio-optical observations, is necessitated by these changes. Future SOCCOM efforts will continue to incorporate bio-optical sensors for both chlorophyll and optical backscatter, as well as adding downwelling irradiance. Each of these parameters provides information on changing biomass and phenology. A sustained array of these observations will provide a novel view of ecosystem change in the Southern Ocean.

Irradiance has not previously been a focus of SOCCOM. The radiometer, which is used to measure downwelling irradiance, will provide a scientifically valuable addition to the SOCCOM suite of measurements. The intensity of incident solar radiation varies substantially over the annual cycle in the Southern Ocean. In ice covered waters, there is considerable interest in the light level that enables the onset of the spring bloom (Horvat et al., 2022). The attenuation of downwelling irradiance is also a useful measure of integrated chlorophyll stocks (Xing et al., 2011). The combination of irradiance and chlorophyll fluorescence can be used to assess nutrient stress in phytoplankton (Schallenberg et al., 2022). The depth dependence of light attenuation also provides important insight into upper ocean heating (Ohlmann et al., 1996). Adding radiometers to the floats deployed in SOCCOM should provide valuable information on these issues across all zones of the Southern Ocean. Within a few years, most SOCCOM floats will carry radiometers, in addition to the five BGC sensors now carried. The addition of more advanced bio-optics, such as Underwater Vision Profilers (Picheral et al., 2022) and hyperspectral radiometers (Organelli et al., 2021), are being tested on profiling floats. These instruments provide additional capabilities for assessing higher trophic levels or plankton functional groups.

The SOCCOM project was explicitly designed as a program to examine the physical and chemical properties of the Southern Ocean at sites with depths in excess of 2000 m. Nearly all SOCCOM and Argo floats deployed to date in the Southern Ocean have adhered to this constraint. The program has the opportunity to expand these goals and objectives as a second renewal proposal is prepared. One of these future objectives is to expand the array into shallower, ice covered waters typical of the very highest latitudes in the Ross Sea, a core part of the Ross Sea Marine Protected Area (MPA). Buoyancy driven gliders are frequently deployed in this region (Jones and Smith, 2017; Kaufman et al., 2014; Meyer et al., 2022) and have provided valuable information on biological process including bloom dynamics and carbon export. However, glider deployments are generally limited to a few months, which requires ships to deploy and recover them. That presents significant logistical challenges if observations are to be sustained. Gliders also have carried a limited suite of sensors, typically bio-optics and oxygen sensors. While Argo floats are generally not intended to operate at depths less than 2000 m, eight UW-produced Argo floats were deployed on the Ross Sea shelf in a region less than 500 m deep late in 2013 (Porter et al., 2019). The float technology and ice-avoidance software proved to be robust, with seven of the floats continuing to operate on the shelf for 4 years or more. The resulting data yielded a unique view of the heat and freshwater budgets on the Antarctic continental shelf over an extended period of time, including new information on the contribution of land-based ice to these budgets (Porter et al., 2019).

These shallow, Ross Sea float deployments open the window for sustained, year-round profiling float operations in waters that had been accessible only in summer. They have led to questions of what such floats might observe if they were equipped with a full BGC sensor suite. In order to investigate the biogeochemical processes in this shelf region, and their links to the physical characteristics of the site, SOCCOM has deployed a set of 5 floats in the same region studied by Porter et al. (2019) that are equipped with O_2, NO_3, pH, Chl, and backscatter sensors, as well as a standard CTD. While both SOCCOM and GO-BGC are intended to be deep water observation networks, the continental shelf around the Antarctic continent is a unique region, where local water mass formation and carbon fluxes may have global implications. Thus, we hope to be able to observe these processes on the Ross Shelf in the near future using profiling float technology. Operation of floats in these shallow waters will provide a unique view into ecosystems, as there are few observations made year around.

The measurements in shallow waters of the Ross Sea MPA will support the UN Southern Ocean Report goal:

- *Ensure science-based and effective MPAs and uphold sustainable fisheries management.*

7. Conclusions

7.1. Lessons learned in operating a basin-scale array

Early planning for BGC-Argo, sponsored by the US Ocean Carbon and Biogeochemistry program, found that deployment of a regional profiling float array would be the next step towards a global system (Johnson et al., 2009). This regional project needed to demonstrate three essential capabilities. The float sensors had to generate "climate-research-quality" data. The system would have to be capable of inter-operating with other components of the ocean observing system including satellites, ships, and data-assimilating models. There had to be an integrated data management system operating in real-time. The SOCCOM project became an early model for this regional system. Along the way, a number of valuable lessons were learned about the effort to go to regional and then global arrays.

Lesson 1: Expanding operations involves many risks that do not manifest themselves until the expansion is well underway. A comment frequently made to SOCCOM personnel about the goal of expanding BGC-Argo to a much larger array was not to start until all aspects were ready. As practical as that advice seems, one cannot assess whether one is ready until the regional, and then global, arrays are built and relatively large numbers of sensors are deployed. For example, as a project transitions from small scale operations to something more akin to mass production a variety of new issues arise. Instruments that were hand built by the engineers and scientists who designed them must now be assembled by a less experienced production team. Inevitable miscommunications in construction of the platforms and sensors will arise with a detrimental effect on operations. When that is combined with an increasing demand for hardware to meet frequent cruise dates and data expectations from users, there will be system failures.

Lesson 2: Systemic failures will occur and vigilant monitoring of an expanding array is required to detect such failures as early as possible. Even in mature programs such as Core-Argo, very small manufacturing changes have resulted in widespread system failures in mature components such as pressure sensors (Barker et al., 2011; Wong et al., 2020) and salinity sensors (Wong et al., 2020). These systemic failures typically span multiple years before they are identified, understood, re-engineered, and then upgraded float deployments are resumed. In the case of pH sensors manufactured at MBARI, a modest manufacturing change resulted in widespread failures of pH sensors deployed in both 2017 and 2018, which illustrates the time scale of these problems. An unrelated problem is now affecting pH sensors manufactured at Sea-Bird Scientific. The extent of real-time monitoring and assessment of system operation which was required was a somewhat unexpected task. If the expectation is that such problems must be cured before basin to global-scale arrays are deployed, then no large scale system would be built.

Lesson 3: A rigorous approach to sensor data validation in the field is an extremely valuable contribution to program success. Much of the success in SOCCOM has resulted because of efforts such as collecting high quality hydrographic data to validate sensor performance (Section 2.6.1). These efforts also identified early sensor performance issues (Johnson et al., 2017b). The validation data guided our development of data adjustment procedures. Such efforts are essential to demonstrate the long-term stability of data.

Lesson 4: The cheapest way to obtain more high quality data is to transfer knowledge to the community. As lessons are learned while scaling up production and data processing, a very effective way to multiply this effort is to transfer that understanding as broadly and quickly as possible. In SOCCOM, several software tools, SAGE (SOCCOM Assessment and Graphical Evaluation) and SAGE-O2 were developed to streamline the quality control of nitrate and pH, and oxygen, respectively (Maurer et al., 2021). These tools are open source and they are now widely used in the BGC-Argo system. This contributes to the amount of high quality data available for research.

In parallel with this effort, a large amount of BGC-Argo data remained in the raw state at the start of SOCCOM without quality control or adjustments. Quality control of data in the Argo system is the responsibility of the principal investigator that deploys the float. However, Argo Data Assembly Centers set up to process Core-Argo temperature and salinity data may not have the complete expertise to quality control biogeochemical data. To mitigate this problem, SOCCOM developed the Argo Oxygen Audit. This program surveys all of the BGC-Argo data, performs an automated assessment of the consistency of the data through several metrics, computes sensor gain correction factors, and then reports these results to each Argo Data Assembly Center. This audit is performed 2 to 3 times per year. It has resulted in an increase in the percentage of quality controlled Argo oxygen data (Argo Adjusted Mode or Argo Delayed Mode data types) from 35% in 2019 to a value of 91% today.

Lesson 5: Expect the unexpected and have a strong management structure to enable rapid solutions. While the SOCCOM project could not anticipate an event such as the Covid-19 pandemic, they seem to find the program. Sole source components for instruments will become unavailable, requiring rushed research and engineering to find alternatives. Cruises will be canceled due to medical or engineering issues on ships. The SOCCOM Executive Team met weekly using remote video platforms from the beginning of the project. These meetings facilitated early recognition of unexpected events and the rapid development of solutions. The management structure helped prevent these problems from becoming frustrations.

7.2. Did SOCCOM meet its goals?

After nine years of operation, the SOCCOM project has established the observing system that was outlined in the initial proposal. Over 260 floats have been deployed. Thousands of profiles have been collected (Table 2) in all regions of the Southern Ocean (Fig. 4). The sensor data have been quality controlled, and made freely available (Maurer et al., 2021). These data extend observations in the Southern Ocean, particularly in the seasonal ice zone, throughout the year. A data-assimilating Biogeochemical Southern Ocean State Estimate has been developed and is now routinely assimilating SOCCOM profiling float data, as well as data from an array of other sources (Verdy and Mazloff, 2017). Insights from the profiling float data and B-SOSE have been used to understand factors that limit the performance of coupled climate models (Beadling et al., 2020, 2020; Bronselaer et al., 2018, 2020).

The profiling float data have been applied to studies of carbon, oxygen, and nitrate cycling, as well as a variety of ecosystem processes throughout the Southern Ocean and over complete annual cycles. More than 170 peer-reviewed papers acknowledge funding from the SOCCOM project. Dozens of papers have been written by scientists outside of the SOCCOM project using data generated by profiling floats of the SOCCOM array, as well as the products of the B-SOSE model. The access by scientists outside of the project demonstrates both the facile access to data and the confidence that the community has in this resource.

The SOCCOM array, and BGC-Argo (Claustre et al., 2020) in general, have demonstrated the robustness of autonomous observations during the height of a global pandemic. The onset of the Covid-19 pandemic led to a suspension of research ship operations in March of 2020. This included cancelation of the GO-SHIP A13.5 cruise, for which SOCCOM floats had already been shipped. Thus, float deployments were directly affected. However, the array of deployed robotic profiling floats continued to collect data (Boyer et al., 2023). The year 2020 will have few biogeochemical ocean records collected from ships. In comparison, there were 19,235 such oxygen profiles collected by all BGC-Argo floats in 2020.

While 2020 was an extraordinary year due to Covid-19, there is a continuing, downward trend over time in biogeochemical observations of essential ocean variables, such as oxygen, that are being reported from ships. Robotic observing systems are required to offset the lack of shipboard data, and the SOCCOM array demonstrates that such arrays can operate at the extent of an ocean basin. Operation of systems such as SOCCOM are an essential tool for observation of change in the ocean interior. Sustaining the operation of this system will be necessary to observe ocean change driven by climate processes.

In summary, SOCCOM has made very significant progress towards its very aspirational goals:

- Goal 1: Quantify and understand the role of all regions of the Southern Ocean in carbon cycling, acidification, nutrient cycling including oxygen, and heat uptake, on seasonal, interannual, and longer time scales.
- Goal 2: Develop the scientific basis for projecting the contribution of the Southern Ocean to the future trajectory of carbon, acidification, nutrient cycling, and heat uptake.

The project has met its three primary objectives to: generate climate research quality data, develop a system capable of inter-operating with the broader ocean observing system, and develop a data system that delivered science quality data in real-time. However, fully achieving the SOCCOM goals will require operating the system for longer periods of time to observe and quantify the emerging, climate driven signals that are expected.

The features of the SOCCOM system clearly address many of the priorities outlined in the UN Southern Ocean Report. While that report was largely aspirational, the SOCCOM project demonstrates that the development of comprehensive observing systems is possible. SOCCOM can stand as a model for observing systems in other basin-scale, sustained ocean observing systems.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Data availability

All data sources are identified in the manuscript

Acknowledgements

The Southern Ocean Carbon and Climate Observations and Modeling (SOCCOM) Project is funded by the National Science Foundation, Division of Polar Programs (NSF PLR-1425989 and OPP-1936222), supplemented by NOAA Grant NA20OAR4320271, NASA Grant NNX14AP49G, and by the International Argo Program and the national programs that contribute to it (http://www.argo.ucsd.edu, http://argo.jcommops.org). The Argo Program is part of the Global Ocean Observing System. Work at MBARI is also supported by the David and Lucile Packard Foundation. We thank all of the personnel who have contributed to the construction of the profiling float array and data system, personnel who have assisted at sea in deployments, and the captains and crew of the vessels that have deployed these floats.

Data Availability

All profiling float data generated by the SOCCOM project are available in a permanent archive at the University of California San Diego digital library with a digital object identifier (10.6075/J0TX3C9X). The archive is updated approximately three times each year. The real-time, quality controlled data are also uploaded, typically within 24 hours of receipt, to the Argo data system where they are available from the Argo Global Data Assembly Centers. See https://argo.ucsd.edu/data/ for a description of the Argo data system. In addition, real-time data with added data products such as computed total alkalinity, dissolved inorganic carbon and pCO2 are available from ftp://ftp.mbari.org/pub/SOCCOM/FloatVizData/.

Shipboard observations made to validate SOCCOM float deployments are available from the CLIVAR and Carbon Hydrographic Data Office (CCHDO; https://cchdo.ucsd.edu) by searching on the keyword SOCCOM.

B-SOSE model output is available from http://sose.ucsd.edu.

ABSTRACT

During summer, distinctive, bottom-trapped, cold water mass of remnant local and remote winter water called Cold Pool Water (CPW) resides as a swath over the mid to outer continental shelf throughout much of the Mid-Atlantic Bight (MAB). This evolving CPW is important because it strongly influences the ecosystem, including several important fisheries. Thus, there is a priority to better understand the relevant ocean processes and develop CPW forecast capability. Over the past decade, repeated high-resolution Slocum glider measurements of ocean water properties along a New Jersey cross-shelf transect have helped to define the variability of the CPW structure off New Jersey. More recently the Mid-Atlantic Regional Association Coastal Ocean Observing System-supported ocean gliders have occupied a series of along-shelf zigzag trajectories from Massachusetts to New Jersey and New Jersey to Maryland. The comprehensive set of March through November 2007 glider measurements has been used to define the annual evolution of the 10 °C Cold Pool in terms of its distribution and water properties. The rather steady warming at the rate of 1 °C per month July through October 2007 is reflected in the 2007 CPW temperature (T) and salinity (S) properties. We describe how a three-glider fleet view of the September 2013 Cold Pool (a) confirmed the Lentz (2017) CPW cold patch and (b) the impingement of a Gulf Stream warm core ring warmed and salted the 2013 CPW. The Gulf Sream 2013 event forced our extension of the CPW T and S properties.

1. Introduction

The Cold Pool is a distinctive, highly-variable, bottom-trapped, cold water mass remnant of the local and remote winter water. It is found during summer over the mid and outer continental shelf between Cape Cod and Cape Hatteras – a region known as the Mid-Atlantic Bight (MAB).

The Cold Pool is an important element in the MAB habitat according to Malone et al. (1983) and Flagg et al. (1994), who have shown that it affects phytoplankton productivity; and Sullivan et al. (2005) and Weinberg (2005) who have shown that it affects the behavior and recruitment of pelagic and demersal fish on the shelf.

The distribution and characteristics of this Cold Pool water mass evolves significantly during its May through October lifetime (Ketchum and Corwin, 1964; Boicourt and Hacker, 1976; Beardsley et al., 1976; Beardsley and Boicourt, 1981). Lentz (2003) present the annual evolution of a MAB-averaged cross-shelf section of the climatological temperature. This sequence shows that well-mixed winter shelf waters cool between January and March. The May section shows how the vernal onset of temperature- and fresh water-induced stratification creates a bottom-trapped, Cold Pool water mass with minimum temperatures dependent on the severity of the previous winter's local cooling.

Once formed, this distinctive Cold Pool goes through a complex evolution during the rest of the spring and throughout the summer. For example, during May–June the northeastern MAB Cold Pool gets colder due to continued inflow of winter water from the Gulf of Maine/Georges Bank (GoM/GB) region (Brown and Irish, 1993; Hopkins and Garfield, 1979; Ramp et al., 1988). The Lentz (2017) map of the NMFS May 1979 data reveals a patch of the coldest waters (or *"cold patch"*) within the Cold Pool. Ou and Houghton (1982) note that locations of the *"cold patch"* during the summer 1979 is consistent with the well-documented general 5 cm/s (~5 km/day) southwestward along-shelf MAB flow.

During the summer, the Cold Pool Water mass (CPW) is warmed by turbulent processes acting on its surface (Chen et al., 2014) and along its inshore boundary (Kohut et al., 2004). The CPW is also heated and salted by a complex array of turbulent processes along its offshore boundary which is the shelf-break front (SBF) (Houghton et al., 1982; 2010). Candidate

across-SBF exchange processes result in episodic warm/salty intrusions into CPW by way of the interior and bottom boundary layers (Linder et al., 2004). Interactions between Gulf Stream Warm Core Rings (WCR) and the SBF undoubtedly contribute to such exchanges.

The cooling of northeast MAB CPW ceases in July, which is followed by a general warming of all the still distinct Cold Pool through September (Lentz, 2017). Then during autumn (primarily in October), the inevitable energetic storms mix the MAB water column well enough to erase the distinctiveness the Cold Pool by November, when and the following year's annual Cold Pool evolution cycle begins anew.

The mysteries of the Cold Pool and its importance to the MAB ecosystem prompt us to seek answers regarding these erosion processes. Such answers are now within our reach because of the newly available technologies, including ocean gliders, remote high frequency radar-derived surface current mapping, modern data-assimilation coastal ocean numerical models, and the development of the Integrated Ocean Observing System (IOOS; Bassett et al., 2010) and the Ocean Observatory Initiative (OOI): Pioneer Array. This paper describes what we have learned about the MAB Cold Pool from primarily glider observations.

2. Measuring the Cold Pool

Rutgers University researchers began deploying Teledyne/Webb Research (TWR) Slocum ocean gliders on the Mid-Atlantic Bight shelf in 2003 (Schofield et al., 2010). This earlier effort evolved into the effort of the Mid Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) to deploy ongoing series of Slocum glider missions along a (a) cross-shelf transect off New Jersey called the Endurance Line (Fig. 1; Leg-6); (b) cross-shelf series of zigzags from Massachusetts to New Jersey in the northeastern part of MAB (NE-MAB; Legs 1–6); and (c) the southwestern part of MAB (SW-MAB; Legs 6–10) is series of cross-shelf zigzags from New Jersey to Maryland. The following description of the different phases of the Cold Pool is based primarily on glider measurements from the most extensive cross-shelf transects represented by Legs 1, 6, and 8, respectively.

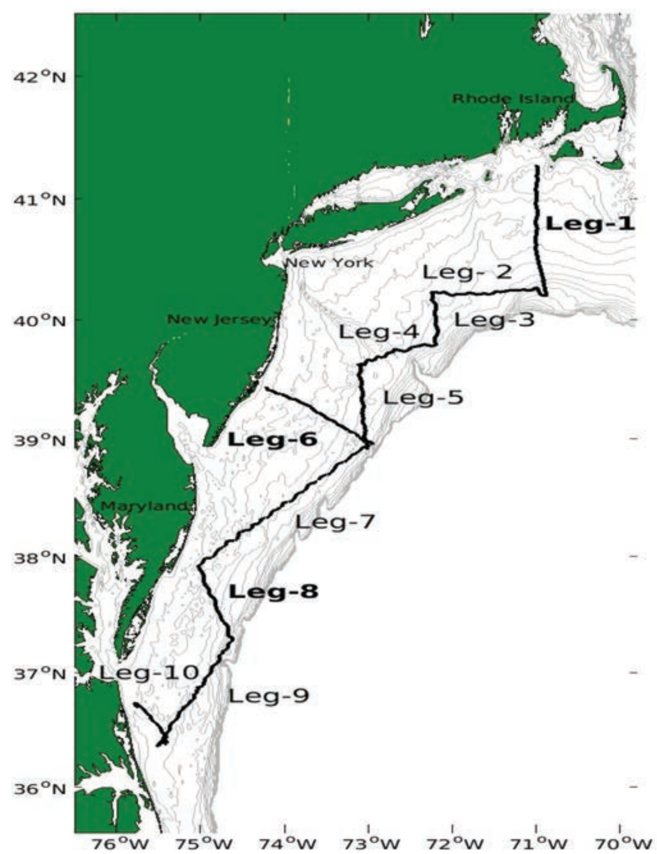

Fig. 1. The definition of the transect sections in this paper in terms of a composite of the May 2007 glider trajectory in the northeastern MAB (NE-MAB; Legs 1–6) and July 2007 in the southwestern MAB (SW-MAB; Legs 6–10). Leg-1, Leg-6 and Leg-8 are emboldened. Some of the MAB states are identified.

The Slocum glider sawtooths its way through the ocean (Schofield et al., 2010) with an average horizontal speed of about 0.25 m/s (½ kt.). A glider slant (27° rel. to horizontal) shelf profile consists of depths of about 3 m–3 m above the bottom. On the shelf, these Slocum gliders make about 20 sawtooth pairs of profiles in 3 h - our typical time between surfacings. We use the zigzag glider slices to estimate the extent and properties of the MAB Cold Pool during each of the glider missions. A typical zigzag run takes a typical 100 m Slocum glider (at ~25 km/day) about 3–4 weeks to transit from Massachusetts to New Jersey. All the gliders considered here measured a standard suite of measurements including pressure (P), temperature (T), pumped conductivity (C) (or derived salinity S), and an estimated glider inter-surfacing segment-averaged ocean velocity (V).

2.1. Pre-cold pool – Late Winter/Early Spring

The glider measurements between 13 March and 12 April 2007 define the MAB winter water mass, which is the basis for the 2007 Cold Pool Water (CPW). The cross-self glider transects show the expected vertically well-mixed "winter water". Leg-1 south of Massachusetts exhibits the coldest transect minimum temperature (T_{min}) at 2.87 °C (Table 1). The salinity at the Leg-1 T_{min} (S_{Tmin}) is 32.80 Practical Salinity Units (psu; see Appendix A for the way to covert those psu salinities into the more modern Absolute Salinity S_A). The Leg-6 transect off New Jersey is somewhat warmer with a T_{min} at 4.94 °C and saltier with a S_{Tmin} at 33.08 psu than the Leg-1 counterparts. The individual transect temperature minima T_{min} is a good proxy for the properties and location of the *core of the Cold Pool* of that section.

2.2. Proto-cold pool – Mid-Spring

Vernal warming of the MAB upper layer leads to the first definition of the 2007 Cold Pool off of New Jersey. This is shown by the 13–19 May 2007 Leg-6 glider measurements (Fig. 2) which contrast with the Leg-1 still well-mixed structure. However, both transect T_{min}s have warmed relative to the March T_{min}s. The along-shelf gradients in the Leg-1 versus Leg-6 water properties are typical of what we see even after the development of 2007 Cold Pool throughout the MAB as presented next.

2.3. Cold pool 2007 established – Spring 2007

The 23–27 May 2007 glider measurements (Fig. 3) show a surface layer that has warmed and freshened enough to isolate and thus define the 2007 Cold Pool Water throughout the MAB. However, note that T_{min} in both transects is somewhat cooler than that seen in April (and thus throughout the MAB). The along-MAB temperature gradients, with the Leg-6 waters generally warmer than the Leg-1 waters at corresponding depths define the cold patch in the northeastern MAB. We speculate that the cooler temperatures are due to the inflow of colder "upstream" waters from the Gulf of Maine/Georges Bank region.

2.4. Cold pool – Summer 2007

The 18–24 July Leg-6 reveals an increasingly distinct Cold Pool with a transect T_{min} of 5.60 °C (Fig. 4-upper). It compares well with the 11–15 June Leg-6 T_{min} of 5.32 °C (Fig. 3) and consistent with the expected translation of the temperature minimum patch. The 18–24 July Leg-6 S_{Tmin} compares well with the 11–15 June Leg-6 S_{Tmin} (Table 1) being only about 0.3 psu greater than its Leg-1 counterpart. The salinity difference is likely the signature of intrusion(s) of high salinity/warmer

Table 1
The 2007 section-minimum temperatures T_{min} and associated salinities S_{Tmin} are presented for a representative set of sections. For sub-thermocline waters ($T < 10$ °C), the means and standard deviations of *temperature departures* ($T_D = T - T_{min}$) and associated *salinity departures* ($S_D = S - S_{Tmin}$) are presented.

(The missing data is due to our glider piloting, while crossing the east-west New York shipping lanes.)

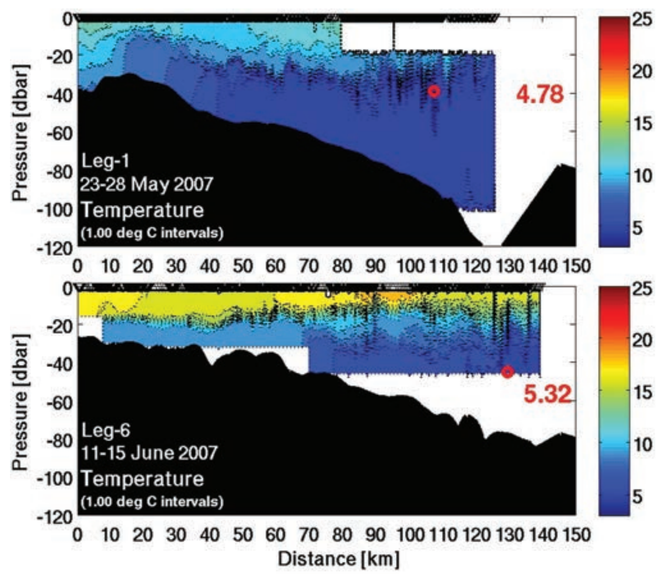

Fig. 3. NE-*MAB* COLD POOL 2007: *Spring*. The 23 May–15 June 2007 *glider RU17 (upper)* Leg-1 temperature section, with section-minimum temperatures indicated (red), and *(lower)* the same for Leg-6, with temperature (°C) legends to the right.

water intrusion across the shelf-break front. Repeated intrusions such as this are thought to be one of the mechanisms that warms/salts the seaward extremes of the Cold Pool during the summer (Gawarkiewiz et al., 2018). The strong vertical stratification with its downward intrusions (Fig. 4-lower) appears to be supporting a strong internal tide. Spatial glider measurements of the internal tide will always be aliased.

2.5. Cold pool – Autumn 2007

Glider measurements in the northeast MAB (Fig. 5) and southwest MAB (Fig. 6) define a still distinct Cold Pool that is even warmer than summer Cold Pool. The warming of T_{min} continues into late autumn (Fig. 7; Table 1); presumably by atmospheric cooling-induced mixing of the water column of the warm upper and cool lower layers. The winter cooling (to come) is forecast by the Leg-6 T_{min}, which in the New Jersey inshore.

There is mid-December evidence (Fig. 7) of the water column is beginning to cool. These measurements capture the beginning of the winter 2007–08 cooling phase of the MAB waters. After more atmospheric cooling of the coastal ocean in January through March, that water mass becomes part of the 2008 Cold Pool.

3. An evolving Cold Pool

This 2007 series of zigzag glider runs provide the most complete view of an annual realization of a clearly evolving MAB Cold Pool to date. With this high-resolution picture of an evolving Cold Pool, we now focus on the more complete set of Cold Pool water mass properties and their evolution. The *thermal cores* of the 2007 Cold Pool for both summer

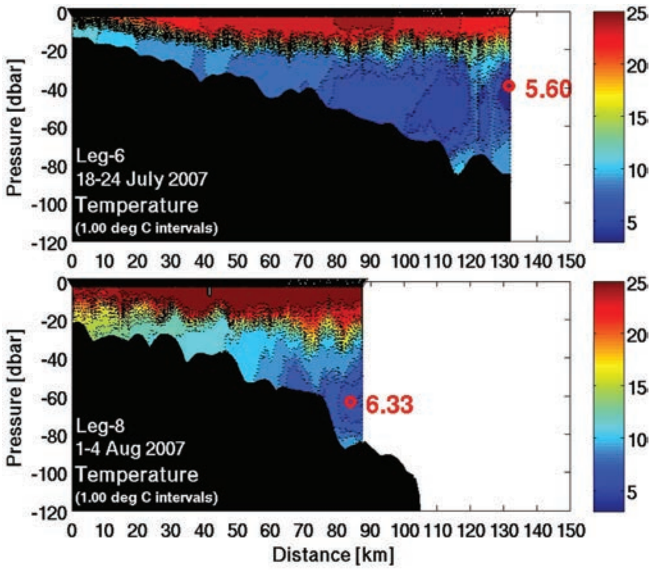

Fig. 4. *SW-MAB* COLD POOL 2007: *Summer*. The 18 July–4 August 2007 *glider RU01 (upper)* Leg-6 temperature section, with section-minimum temperatures indicated (red), and *(lower)* the same for Leg-8, with temperature (°C) legends to the right.

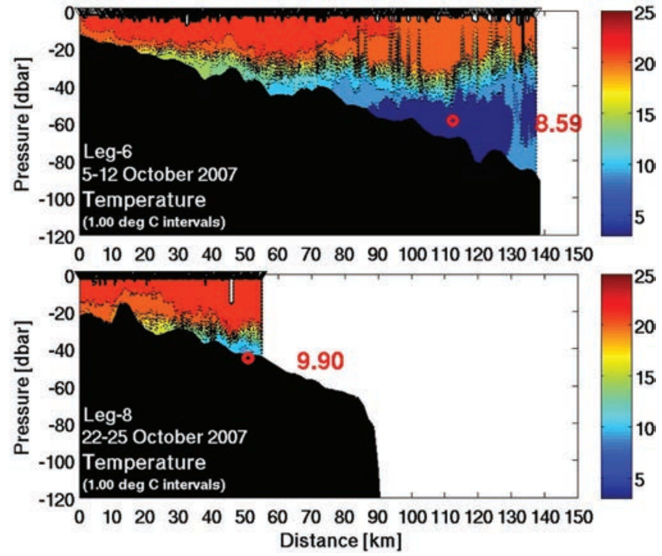

Fig. 6. *SW-MAB* COLD POOL 2007: *Autumn*. The 7–26 October 2007 *glider RU06 (upper)* Leg-6 temperature section, with section-minimum temperatures indicated (red), and *(lower)* the same for Leg-8, with temperature (°C) legends to the right.

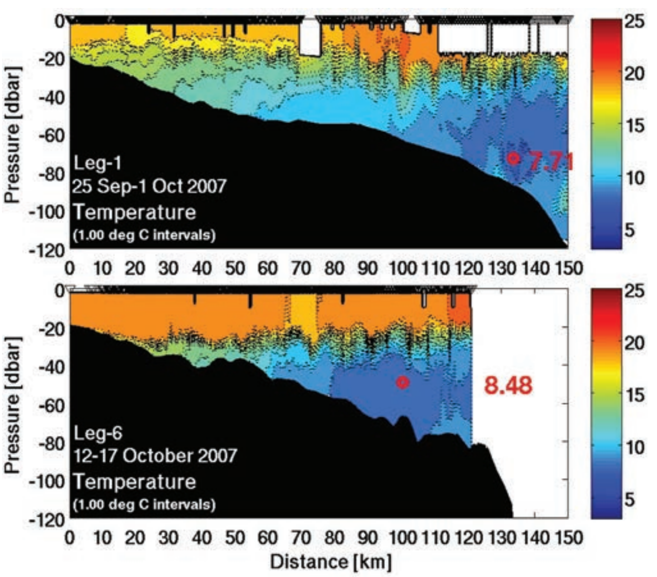

Fig. 5. *NE-MAB* COLD POOL 2007: *Autumn*. The 25 September–17 October 2007 *glider RU05 (upper)* Leg-1 temperature section, with section-minimum temperatures indicated (red), and *(lower)* the same for Leg-6, with temperature (°C) legends to the right.

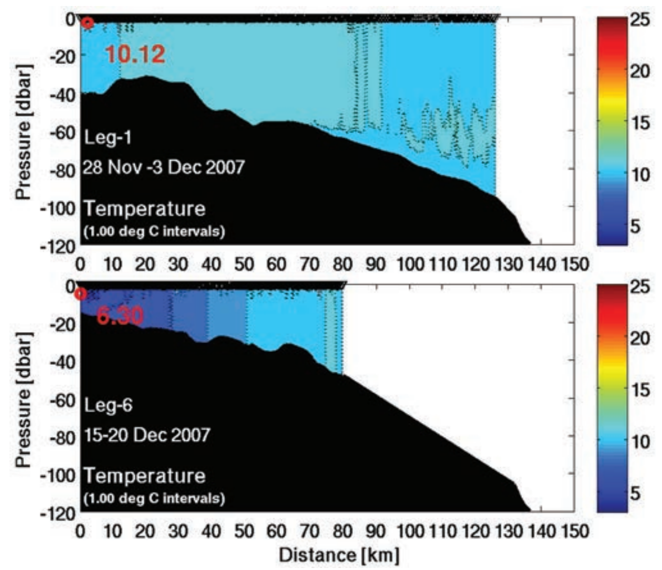

Fig. 7. NE-COLD POOL 2007: *Late Autumn*. The 28 Nov.–20 Dec. 2007*glider RU01 (upper)* Leg-1 temperature section, with section-minimum temperatures indicated (red), and *(lower)* the same for Leg-6, with temperature (°C) legends to the right.

and autumn are defined by the section temperature minimums T_{min}s, as we can see in Figs. 8 and 9. The locations of the T_{min} show that the Cold Pool core is near, if not in the shelf-break front (SBF) during both seasons. Thus, the Cold Pool hydrography geostrophically supports the SBF jet, which are exemplified by some of the fastest along-shelf flows. The fact that T_{min}s are usually 10 m–20 m above the bottom is consistent with the location of the SBF jet. Thus, the SBF jet advects the outer part of the Cold Pool generally from northeast to southwest along the outer shelf.

The section minimum temperature T_{min} is an excellent proxy for the seasonal variability of Cold Pool temperature at different sections of the MAB. For example, the T_{min} of Leg-1 and Leg-6 (two of more complete cross-shelf transects) warmed between March and April 2007 (Table 1). This *warming phase* was followed during May by a dramatic cooling of the Leg-6 waters. The fact that the Legs-1 through −4 tends to support the Lentz (2017) argument that a cold patch centered on the Hudson Valley is responsible for this observation. Consequently, the substantial Leg-6 T_{min} minus Leg-1 T_{min} difference of 2.0 °C at the beginning of May decreased rapidly to 0.7 °C by mid-June. The 2007 Cold Pool was established throughout the MAB at this time.

In early July, the MAB-wide Cold Pool Waters (CPW) began to warm at about a rate of ~1 °C/month. Estimates of the warming rates highlight the contrast between the *Spring* (Apr–May) cooling and *Summer* (May–October) warming in the northeastern segment of the MAB (NE-MAB) Cold Pool. The summer warming of the MAB Cold Pool (Fig. 10) could be

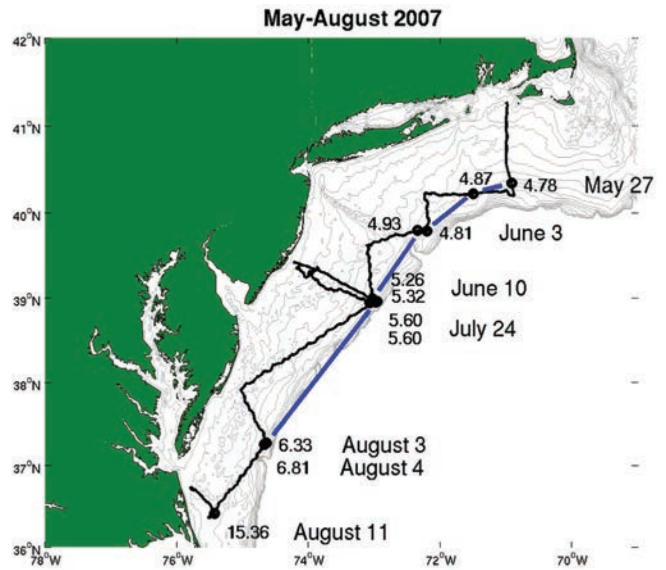

Fig. 8. The composite of the glider trajectories in the northeastern (NE) MAB *(RU17)* and the southwestern (SW) MAB *(RU01)* during the *summer* 2007. The section-minimum temperatures T_{min} (o) are highlighted by the blue line. The dates are located according to their alongshelf location of the gliders.

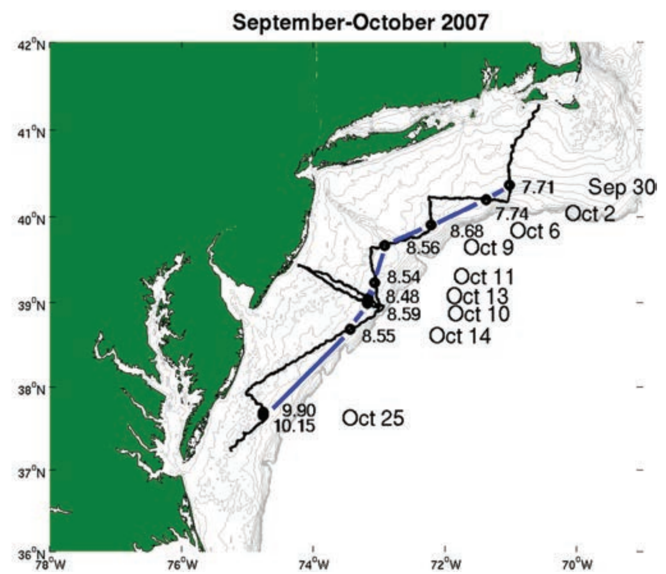

Fig. 9. The composite of the glider trajectories in *autumn* 2007: NE MAB *(RU05)* and SW MAB *(RU06)*. The section-minimum temperatures T_{min} (o) are highlighted by the blue line. The dates are located according to their alongshelf location of the gliders.

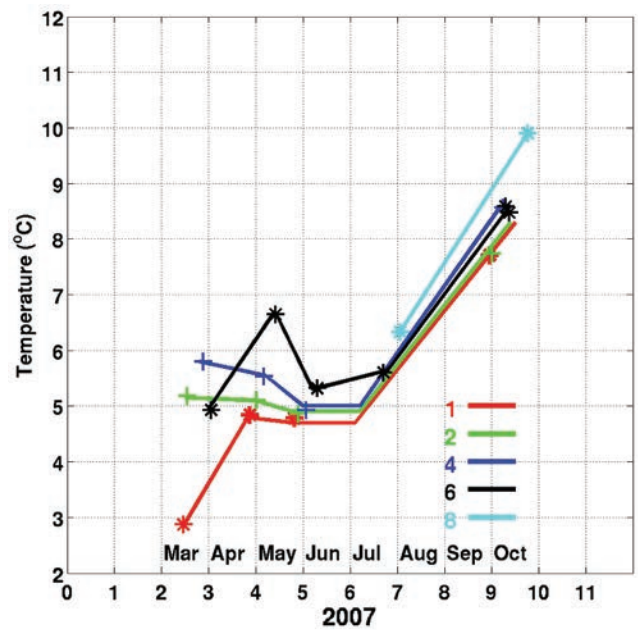

Fig. 10. The 2007 section-minimum temperature T_{min} versus time for Legs-1 (red *), 2 (green +), 4 (blue +), 6 (black *) and 8 (cyan *). Note that the Apr.–May 2007 cooling rates, which range from largest at Leg-6 and smallest at Leg-1, are followed by a shelf-wide average Jun.–Oct. 2007 warming rate of 1.05 °C/month.

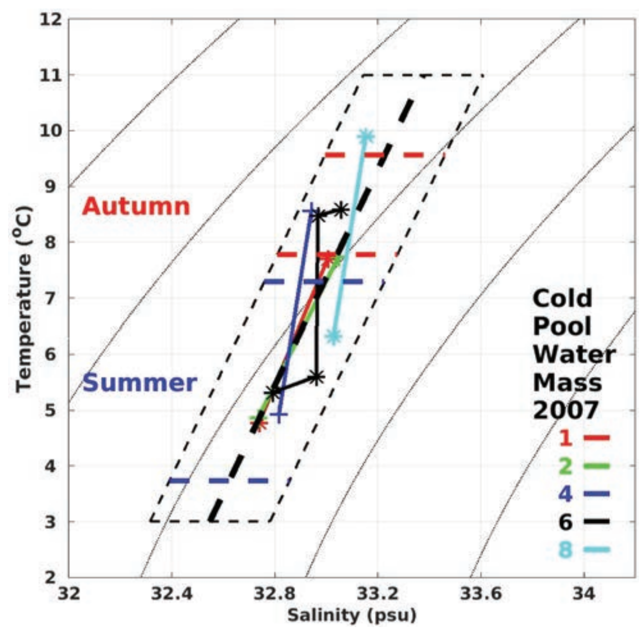

Fig. 11. A statistical definition of 2007 Cold Pool Water properties (CPW; black dashed trapezoid) is based on the average 2007 section T_{min}–S_{Tmin} relation (bold dashed line); which is a linear statistical fit to the May–October 2007 T_{min}/S_{Tmin} observations for the Legs-1 (red*), 2 (green+), 4 (blue+), 6 (black*), and 8 (cyan*). The trapezoid width is a constant $\pm$ S_D standard deviation (σ) of all sub-10 °C waters (see main text). The 2007 summer (blue dashed) and autumn (red dashed) CPW temperature bounds are shown.

due to several processes including turbulent transport of heat from the (a) surface layer above, (b) offshore waters beyond the shelf-break front (SBF), and (c) landward boundary via upwelling/downwelling exchange. The question of which of these processes dominate during the different phases of the Cold Pool evolution will be addressed below.

The 2007 T_{min}/S_{Tmin} are used to define the Cold Pool's TS water properties between 3 °C and 11 °C (Fig. 11) for several representative transects. A linear fit to the observed T_{min}/S_{Tmin} represents the average 2007 T_{min}–S_{Tmin} relationship (Fig. 11; bold dashed line). This T_{min}–S_{Tmin} relationship shows as the Cold Pool core waters warm their salinity increases. The trend toward higher temperatures during the summer could be due to the processes mentioned above. However, the trend of this T_{min}–S_{Tmin} relationship toward higher salinities is only consistent with exchange between the Cold Pool and Slope Sea water across the SBF.

Sub-thermocline Cold Pool water properties through mixing with other adjacent water masses (e.g., Slope Sea and MAB shelf waters). The extents of the Cold Pool Water properties on a specific transect T^t and S^t in Fig. 11 were determined by the statistics of their respective departure properties T_D/S_D computed according to:

$$T_D\ (x, s, z) = T^t\ (x, s, z) - T_{min}(s)$$

and

$$S_D\ (x, s, z) = S^t\ (x, s, z) - S_{Tmin}\ (s),$$

where T^t/S^t is any temperature/salinity pair in the transect with respect to T_{min} (s)/S_{Tmin} (s); "*x*" is an inshore coordinate referenced to the alongshore location of the "s" and "*z*" is upward.

Thus, for measured sub-thermocline water temperatures (<10 °C), we computed the departure of temperatures from T_{min} (T_D); and salinities from the corresponding S_{Tmin} (S_D). Note in Table 1 that the S_D standard deviations are virtually constant throughout the summer (1σ ~ 0.24 psu). That is the basis for the dashed lines on either side of the average T_{min}–S_{Tmin} relationship in Fig. 11. In contrast to the salinities, the T_D statistics are seasonal – reflecting the warming noted before. Thus, we use a average $T_{min} \pm T_D$ 1σ window to define the Cold Pool Water (CPW) mass in the region of a specific cross-shelf section with a specified T_{min}. Examples of the temperature boundaries ± 1σ relative the average T_{min} for the respective *summer* and *autumn 2007* are given in Fig. 11.

4. Cold Pool 2007 Water masses

A few glider measured-transects can be used to define the seasonal cycle of the bathymetric extent of properties of the 2007 MAB Cold Pool. We determine the footprint of the of the *summer* 2007, sub-10 °C Cold Pool from a composite of measurements by (a) glider RU17 in the northeastern MAB during *late May-early June* and (b) glider RU01 in the southwestern MAB during *late July–early August*. The traditional approach in defining the Cold Pool extent is to use the 10 °C isotherm. Following this approach, we locate the inshore intersection of the 10 °C isotherm with the bottom – "the bottoming" – in each temperature section.

In addition, we built a model for estimating the Cold Pool volume. We wrote a Matlab program to estimate the Cold Pool (CP) volume using real estimated bathymetry. The inputs are the glider-measured/estimated geometry of the sub-10 °C (or sub-12 °C based glider missions) Cold Pool and the uniform-thickness warm layer above the Cold Pool. Then, we ran the estimation model, with a various warm layer thicknesses (based glider measurements) for the different cases. For each case, the CP volume mean ± one standard deviation are given.

4.1. *Summer 2007 Cold Pool: 10 °C isotherm*

Both the RU17 and the RU01 glider missions just did not go far enough offshore to pierce the Shelf-Break Front (SBF; Linder et al., 2004). However, the SBF hovers around the 100 m isobath, and contains the 10 °C isotherm. Therefore, we assume that the seaward boundary of the 2007 10 °C Cold Pool to coincides with 100 m isobath. We built a crude model to estimate the Cold Pool volume (4119 ± 9 km^3) and the bottom footprint of the *summer 2007 sub-10 °C Cold Pool* map (Fig. 12). The error involved with the assumption stated above was small.

4.2. *Autumn 2007 Cold Pool: 10 °C isotherm*

We construct a map of the *autumn 2007 sub-10 °C Cold* map (Fig. 13) following the above approach with the September/October 2007 glider RU05 and RU06 transects (see Brown et al., 2015). Note that gliders RU05 and RU06 occupied the New Jersey transect - Leg-6 - within a week of each other and measured very similar 10 °C isotherm bottoming locations and T_{min}s. The footprint of the *autumn 2007* Cold Pool is clearly smaller, about 3 °C warmer and 0.1 psu saltier than the *summer 2007 CPW*. The *autumn 2007* Cold Pool does not go inshore, as much as its *summer* counterpart. However, it does indicate an off-shelf escape

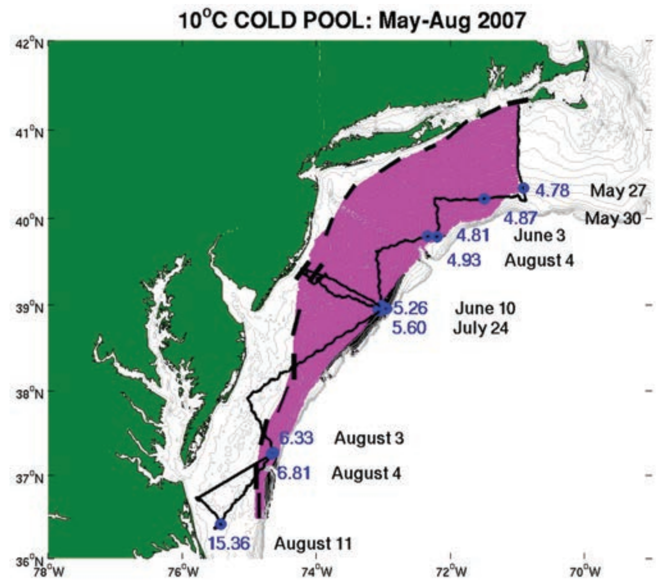

Fig. 12. The *summer* 2007, sub-10 °C Cold Pool Water (CPW) footprint (pink) is defined by *glider RU17/RU01* survey measurements. The section-minimum temperatures (blue o) – defining the Cold Pool core – are located. Estimated CPW Volume = 4119 ± 9 km^3.

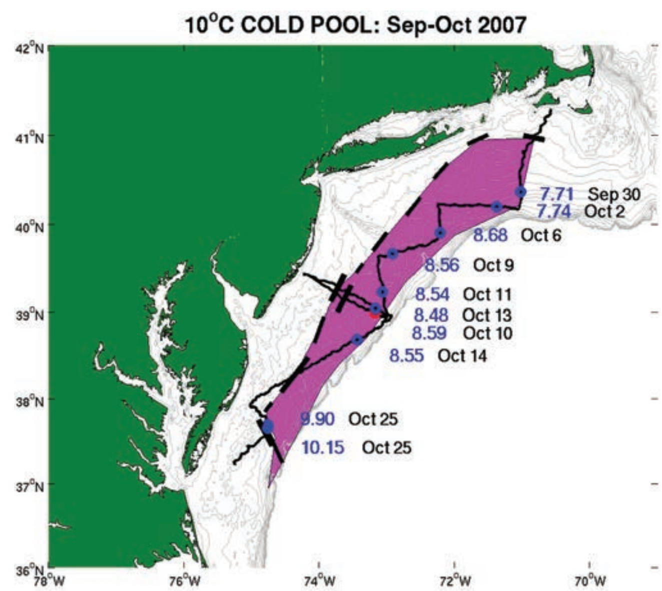

Fig. 13. The *autumn* 2007, sub-10 °C CPW footprint (pink) is defined by *glider RU05/RU06* survey measurements. The section-minimum temperatures (blue o) – defining the Cold Pool core – are located. Estimated CPW Volume = 2310 ± 45 km^3.

route offshore of the mouth of the Chesapeake Bay. We have assumed a uniform depth of 30 m for the thermocline, which contains the 10 °C isotherm and estimated the volume of the autumn 2007, sub-10 °C Cold Pool to be 2310 ± 45 km^3.

4.3. *September 2013 Cold Pool: 10 °C isotherm*

MARACOOS organized a 9-glider deployment consisting of glider operations all along the American coastal ocean between Nova Scotia and Florida – *GliderPalooza 2013*. We focus on a three-glider subset of missions in the Mid-Atlantic Bight (MAB) consisting of the almost simultaneous glider Blue, RU-23 and RU-22 missions (Fig. 14). The

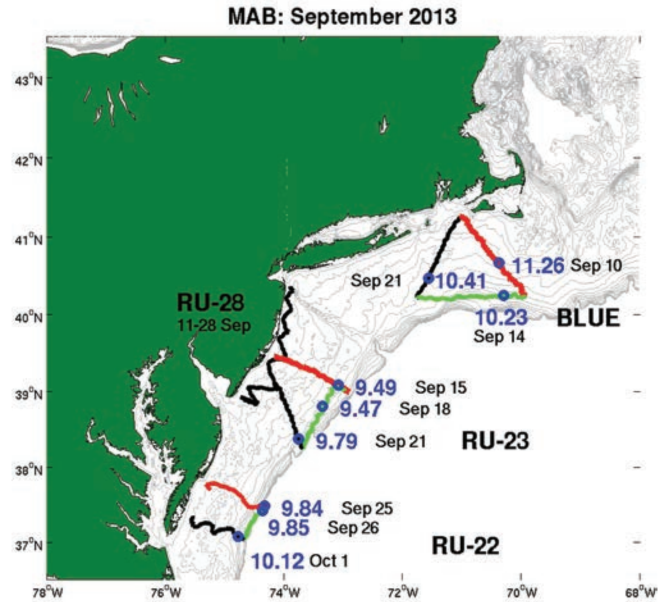

Fig. 14. The MAB trajectories of *gliders BLUE, RU-23, RU-22, and RU-28*. The glider Blue triangle in the Southern New England Bight consists of Legs-1 (red), -2 (green), and -3 (black); as was the *glider RU-23* trajectory off New Jersey (NJ); as was the *glider RU-22* trajectory east of Maryland (MD). The *glider RU-28* trajectory (blk), inside of the 30 m isobath, completed the triangle in the NJ region. The Leg-T_{min}/dates are indicated.

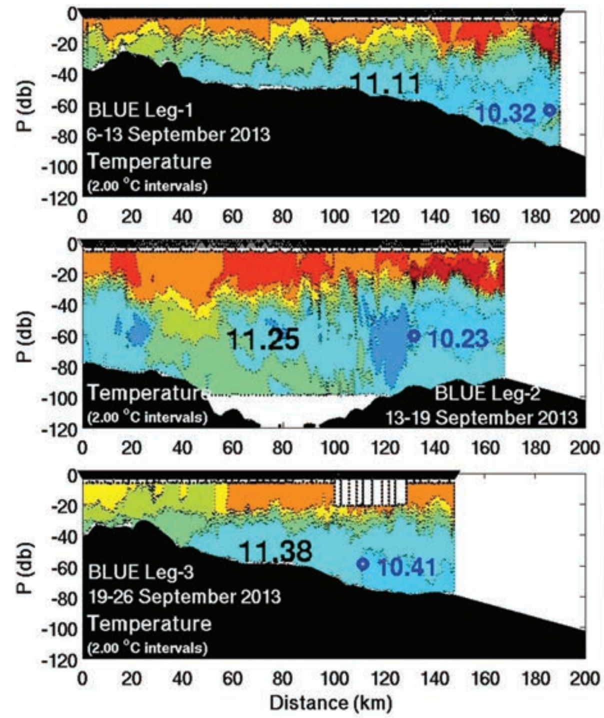

Fig. 15. Glider Blue's temperature (T°C) sections for *(upper)* Leg-1; *(middle)* Leg-2; and *(lower)* Leg-3 are presented. Section minimum temperatures T_{min} (blue) are located and the average lower-layer temperatures ≤12 °C (black) are indicated. The missing data in Leg-3's upper layer is because we restricted the glider's maximum depth to 17 db in the New York's east-west shipping lanes except for surfacing (lines).

September 2013 Cold Pool was warmer than the autumn 2007 Cold Pool.

Glider Blue's conducted its mission in the Southern New England Bight just south of Rhode Island (SNEB). The near-equilateral triangular trajectory sliced through the cold water (a redefined Cold Pool – see below) twice (Fig. 14). During glider Blue's east-west Leg-2 penetrated the shelf-break front (SBF) once. The middle panel of the three-leg display of glider Blue's contoured temperatures (Fig. 15) shows the measuring temperatures above 12 °C (green).

Almost simultaneously, glider RU23 penetrated beyond the SBF as it sliced through the Cold Pool twice (Fig. 15). This coldest patch of Cold Pool water in the New Jersey sector of the MAB. RU-28 patrolled the inner shelf in water depths less than 30 m along the NJ coast at the same time. These gliders also tested the hypothesis that triangular patterns are particularly effective for data-assimilation numerical modeling of MAB flow with a general 5 km/day southwestward flow.

A week or so later, glider RU22 was deployed at an inshore site off Maryland. RU22 sliced through the Cold Pool and SBF twice (with a non-triangular trajectory). Notice that the glider RU23 section minimum temperatures (Figs. 14 and 16) were clearly colder than those of either gliders Blue to the north and RU22 to the south.

The September 2013 glider Blue leg T_{min}s are greater than sub-10 °C (in the SNEB region of the MAB) were warmer than the 10 °C waters in September–October 2007. The gliders in the NJ and MD measured leg T_{min}s were sub-10 °C. So, the Sep.–Oct. 2013 sub-10 °C Cold Pool footprint (Fig. 17) is smaller than its autumn 2007 counterpart. The sub-10 °C CPW volume 1132 ± 47 km^3 is about half as much as the comparable Cold Pool volume in Sep.–Oct. 2007 (2310 ± 46 km^3).

We have concluded that the Cold Pool waters were being warmed by the cross-SBF mixing with the warmer/saltier waters of the Sep. 2013 Gulf Stream warm core ring (GS-WCR; Fig. 18). Gulf Stream water core rings influence the MAB in all seasons; systematically warming and salting Cold Pool properties.

The influence of the GS-WCR on the Cold Pool temperature prompted us to reconsider using a sub-10 °C definition for Cold Pool. Based on the observations described below, we expanded the "typical" Cold Pool

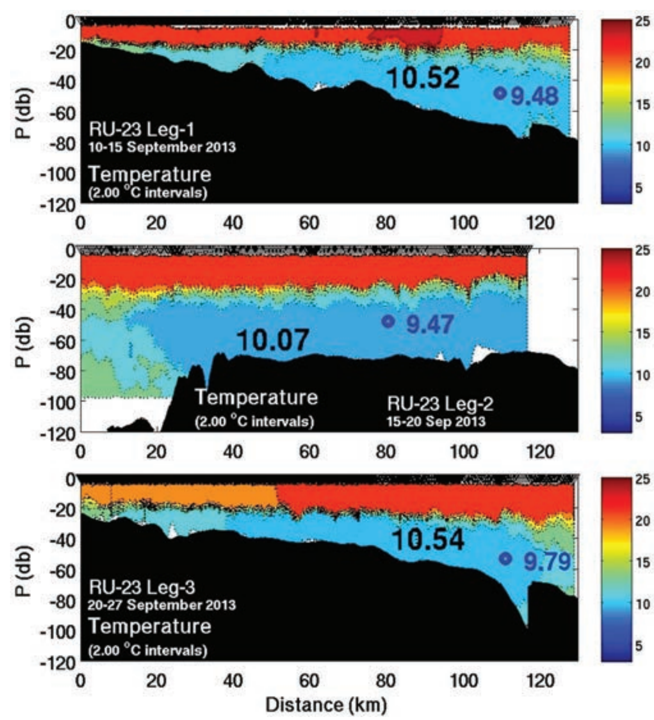

Fig. 16. Glider RU23's temperature (T°C) sections for *(upper)* Leg-1; *(middle)* Leg-2; and *(lower)* Leg-3 are presented. The blue lines at the ends of Legs1 & 2 mark "duplicate" sections. Section minimum temperatures T_{min} (blue) are located and the average lower-layer temperature T ≤ 12 °C (black) is indicated.

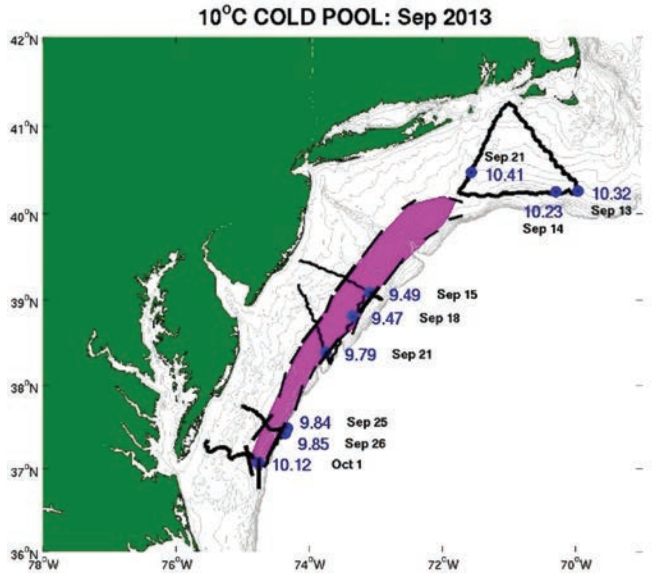

Fig. 17. The sub-10 °C MAB Cold Pool (pink) for September 2013 is defined by the trio of glider measurements: *glider Blue* in the northeast MAB, *glider RU23* in mid-shelf MAB and *glider RU22* in the southwest MAB. The section-minimum temperatures T_{min} (blue o) are located. *Estimated CPW Volume* = 1132 ± 47 km^3.

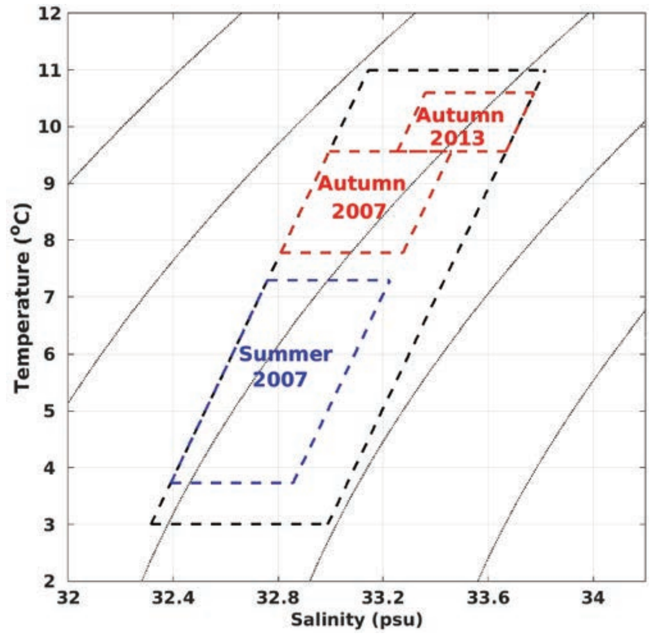

Fig. 19. The "global" definition of the Cold Pool water mass (blk dashed) includes seasonal sub-definitions: Spring/Summer 2007, Autumn 2007 and Autumn 2013.

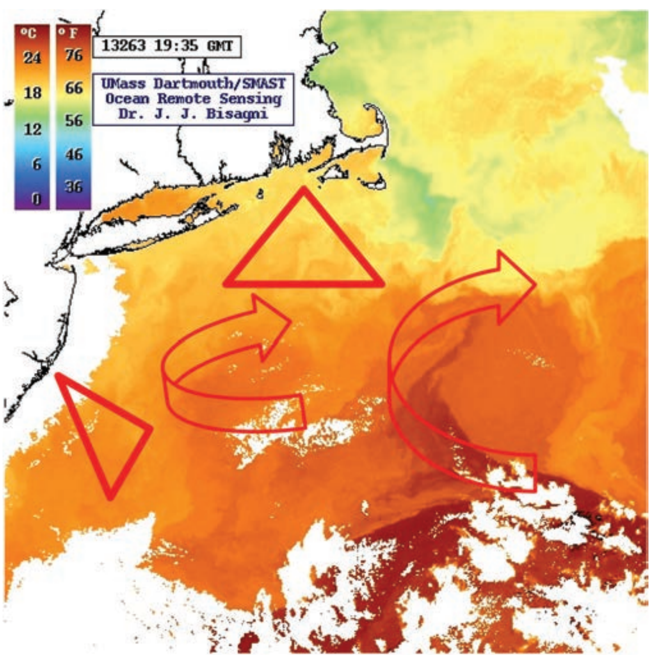

Fig. 18. A NOAA-18 AVHRR SST image of a warm ring and streamer that are influencing the MAB region on Sep. 20, 2013. The anti-cyclonic circulation around Gulf Stream warm core ring and streamer are indicated.

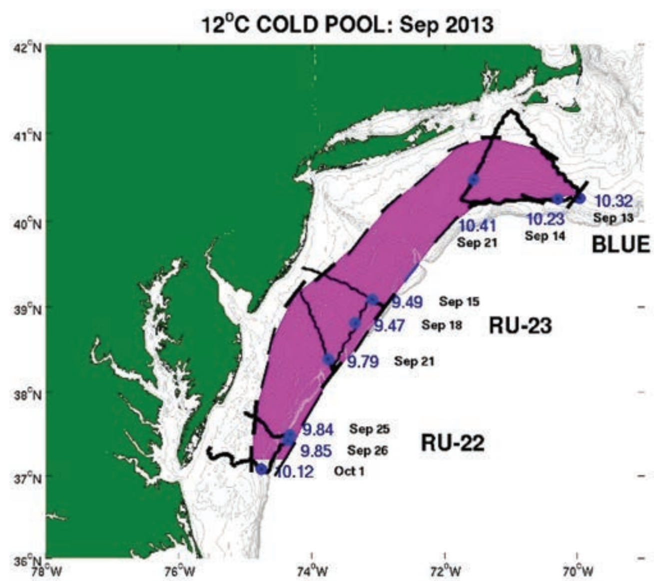

Fig. 20. The sub-12 °C MAB Cold Pool (pink) for September 2013 is defined by the trio of glider measurements: Blue (SNEB sector), RU23 (NJ sector) and RU22 (MD sector). The section-minimum temperatures T_{min} (blue o) are located.

water mass properties to higher salinities (Fig. 19). Rather we used a sub-12 °C definition for the CPW for the 2013 season. All MAB glider-derived temperature sections during Sep. 2013 displayed a distinctive sub-12 °C Cold Pool (Figs. 15 and 16). This sub-12 °C definition of CPW properties, allowed us to define the 2013 CPW mass shown in Fig. 20. The CPW "footprint" is shown in Fig. 20 is associated with an estimated the CPW mass volume to be 4109 ± 15 km^3.

Estimated CPW Volume = 4109 ± 15 km^3

The extent of the sub-12 °C CPW is shown in Fig. 20. Embolden short lines mark where the glider's measurements indicated the 12 °C isotherm intersected with bottom on the inshore end of the leg. The seaward end of the 12 °C isotherm is assumed to in the SBF, which is assumed to run along the 100 m isobath. The details for the SNEB (Blue), NJ (RU23) and MD (RU22) are presented next.

4.3.1. SNEB region

At the inshore end of glider Blue's Leg-1 temperature section (Fig. 15), the 12 °C isotherm intersects with the bottom near the 40 m isobath. Glider Blue measurements along Leg-2 indicate seaward end of the 12 °C isotherm extends 20–30 km beyond the shelf-break in the westward direction. At the Blue's Leg-2 near the western end, we see the Cold Pool water extension of Leg-3 and the signature (Fig. 15 -green) of the SBF at about 100 m isobath. Within the SBF, the 12 °C isotherm intersects with the bottom near the 85 m isobath. At the Leg-3 seaward end of glider Blue's Leg-2 section, the 12 °C isotherm intersects the bottom at 45 m.

4.3.2. NJ region

At the inshore end of Leg-1 temperature section (Fig. 16), the 12 °C isotherm intersects with the bottom near the 25 m isobath. Glider RU-23 did not go far enough to cross the SBF on Leg-1. Most of Leg-2 is less 80 m and the temperature data indicates the Cold Pool Water extends seaward. It is toward the southwestern end of Leg-2 that it deeper 80 m and the 12 °C isotherm in SBF intersects with the bottom near the 85 m isobath. At the seaward end of Leg-3, we also see the 12 °C isotherm in SBF intersects with the bottom near the 85 m isobath. At the inshore end of Leg-3 section, the 12 °C isotherm/bottom intersection occurs at a depth of about 30 m.

4.3.3. MD region

At the inshore ends of temperature sections of Leg-1 and Leg-3, the 12 °C isotherm with the bottom near the 35 m isobath (not shown). The seaward temperature data (not presented) is consistent with a at least part of the Cold Pool is leaving shelf here.

The September 2013 glider-measured water properties are consistent with our Cold Pool water mass definition. For both the SNEB and NJ regions, the T_{min} station T/S profiles intersect our Cold Pool water mass definition (Fig. 21). The SNEB/Blue region of the TS diagram suggests that the deepest Cold Pool waters mix with warm slope water (WSW). Also, the TS diagram information indicates that inshore water properties are strongly influenced by lateral mixing with Cold Pool waters (Fig. 21). These results suggest that a quantitative water mass analysis – beyond the scope of this effort – could lead to cross-SBF mixing rates.

5. Summary of results

A series of Slocum glider observation missions in 2007 and 2013 have been used to define the time-space variable Cold Pool between Cape Cod and Cape Hatteras. We describe the time-space evolution of the 2007 Cold Pool in terms of a spring/autumn series of *single glider* zig-zag missions with from northeast to southwest down the shelf. The Cold Pool was defined by the thermocline at the bottom of warm upper layer, which varied spatially from 25 to 45 m.We used the 2007 glider water property measurements to define sub-10 °C Cold Pool – an important, evolving habitat feature of the Mid-Atlantic Bight (MAB). Based on the 2007 glider measurements, we found that a trapezoidal T–S definition of Cold Pool Water, highlighted by an increased about 1 °C warming/mon. and 0.11 psu salting/month after June (Fig. 11). This all happened to Cold Pool, while the MAB water were flowing southwestward at an average velocity of 5 km/day.

The 2007 glider measurements show that the core of the Cold Pool (defined by the transect minimum temperatures – T_{min}) hugs the outer shelf in the vicinity of the well-known Shelf-Break Front (SBF; Figs. 8 and 9). The Cold Pool salts due to exchanges with Slope Sea waters as the Cold Pool waters flow from northeast to southwest along the MAB. The vertical mixing caused by autumn storms gradually erase the temperature distinctiveness of the Cold Pool. The vertical mixing late November–early December 2007 produce the vertically well mixed temperature profiles in Fig. 7. The intense winter cooling is hinted at in the inshore profiles of Leg-6 of Fig. 7.

Our early summer 2007 mapping, based on only two zigzag glider measurements of a *sub-10 °C waters,* ranging from full shelf-width CPW in the SNEB region to a very narrow strip southwestward in locations off Maryland (Fig. 12). We estimated the summer 2007 Cold Pool volume to be 4119 ± 9 km^3. The warming of CPWs in the MAB continued throughout summer leading to a decrease in CPW volume. This reduced autumn 2007 estimated volume of 2310 ± 46 km^3 (Fig. 13). This loss of sub-10 °C CPW volume is associated with increased salinity (Table 1) and is consistent with the southwestward average flow 5 km per day.

During September–October 2013, we have also explored the Mid-Atlantic Cold Pool with the contemporaneous *trio of glider* missions highlighted in Fig. 14. With that set of nearly simultaneous glider measurements, we showed that the *September 2013* Cold Pool in the NJ region was colder than in 2007 than the rest of 2013 Cold Pool.

We also showed that the SNEB region the *2013 Cold Pool* was warmer than the 2007 Cold Pool in this region. That warming of the SNEB region of the Cold Pool was probably due to the influence of a nearby Gulf Stream Warm Core Ring (Fig. 18). This led us to widen of the trapezoidal T–S definition of Cold Pool Water properties -salinity in particular (Fig. 19). We changed from the sub-10 °C cold Pool definition to a 12 °C definition for the 2013 Cold Pool. This resulted in a *sub-12°C* 2013 Cold Pool has an estimated volume of 4109 ± 15 km^3 (Fig. 20).

The September/October 2013 glider measurements (as well as in October 2007) document the autumn Cold Pool 2013, during which the Cold Pool loses its distinctiveness due to storm mixing. [Of course, the SNEB region 2013 Cold Pool water properties are consistent with our redefined trapezoid of Cold Pool water properties (Fig. 21)]. All three sub-regions – SNEB, NJ and MD – exhibited inshore water properties that reflected mixtures with the local Cold Pool waters. The T_{min} T–S relationships indicated deeper water properties that hinted at slope water influence. The possibility CPW origins of "upstream" from the Gulf of Maine is explored in Appendix B. The inter-annual variability of Cold Pool Waters was explored through glider measurements of autumn

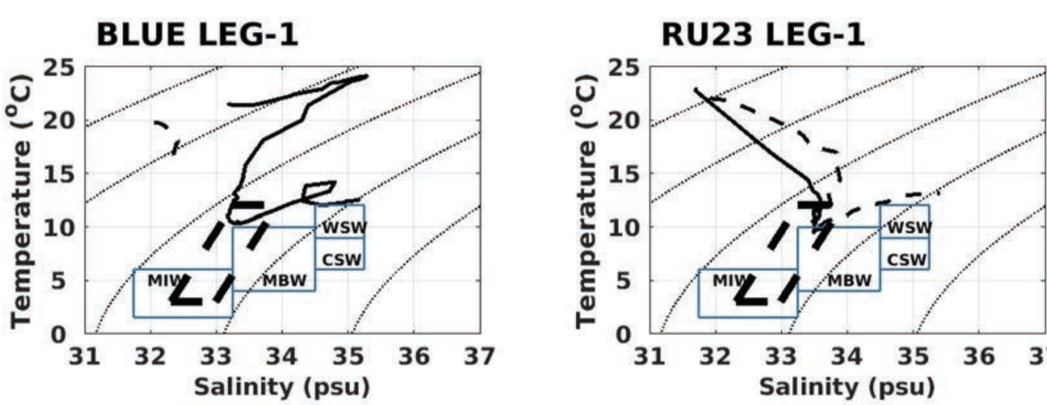

Fig. 21. The (left) SNEB region glider Blue Leg-1 and (right) NJ region glider RU23 Leg-1 T–S relations for the T_{min} station (solid) and most shoreward station (dashed) for the September 2013 measurements. The global Cold Pool water mass is defined by the dashed trapezoid. The rectangular boxes define the Brown and Irish (1993) Gulf of Maine water masses – MIW and MBW and the warm (WSW) and cold slope water (CSW).

2013. The nearly simultaneous 2013 trio of glider measurements (Fig. 14) were used to show how the 2013 MAB Cold Pool Waters in the northeastern sector were warmed and salted by the impingement of a Gulf Stream Warm Core Ring. However, these results suggest that a quantitative water mass analysis – beyond the scope of this effort – could lead to cross shelfbreak front mixing rates.

Appendix A. Covert Practical Salinity to Absolute Salinity (S_A)

We expressed salinities in this paper as PSS-78 Practical Salinities (S_P); with units as psu). Pawlowicz (2013) maintains that "However, for all purposes S_A (Absolute Salinity) according to the TEOS-10 definition is required". Determining S_A from S_P requires the following.

(1) For waters in the "Neptuian" range (i.e., $2 < S_P < 42$; $-2\ ^\circ C <$ ITS-10 temperature $<35\ ^\circ C$), a Reference Salinity S_R on the Reference Composition Salinity Scale (Millero et al., 2008) be estimated as

$$S_R \Big/ \left(\mathrm{g\ kg^{-1}}\right) = \frac{35.16504}{35} \times S_P$$

The Reference Salinity is the mass fraction of solute in an artificial seawater with a precisely defined Reference Composition.

(2) "Because the composition of seawater is not exactly constant, this Reference Salinity is not exactly as the same as the actual Absolute Salinity. Instead, they differ by a small correction factor δS_A:

$$S_A = S_R + \delta S_{A.}$$

This correction factor is usually, but always positive." It can be large as 0.02 g/kg in the open ocean, and as 0.09 g/kg in some coastal areas. Pawlowicz (2013) recommends estimate $\delta S_A = 0$ for coastal regimes such as we have here and states in ignoring this correction is roughly equivalent to using the PSS78/EOS80 approach.

Appendix B. Cold Pool Water Origins

We have used the New England Shelf Flux Experiment (NSFE) data (Ramp et al., 1988) to characterize the inflow variability to the Mid Atlantic Bight (MAB) Cold Pool through a section south of Nantucket during spring/summer 1979. The multi-mooring array configuration is shown Fig. B1. The variability of the westward transport of waters of less than 10 °C through the NSFE (N1–N4) section in Fig. B2 shows that the sub-10 °C water inflow ceased by the end of June 1979.

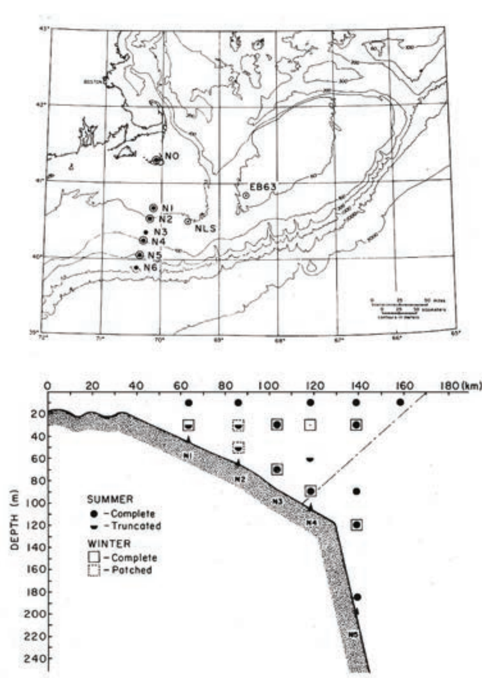

Fig. B1. *(upper)* A map the NSFE mooring array: N1 (depth = *46m*), N2 (*66m*), N3 (*88m*), N4 (*105m*), N5 (*196m*) and N6 (*250m*). *(lower)* The temperature and current measurements making up the year long NSFE. The focus of our interest in the "summer" measurements. (from Ramp et al., 1988).

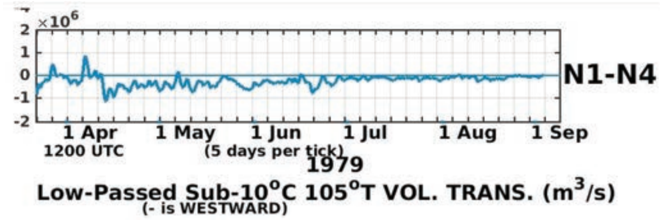

Fig. B2. The major portion of the volume transport of sub-10 °C waters (in 10^6 m^3/s) (spans moorings N1 and N4) normal (105°T) to the 1979 NSFE mooring array. Negative transport is toward the MAB (185°T).

This typical April–June process leaves a distinctive pocket of very cold water that is advected west and southwestward along the MAB. This cold water pocket feeds the evolving Cold Pool, which warms from July onward … as described above in the main text.

What is the origins of the springtime cold water inflow to the MAB Cold Pool? One possibility is that Gulf of Maine Intermediate Water (MIW) escape to feed the MAB Cold Pool. Another possibility is that the Cold Water derives from the Scotian Shelf via the south flank of Georges Bank. We explore both of those possibilities below.

This study tracks MIW outflow from Wilkinson Basin through the set of hydrographic transects (henceforth RIM) from the Gulf of Maine 1986–87 Experiment (Fig. B3 – Brown and Irish, 1993). In particular, note the similar-looking T–S diagrams of the T_{min} stations in each of the transects. The corresponding T–S diagram is shown in Fig. B4. It indicates the presence of Maine Bottom Water (MBW), which Brown and Irish (1993) and others have shown is a mixture between Maine Intermediate Water (MIW characterized by T_{min}) and Slope Water after its entry into the Gulf of Maine (GoM) through the Northeast Channel (NEC). From this evidence, we conclude that significant amounts of MIW, which we know is produced in Wilkinson Basin in the western GoM, is flowing out of the Gulf at a depth in and around 100 m - below the minimum depth of the sill in the great South Channel.

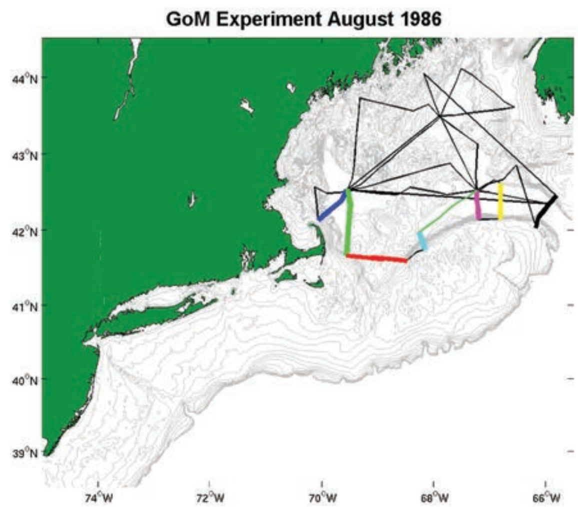

Fig. B3. Composite of the August 1986 Hydrographic Survey Color-Coded RIM Transects: Leg-6a (blue), Leg-1b (green), Leg-7 (red), Leg-7a (cyan/green), Leg-4a (maroon), Leg-3 (yellow), and Leg-5 (black).

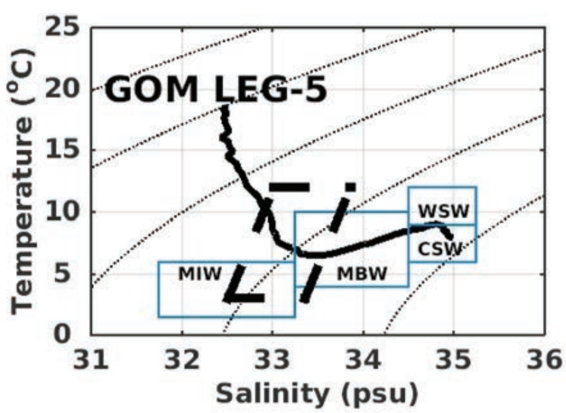

Fig. B4. The T–S diagram for the T_{min} station of the Aug 1986 RIM transect 5 (in Fig. B-3 – black). The global Cold Pool water mass properties is defined (dashed trapezoid). The rectangular boxes define the Brown and Irish (1993) Gulf of Maine water masses – MIW and MBW and the warm (WSW) and cold slope water (CSW).

***Abstract*— On September the 15th of 2020, Hurricane Sally traveled within 35 km from the location of NOAA NDBC Sea-glider (SG) 601 situated south of De Soto canyon. In this study, upper ocean observations from SG601 were compared to Hybrid Coordinated Ocean Model (HYCOM) and Navy Coastal Ocean Model for American Seas (NCOM-AmSeas or NCOM), coupled atmospheric-ocean models mainly used in hurricane science. Results from this study show that water temperatures, from the HYCOM simulations, were >29°C in the upper 30m and differ from SG observations by a 1°C. On HYCOM modelled upper ocean salinity, the differences (2-3PSU) are noticeable on two days (09/15 and 09/16). NCOM simulations, on the other hand, show a difference of 0.5-1°C (1.5-2PSU) in upper ~30 m water temperatures (salinity) of 09/15. Furthermore, when a 1D PWP model was initialized with a temperature and salinity profile with a barrier layer (barrier layer removed) to evaluate the influence of barrier layer on Hurricane Sally (HS), a 0.1-0.15°C (0.15°C-0.20°C) cooling of the mixed layer was noticed on 09/15.**

Keywords—upper ocean water temperature and salinity; salinity stratification; barrier layer

I. Introduction

In 2020, the poorly predicted, both in intensity and track, Hurricane Sally (HS), produced hurricane force winds along the coasts of Mississippi, Alabama, and western Florida. On 09/15, HS began a rapid intensification with an increase in intensity from 80 mph at 1800 UTC to 109 mph by the morning of the following day [1]. A NOAA report on HS [1], indicated that the upper-level atmospheric divergence increased by twofold on 09/15, which led to the observed intensification despite the deep layer vertical shear in the atmosphere near HS [1]. Between 0500-0600 UTC of 09/16, HS began moving onshore and affected Baldwin County (Alabama) within the next 3hours. HS made landfall at 09:45 UTC at Gulf Shores, Alabama with maximum sustained winds of ~110 mph.

Understanding the ocean environment and the complex two-way responses, between the ocean and atmosphere, that favor rapid intensification is critical to providing more accurate hurricane forecasts to the gulf coast communities. The path of HS, fortuitously, came across that of NOAA NDBC Sea glider, SG601. SG 601 provides an observational perspective of the upper ocean under HS low pressure system. Hence, inthis study, we compared the SG601 observations to numerical experiments (NCOM-AmSeas or NCOM, Navy Coastal Ocean Model; HYCOM, Hybrid Coordinated Ocean Model) and analyzed the extent to which the observed salinity stratification potentially suppressed surface ocean cooling and promoted the observed intensification of HS on late 09/15/2020.

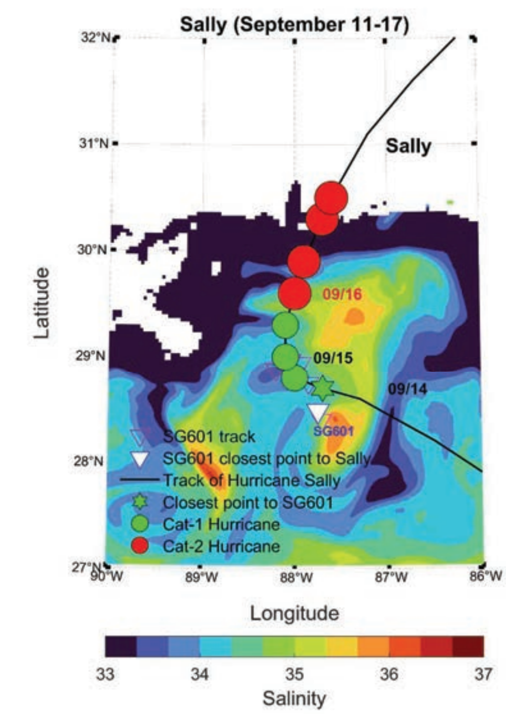

Figure 1: describing the study area, dominated by fresh sea surface salinity (underlying colormap) from NCOM-AmSeas (or NCOM) experiments. The circles, green and red, represent respectively, the intensities and position of HS. Figure 1 also describes the track of HS (black track plot), downward pointing (white) triangle and the track of SG601 (downward pointing, magenta, triangle). Furthermore, figure 1 shows where SG 601 was closest to HS track.

II. Data and Methods

The Hybrid Coordinated Ocean Model (HYCOM) for the Gulf of Mexico (GoM), is a 1/25° regional model and discussed extensively in [2]. Hence in this study, a short description is provided. HYCOM is a nested grid modelling system, with a fine resolution of inner model embedded inside the coarser outer model [2]. HYCOM extends northward from 18.1˚ and westward from -77.4˚. The inner model's resolution is twice the outer (1/12˚). HYCOM has 20 hybrid layers vertically. Many studies have used HYCOM analyses to examine the upper ocean response to tropical cyclones and hurricanes in the Gulf of Mexico [2]–[5].

NCOM-AmSeas (or NCOM) is the Navy Coastal Ocean Model for the Gulf of Mexico and Caribbean Sea, which is operated by the Fleet Numerical Meteorology and Oceanography Center (FNMOC). NCOM-AmSeas has a ~3km horizontal resolution. Information on this product is available at https://www.ncei.noaa.gov/products/weather-climate-models/fnmoc-regional-navy-coastal-ocean. NCOM uses NCODA (Navy Coupled Data Assimilation) to assimilate quality controlled ocean observations from the GoM, including glider datasets, satellite derived temperature and heights of the sea surface [6], [7]. NCOM together with HYCOM were compared to SG601 data to evaluate the performance of these coupled atmosphere-ocean models in modelling the upper ocean.

Upper ocean surveys ahead of HS were conducted using NOAA sea glider, SG601. SG601 is a buoyancy driven autonomous underwater vehicle. SG601 profiles the ocean vertically down to 1000m. Glider observations presented here were extracted from the Integrated Ocean Observing System (IOOS) Glider Assembly Center (GDAC). Moreover, SG601 observations from the IOOS-GDAC were quality controlled [8] to the best international practices. To examine the extent to which the observed salinity stratification suppressed sea surface cooling during HS, two experiments (one with a barrier layer and other without a barrier layer) were conducted utilizing a 1D ocean mixing model, Price-Weller-Pinkel one-dimensional model, [9]. [10], [11] have used the PWP 1D model in studying ocean mixing during a hurricane. PWP includes shear driven mixing and buoyancy forcing processes [9]. PWP 1D uses three stability criteria (static instability, bulk, and gradient Richardson number) to account for vertical mixing. The bulk and gradient Richardson number were set to 0.65 and 0.25, respectively, to stability criteria. The 1D model was further forced with wind and surface heat fluxes from the North American Mesoscale Forecast System analysis. Moreover, the temperature and salinity profile close to the track of HS were used in the 1D model. This initial profile was evaluated for the presence of a barrier layer. The barrier layer was calculated using the methods of [12], [13] using
$\Delta\sigma\theta = \sigma\theta\,(T_o - \Delta T, S_o) - \sigma\theta\,(T_o, S_o)$, where To and So are, respectively, the 2m temperature and salinity. ΔT is 0.8°C as in [13].

III. Results and Analyses

HYCOM and SG601 water temperature and salinity sections (figure 2) depict contrary descriptions of the upper ocean. On 09/14, in the upper 30m, the HYCOM simulations of the water temperature appear analogous to that of SG601. However, the variations began at the later hours of 09/14. These observed variations continued into the hours of 09/15. Figure 2 (upper middle panel), SG601, shows water temperatures were >29°C in the upper 30m and differ from the HYCOM simulations (upper right panel) by 1°C. Observations from SG601 indicates that water temperatures stayed above 26°C, even after the passage of HS on the 09/15. About the upper ocean salinity, there is a striking divergence in the upper ocean salinity between SG601 and HYCOM. Figure 2 (lower panel) describes that the salinity values of the upper 30m in HYCOM range from 35.5-36PSU while SG601 indicates 34-36PSU at the same depth range. Evident in figure 2 (lower right panel) are the differences in salinity between HYCOM and SG601. Figure 2 (lower right panel) shows that these differences are noticeable on two days (09/15 and 09/16). Above all, the variations in the upper ocean sallinit appear reaching ~60 m depth.

The NCOM-AmSeas (or NCOM) simulations, left upper panel (figure 3), depict temperatures of 29°C in the upper ~30 m from 09/14 to 09/16 while water temperatures in depths >40m appear like those of SG601. The difference in water temperatures between NCOM simulations and that of SG601 (right upper panel, figure 3) shows a range of 0.5-1°C in the upper ~30 m on 09/15. These differences suggest that NCOM simulations of upper ocean water temperatures appear more comparable to the observations (SG601) than HYCOM. The lower panel of figure 3 shows the water salinities (34-35.5PSU). Salinities in NCOM simulations appear fresher in the upper ~30m than what is observed in SG601. Moreover, the observed low salinities (center lower panel, figure 3), SG601, appear shallower than what is modelled in NCOM. This difference raised the question on how riverine inputs are assimilated into both HYCOM and NCOM. According to [14], HYCOM riverine inputs are inter-annual flows, while in the case of NCOM, rivers inflows are based on monthly means because real time river discharges are difficult to obtain in the time frame needed for operational modelling [15]. Furthermore, using a monthly mean river discharge has improved upon simulations in global NCOM [15]. Despite the differences between NCOM and HYCOM, both stimulations point to a salinity stratified upper ocean.

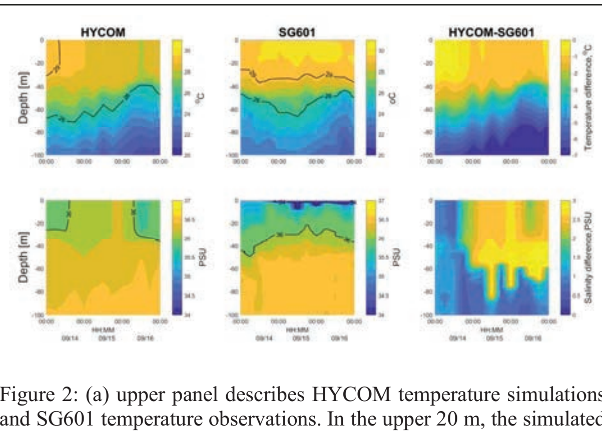

Figure 2: (a) upper panel describes HYCOM temperature simulations and SG601 temperature observations. In the upper 20 m, the simulated temperatures appear analogous to the observations of SG601 on 09/14. However, on the 09/15, temperature simulations in the upper 30m drift away from SG601's temperatures; and these differences (1°C) are evident in the right upper panel. Furthermore, the differences between HYCOM and SG601 indicate that the modelled temperatures at depths >40m are close to the observed temperatures. (b) lower panel describes the HYCOM simulations of salinity. The lower panel describes a noticeable divergence in upper ocean salinity. The HYCOM modelled salinity ranges from 35.5PSU to 36PSU while SG601 indicates salinity range of 34-36PSU in the upper 30m.

The question therefore is whether this physical feature (salinity stratification or barrier layer) potentially influenced HS.

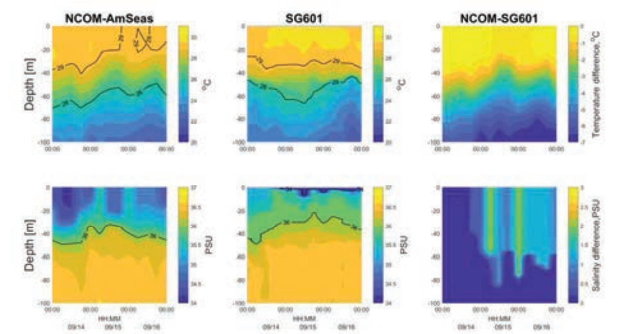

Figure 3: (a) upper panel describes NCOM-AmSeas (or NCOM) temperature simulations depict a 29°C in the upper ~30 m from 09/14 to 09/16 while water temperatures in depths >40m appear alike to that of SG601. The difference in water temperatures, between NCOM simulations and that of SG601, shows a 0.5-1°C temperature difference in upper ~30 m of 09/15. (b) lower panel describes the NCOM simulations of upper ocean salinity. The NCOM modelled salinity ranges from 34PSU to 35.5PSU while SG601 indicates salinity range of 34-36PSU in the upper 30m.

Figure 4 illustrates two experiments in the 1D PWP model, used to analyze the potential effect of the barrier layer on HS intensification. The first experiment (upper panel) describes the upper ocean response to HS when a barrier layer is present. In this experiment, the barrier layer is responsible for 0.1-0.15°C cooling of the mixed layer while the second experiment (lower panel), without a barrier layer, shows that the mixed layer cooled from 0.15°C to 0.20°C on 09/15. The reduced cooling exhibited in the first experiment attests to the hypothesis that salinity stratification (or barrier layer) inhibits cooling of the upper ocean [10], [11], [16], [17]. Although the modelled 1D PWP cooling, in this study, is small (0.05°C) compared to 0.3°C and 0.4-0.8°C of previous studies [11], [17] respectively, the potential impact of salinity stratification on HS was apparent. Above all, the low cooling is also connected to the low intensity (higher Category 1) of HS [10] on the 09/15.

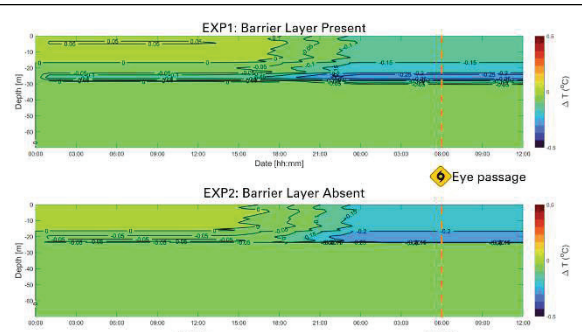

Figure 4: (a) the upper panel describes an experiment in PWP with temperature and salinity profile (with a barrier layer). In this experiment, the barrier layer is responsible for 0.1-0.15°C cooling of the mixed layer on 09/15. (b) the lower panel, on the other hand, describes an experiment in PWP with temperature and salinity profile (without a barrier layer, or barrier layer removed). In this experiment the mixed layer cooled from -0.15°C to -0.20°C.

IV. Conclusion

This study highlights the influence of the river discharge in modulating hurricane driven SST cooling in our region of interest. Although the HYCOM simulation showed striking differences between the observed and the modelled upper ocean salinity, both NCOM and HYCOM demonstrate the influence of freshwater on upper ocean stratification. In this study, using a 1D PWP model, the salinity stratification has been demonstrated to affect SST development, which in turn has an influence on tropical storm intensity. This finding agrees with previous studies that had used the same 1D PWP to study barrier layers and their influences on tropical cyclones and provides further evidence of the importance of fluvial inputs for tropical cyclone intensification in the northern Gulf of Mexico.

Abstract—**Global ocean observing systems utilize autonomous underwater vehicles (AUVs) to monitor coastal ocean conditions. These vehicles collect data while facing challenges of shallow waters, changing currents, and stratification. In addition to these natural challenges, AUVs share the waters with increased marine traffic, leading to potentially catastrophic ship strikes. Autonomous vehicles lack the ability to sense vessels, creating a need for a ship detection system leading to evasive maneuvers. Before vessel avoidance behaviors can be effectively implemented, baseline analysis is needed to understand the proximity of vessels to deployed AUVs. This research examines vessel traffic in New Jersey during an underwater glider mission using Automatic Identification System (AIS) mapped vessel movement, and glider data from Rutgers University. We quantify the probability of vessel co-location with a glider by distance, and vessel characteristics including their type and draft. Results show that most ships were not an immediate threat to the glider, with most in the range of 35–110 km. During the mission, less than 0.6% of ship position reports were within 20 km. Many ships were fishing vessels with a distance over 35 km from the glider. The average ship draft was 8 m with a maximum of 19 m. While most vessels were found beyond 35 km of the glider, there was a small but significant number of vessels that could be avoided if the glider were equipped with a ship detection system to make evasive actions.**

Keywords—underwater glider, AUV, path planning, collision avoidance, AIS, vessel traffic, acoustic

I. Introduction

Autonomous underwater vehicles (AUVs) are sensor platforms of the Global Ocean Observing System. Their data are used for tracking environmental changes, ocean floor mapping, hurricane prediction, wildlife tracking, marine archaeology, geologic formations, and search and rescue [1, 2, 3, 4, 5]. Oil and gas industries are using autonomous vehicles for inspection and repair of infrastructure [6]. The Blue Economy is creating more opportunities for AUV obtained data including wave forecasting, recreational fishing, commercial shipping, aquaculture, and mariculture [7].

Underwater gliders are a type of AUV capable of longer missions (~month to months). These vehicles use a buoyancy pump to move vertically through the water in a sawtooth motion [8]. Their pump and wings make them energy efficient. They rely on the global positioning system (GPS) for navigation and can only transmit data and receive commands through satellite when they surface [8]. These robots lack the ability to sense ships and react to the potential danger of ship strikes. Large cargo ships are not the only threat, as even a small pleasure craft can damage a glider fin or wing, causing a mission failure and a potential expensive loss. Many glider missions focus on coastal waters near busy ports and estuaries as seen in [9, Fig. 1]. During these deployments, remotely situated glider pilots face the challenge of navigating busy shipping lanes and dense recreational boat traffic with little strategy other than pilot commands that restrict a glider to deeper depths.

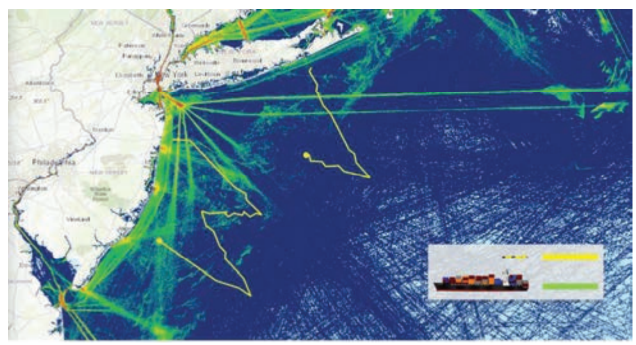

Fig. 1. Typical glider paths and shipping lanes of New Jersey/New York.

Our research establishes the level of vessel traffic risk as it pertains to an underwater glider in busy New Jersey coastal waters. It identifies the probability of a ship encountering the glider during a typical mission and the distance between ships and glider. Details of encountered vessels, including type of ship and draft are evaluated. Our interest is whether a future ship detection system may be able to thwart a ship strike. We hope this information is beneficial for improving navigation strategies for glider pilots and improving safety in waterways.

A. Background

The New Jersey coast offers a rich test site, with abundant glider missions from Rutgers University and other regional partners, and busy shipping lanes serving ports in New York and New Jersey. Automatic Information System (AIS) data provide a time series of reported vessel positions in the area. AIS is a

New Jersey Research and Monitoring Initiative, Ørsted ECOPAM

979-8-218-14218-6 ©2023 MTS

shipboard broadcast system that uses a VHF channel to share travel information [10]. Ships transmit key data including ship name, GPS, time, vessel type, and draft. Ships also receive AIS data for the surrounding area, aiding navigation. AIS data for New Jersey in [11, Fig. 2] confirms that vessels transit throughout the coastal waters.

Fig. 2. Recent AIS data.

Large types include tankers, cargo, passenger, and dredging vessels. In 2022, the New York-New Jersey seaport ranked 2nd highest in the nation with a 27% increase over 2019 due to rerouting of ships from COVID [12]. This busy vessel area overlaps with many Rutgers glider missions monitoring the oceanographic and ecological characteristics of the coastal ocean.

B. Review of Literature

Vessel movement is not just a concern for glider pilots. The Port Authority of New York and New Jersey monitors activities of cargo vessels and marine traffic as it relates to economy and safety (https://www.panynj.gov/). Offshore wind development has a need to understand marine traffic before and after construction with researchers looking at "near misses" of vessels on the Atlantic Coast [13]. The number of whale ship strikes is a growing concern, with studies in the New York Bight comparing sightings with AIS data to understand vessel risk [14].

Although ship strikes are of interest, there is a lack of research on potential collisions with AUVs. The potential loss of gliders due to ship strike in the German Bight has been analyzed using probability models and Monte Carlo simulations [15]. An estimate of damage to a small ship colliding with a glider at a speed over 7.5 m/s shows an outcome of severe hull damage [16]. There are numerous studies on path planning for AUVs utilizing algorithms and modeling [17, 18, 19]. One of the challenges of this research is determining which factors to include for algorithms and modeling. Speed, time, heading, obstacles, currents, and other environmental hazards may be considered. Another challenge is dealing with the difference between gliders and ships, both in their shapes and the depths they occupy. Lastly, for path planning information to be helpful, it must be based on data from the specific area of interest.

In the next section, we discuss the methods used to obtain and prepare data. Following the methods, we introduce the results, showing plots of vessel and glider data. A discussion follows with implications of the study, as well as a conclusion summarizing the findings.

II. Methodology

To better understand the interaction between marine traffic and coastal glider activity, we compared a concurrent glider mission to ship traffic off the busy New Jersey coast. Glider data were procured from the Ørsted ECO-PAM project [20]. The ECO-PAM project was led by Rutgers University in partnership with Woods Hole Oceanographic Institution and the University of Rhode Island [21]. A key component of the project was to deploy glider missions in and around the Ocean Wind 1 offshore wind lease area to monitor North Atlantic right whales (*Eubalaena glacialis*) [21]. The gliders are equipped with hydrophones, which can detect the sound of marine life and anthropogenic noise. This analysis focuses on a single mission deployed from February 15–March 15, 2022, transecting the New Jersey coast near Atlantic City to the shelf break. This mission is representative of a typical coastal glider deployment based on mission duration and lack of mechanical errors. Matching AIS data for the New Jersey coast for the same period were downloaded from https://marinecadastre.gov/ais [22].

Data were processed using Python 3 and its libraries, NumPy, Panda, and Matplotlib. A library developed at Rutgers University, Cool Maps (https://github.com/rucool/cool_maps), facilitated map plots. Files were sorted by time to the nearest minute, and missing data treated as not-a-number (NaN), as opposed to zero. Plots were created showing the glider mission path and probability of a ship in the area. Distance between vessels and glider were calculated based on GPS coordinates. Distribution of types of vessels encountered during the mission, and drafts for the types of vessels were also considered.

III. Results

A. Percentage Vessel Likelihood

A comparison of glider and AIS data reveals information about the proximity of the glider and surrounding ships. The glider mission shown in Fig. 3 includes an east-west transect to the shelf break, returning close to the same track during its mission. The likelihood of a ship off the coast of New Jersey to be in any one location at a given time is predominately 6% or less during the mission as shown in Fig. 4. Points above 10% are frequently in higher trafficked shipping lanes.

B. Distance of Ships to Glider

To understand encounters, we used AIS data to determine the distance between the glider and all ship positions reported during the mission. Fig. 5 shows ship position reports were predominately 35–110 km from the glider. 0.6% of ship position reports were in the 20 km range during the mission. The largest category of ships encountered in the 20 km range was fishing vessels, followed by cargo/tanker ships.

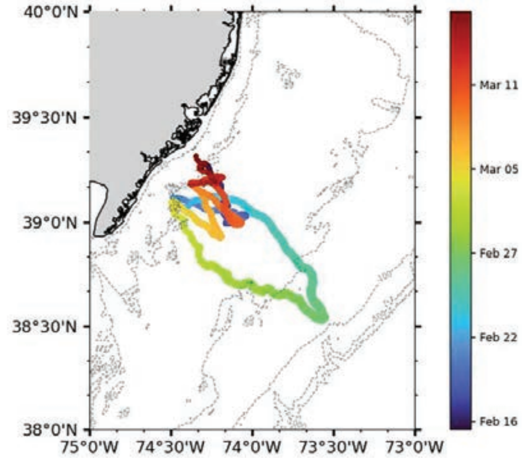

Fig. 3. Glider path mission near New Jersey coast.

C. Glider Depth With Distance to Ships

Plotting the glider depth in relation to ship traffic shows a similar range of 35–110 km as shown in Fig. 6. Ship positions reported were primarily 40–70 km from the glider. The average ship draft was 8 m, and the maximum draft was 19 m.

D. Ship Drafts

Further examination of ship draft in Fig. 7 reveals cargo/tanker ships with the largest draft at 5–18.5 m. Passenger ships have the second largest draft at 2.4–10.5 m. The "Other" category had many outliers, due to the varied assortment of boats and ships. Ships encountered in the 20 km range from the glider are likely fishing vessels or cargo/tanker ships, which creates a split between small drafts and exceptionally large drafts.

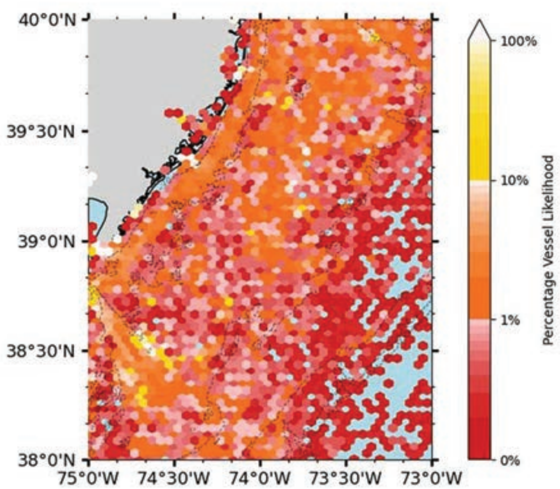

Fig. 4. Percentage vessel likelihood during mission.

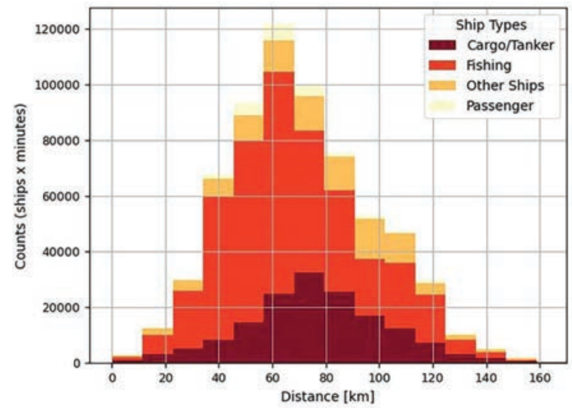

Fig. 5. Distance of ships to glider. This bar plot shows the cumulative distance of vessels to glider during the mission by ship type. The category "Other Ships" includes towing, dredging, diving ops, military ops, sailing, pleasure craft, high-speed craft, pilot vessel, search/rescue, tug, port tender, anti-pollution, law enforcement, non-combatant, and medical transport.

IV. Discussion

Ships and gliders must coexist in coastal waters, and both are growing. We must find ways to minimize interactions, starting with an understanding of the frequency of interactions and vessel classes. Data show 0.6% of total ship position reports are within 20 km of the glider during the mission. Most ships are found at a distance greater than 35 km. The results suggest there is a small, but significant number of ships that may be avoidable with a ship detection system. The ships of concern are likely fishing vessels that have a small draft, although cargo ships and tankers may also pose a threat. The small draft of fishing ships allows gliders the opportunity to dive to safety. Cargo/tanker ships have a large draft and lack maneuverability, creating a challenge for gliders.

Crossing shipping lanes is a navigation concern. Our research clarifies the risk of a glider moving east–west, with shipping lanes positioned north–south. This parallels research by Merckelbach [15], in which he concluded that east–west transects in the German Bight were a greater risk than north-south. While we do not yet have a simulation to prove our

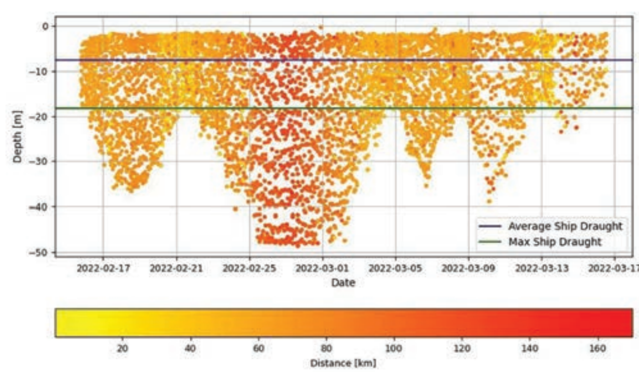

Fig. 6. Glider depth with distance to ships. Average ship draft and maximum ship draft are based on ships in the area during the glider mission.

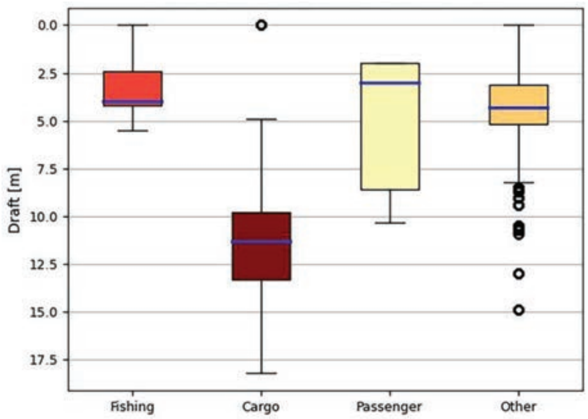

Fig. 7. Ship drafts during glider mission.

situation in New Jersey, our view of ship distances is a step towards understanding the risk. Another aspect of navigation concern is the reverse premise of our research—the threat of gliders to boats. According to Drücker et al. [16], there is more concern for a glider impacting a boat than there is for a boat impacting a glider. This is a point well taken, and our research also contributes to this focus of work since the goal is to understand the risk of collision.

Limitations of this research fall into two categories—data challenges and researcher challenges. The data are skewed in favor of the glider evading ships. Glider pilots are aware of shipping lanes and program gliders to stay deeper and surface less frequently when crossing. Results were based only on distances calculated using GPS points of the glider and ships. Breithaupt et al. [13] used a more complete calculation in their analysis of navigation conflicts between ships, using speed and heading. They also described the type of encounter as "crossing", "overtaking", or "head-on" [13]. Another data challenge in our research is the simplification of ship categories. We combined multiple classes of ships in the "Other" category when numbers were determined to be low. "Ghost ships", vessels that do not provide their information to AIS, also pose a risk, and were not considered in this analysis. Researcher challenges include a constraint on project time which only allowed one glider mission to be analyzed. These limitations result in research that is a "first look" at the risk gliders may face in New Jersey waters.

There is more information to absorb from this analysis, particularly the depth of the glider compared to distances of ship positions shown in Fig. 6. The light yellow/orange shaded areas near the beginning and end of the mission may coincide with shipping lanes. At the end of the mission, a pilot confines the glider to a location near the coast for recovery. The glider may travel back and forth between multiple waypoints, placing it at risk near shipping lanes. It would be helpful to compare the GPS coordinates for the shipping lanes and time stamps of the mission.

Future work should tackle the means for a glider to obtain ship data for a detection system. Hydrophones are frequently used on gliders for marine mammal tracking and other acoustic surveys [23, 24]. Data for our research include the hydrophone's acoustic files for the same period. Acoustic files are stored and compressed on a Digital Acoustic Monitoring (DMON) instrument that works in conjunction with the hydrophone [25]. Files can be converted to spectrograms which show audio signals of the environment. These signals are used to identify whale species and anthropogenic noise. Using machine learning, it may be possible to use acoustic signals to isolate ships that risk the glider mission. A machine learning model processing acoustic files from moored hydrophones classified large ships with an accuracy of 98.04% [26].

An alternate method for ship detection capitalizes on AIS data. Researchers have proposed relaying data to the glider from a nearby ship or beacon using a modem [27]. Another potential method is for the glider to receive AIS data directly from a VHF antenna. There are challenges to overcome with both acoustic and AIS methods. A glider's CPU (central processing unit) is limited by memory and processing capability [28]. Energy consumption must be kept at a minimum [28], and any attachments such as antennas or extra hardware may affect performance.

V. Conclusion

In this research we examined whether New Jersey vessel traffic is a threat to underwater gliders. The findings suggest the threat of vessel traffic is low. Distances of ship positions to the glider were calculated using AIS data. We found the occurrence of reported ship positions within 20 km of the glider to be 0.6% of the total mission, while most reported ship positions were found over 30 km. The greatest number of ships encountered were fishing vessels, while cargo/tanker ships were also a concern. The median ship draft was 8 m, and the maximum was 19 m.

The low, but nonzero, occurrence of vessels close to a coastal glider indicates a glider may benefit from a ship detection system. Future research should focus on methods for the glider to obtain ship data for a detection system. Two potential methods include using a hydrophone for acoustic data, and an antenna or modem for receiving AIS data.

Some limitations of our research include skewed data from effective glider piloting, lack of data due to ships that do not report their AIS information, and time constraints. The main limitation is the basic distance calculation which does not include other variables such as ship size, speed and heading. Although our method is simplistic, it relates to research in Germany examining the possibility of ships colliding with gliders [15]. Our work also shares an interest in gliders colliding with ships [16]. Together researchers must continue to work on a solution to protect lives and marine assets with the growing New Blue Economy.

Acknowledgment

The authors acknowledge and respect the ancestral territory of the Lenape people where Rutgers University, New Jersey, is located. The authors would like to thank Ørsted and Rutgers University for providing glider data. Additional thanks given to Marine Cadastre for AIS data.

Stennis Space Center, MS, United States

Tropical cyclones are +ne of the costliest and deadliest natural disasters globally, and impacts are currently expected to worsen with a changing climate. Hurricane Ida (2021) made landfall as a category 4 storm on the US Gulf coast after intensifying over a Loop Current eddy and a freshwater barrier layer. This freshwater layer extended from the coast to the open ocean waters south of the shelf-break of the northern Gulf of Mexico (GoM). An autonomous underwater glider sampled this ocean feature ahead of Hurricane Ida operated through a partnership between NOAA, Navy, and academic institutions. In this study we evaluate hurricane upper ocean metrics ahead of and during the storm as well as carry out 1-D shear driven mixed layer model simulations to investigate the sensitivity of the upper ocean mixing to a barrier layer during Ida's intensification period. In our simulations we find that the freshwater barrier layer inhibited cooling by as much as 57% and resulted in enhanced enthalpy flux to the atmosphere by as much as 11% and an increase in dynamic potential intensity (DPI) of 5 m s^{-1} (~9.72 knots) in the 16 hours leading up to landfall. This highlights the utility of new ocean observing systems in identifying localized ocean features that may impact storm intensity ahead of landfall. It also emphasizes the northern Gulf of Mexico and the associated Mississippi River plume as a region and feature where the details of upper ocean metrics need to be carefully considered ahead of landfalling storms.

KEYWORDS

hurricanes, barrier layers, uncrewed systems, ocean observing networks, and upper ocean mixing

1 Introduction

Tropical cyclones (TCs) are one of the costliest and deadliest natural disasters on the planet (Smith, 2020). The ability to forecast TC intensity has improved recently (Cangialosi et al., 2020), however intensity forecast errors remain large (~12 kts at 72 hours). The primary controls of the intensity of mature TCs are vertical wind shear, dry air intrusion,

10.3389/fmars.2023.1224609

and the fluxes of enthalpy and momentum between the surface ocean and atmosphere (Emanuel, 1986). Numerous studies have shown that the upper ocean can evolve rapidly beneath TCs and feedback on storm intensity (Cione and Uhlhorn, 2003; Black et al., 2007; D'Asaro et al., 2007; Zedler et al., 2009; Mrvaljevic et al., 2013; Steffen and Bourassa, 2020) among many others therein. Recent studies have focused on coastal ocean processes and their feedbacks on storm intensity, including coastal upwelling, downwelling, and enhanced shear-driven mixing (Glenn et al., 2016; Seroka et al., 2016; Miles et al., 2017; Seroka et al., 2017; Zhang et al., 2018; Dzwonkowski et al., 2021; Gramer et al., 2022), with a particular focus on highly stratified water columns. A common hurricane intensity forecasting challenge in regions with large river runoff are upper ocean salinity barrier layers (Lukas and Lindstrom, 1991; Sprintall and Tomczak, 1992; Foltz and McPhaden, 2009; Grodsky et al., 2012; Steffen and Bourassa, 2018). Generally, stratification can inhibit vertical mixing and limit entrainment of cool subsurface waters into the mixed layer during TC passage (e.g. Rudzin et al., 2018). These ocean features are found on continental shelves, near river outflows (Sengupta et al., 2008), and over the open ocean with offshore transport of freshwater (Pailler et al., 1999; Grodsky et al., 2012). Barrier layers increase the potential energy gradient, inhibit sea surface temperature (SST) cooling, and can support enhanced enthalpy fluxes into the atmosphere during hurricanes (Wang et al., 2011; Balaguru et al., 2012; Rudzin et al., 2018; Rudzin et al., 2019; Balaguru et al., 2020; Rudzin et al., 2020; Sanabia and Jayne, 2020). Only a few observations and studies have explicitly focused on the interactions of TCs passing over the Mississippi river-induced salinity barrier layer (Le Hénaff et al., 2021; John et al., 2023). This barrier layer is a product of the largest river outflow in the US from the Mississippi River, in a region where strong hurricanes make landfall and coastal communities have repeatedly been devastated by powerful landfalling hurricanes, including Hurricane Ida in the summer of 2021.

Hurricane Ida (2021) underwent rapid intensification (RI) over the warm waters of the Gulf of Mexico (GoM) (Figure 1), with an increase in maximum wind speed of 60 kts (~30 m/s) in 24 hours (Beven et al., 2022). Ida continued to intensify as it passed over the continental shelf before making landfall as a category 4 hurricane in Louisiana on August 29th (Figure 1) as the second costliest storm to make landfall in the region after Hurricane Katrina (2005); (Smith, 2020). A recent study (Zhu et al., 2022) identified that nearshore SSTs ahead of Ida were >30°C, above the mean SSTs (28.7°C) that other major hurricanes crossed over in the region. They also

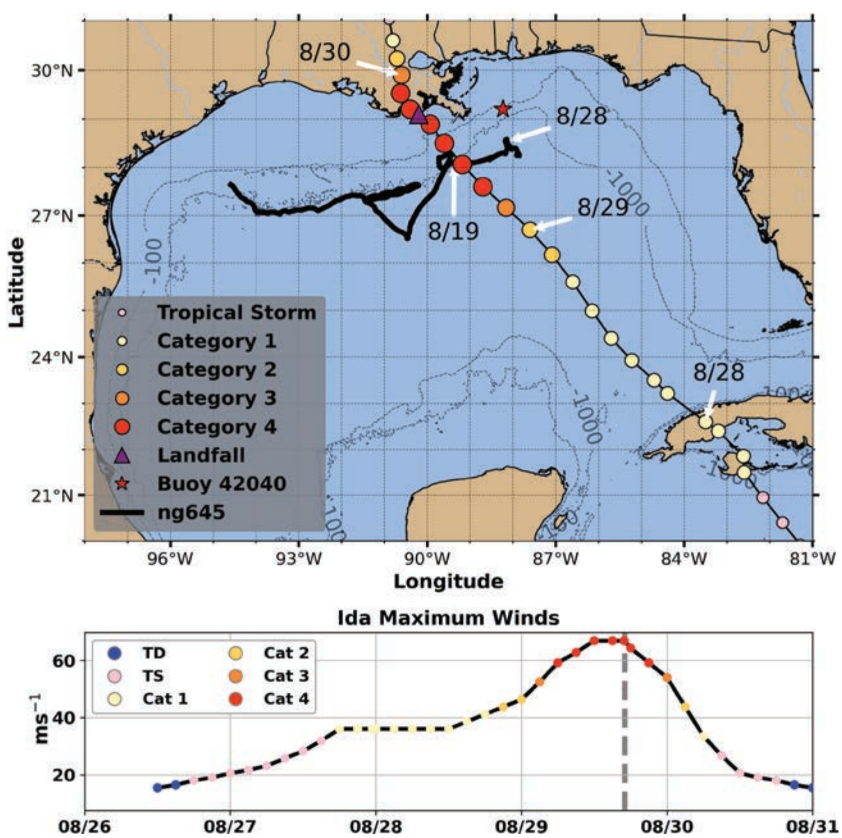

FIGURE 1
A map (top) of Hurricane Ida's NHC best track with colored circles denoting the storm's category in three-hour increments, with an additional purple triangle denoting landfall. Arrows pointing to track locations indicate Ida's position on 8/28, 8/29, and 8/30 for reference. The black line indicates the NG645 glider track, with additional arrows indicating the glider position on 8/19 and 8/28 for reference to profiles used to initialize our PWP experiments. NDBC Buoy 42040 is represented by the red star. A time-series (bottom) of Ida's NHC best track maximum wind speed and intensity (colored circles) as well as the storms landfall time (dashed grey line).

indicated that slow translation speeds kept the backside of the storm over these warm and fresh waters for an extended duration, contributing to Ida's slow weakening after landfall. While there is a large body of research on freshwater plume, or salinity barrier layer, impacts on hurricane intensity there are only a few focused on the Mississippi River plume (Le Hénaff et al., 2021; John et al., 2023). Despite major hurricanes regularly transiting this region, there are limited upper ocean observations during storm events in this region. For example, in the highly dynamic region where Ida rapidly reached and maintained category 4 (Figure 1) from 27.5° to 30° N and between 91° and 88.5° W only 20 Argo floats and 252 profiles are available in the last 20 years (~13 profiles/year) during hurricane season (https://erddap.ifremer.fr/erddap/index.html).

According to Beven et al. (2022), official forecasts for Hurricane Ida (2021) generally outperformed guidance and the previous five year mean official forecasts for the full storm period. However, few models or official forecasts captured Ida's peak winds at landfall including as Ida rapidly intensified over the warm waters of the central GoM and fresh Mississippi River plume coastal waters (Figures 2, 3). Fortunately, as part of the 2021 Hurricane Glider Program (Miles et al., 2021) a Navy operated and NOAA coordinated autonomous underwater glider, NG645, was deployed ahead of and during Ida's eye passage over the region (Figures 1–3). Ahead of the storm, in the deep ocean (>100m depth) just south of the GoM northern escarpment NG645 observed (Figure 2) warm sea surface temperatures, low salinity, and heat content near a threshold (60 kJ cm^{-2}) typically conducive for intensification (Mainelli et al., 2008). The presence of the freshwater barrier layer and elevated SSTs suggest that, even with marginal ocean heat content, these ocean conditions are conducive to storm intensification. In this study we investigate upper ocean metrics for storm intensification in the region Hurricane Ida (2021) passed over, as well as the sensitivity of SST cooling to the strong vertical salinity stratification in the region ahead of landfall. To carry out this work we combine the *in-situ* observations from NG645 and satellite remote sensing with a 1-D mixed layer model sensitivity experiments to evaluate the impact of barrier layer presence and absence with the Price-Weller-Pinkel (PWP) model (Price et al., 1986).

2 Methods

Ocean observations ahead of and during Hurricane Ida were obtained from Slocum glider (Schofield et al., 2007) NG645, operated by the Naval Oceanographic office in close collaboration with the Integrated Ocean Observing System (IOOS) Hurricane Glider Program. Slocum gliders are buoyancy driven uncrewed underwater vehicles that can profile vertically (up to 1000 m at ~20 cm s^{-1}) and horizontally (~ 20 km day^{-1}). They typically collect data at up-to 2 second intervals, resulting in high (<1m) vertical resolution. These systems have been used over the past decade to study upper ocean processes during TCs (Domingues et al., 2015; Glenn et al., 2016; Seroka et al., 2016; Miles et al., 2017; Seroka et al., 2017; Lim et al., 2020) and to provide near real-time data for assimilation into operational hurricane forecast models (Miles et al., 2021). NG645 specifically was operated as part of an agreement between NOAA and the Navy with the goal of providing real-time *in-situ* glider observations to improve and inform hurricane intensity forecasts.

NG645 was deployed on June 13th, 2021, offshore of the continental shelf at 27.6°N and 94.6°W. In mid-August the glider was navigated eastward south of the escarpment of the northern GoM (Figures 1–3), through the northwestern edge of a loop current eddy (LCE) and into a gap region south of the continental shelf, but north of the LCE. The glider transited in the deep (>1000 m) of water off the continental shelf for the duration of the mission. NG645 crossed ahead of Ida's track at 89.23°W and 28.12°N on August 19th, 60 km from the shelf-break and 100 km from the nearest land point. The glider did not station keep at this location but was piloted to collect a broad swath of data further eastward before station keeping on August 27th ahead of the storm at 88.17°W and 28.57°N. The region to the east of Ida's track was a gap region between the continental shelf to the north and the LCE to the south. In this study we present data from NG645 through August 31st, however the glider continued sampling through September 24th in further support of hurricane forecast models. NG645 was equipped with a standard Seabird Scientific, Inc. (SBE) pumped conductivity, temperature, and depth sensor (CTD), which reported data in at ~8s intervals. The Naval Oceanographic Office submitted data in near real-time and for archiving via the IOOS Glider Data Assembly Center (DAC). However, post-deployment data was not made available, thus intermittent data transmission issues resulted in periodic data gaps.

2.1 Upper ocean metrics

Upper ocean metrics relevant to hurricane intensity and salinity barrier layers were calculated from NG645 CTD data extracted from the IOOS GDAC (https://gliders.ioos.us/erddap/tabledap/index.html). This includes sea surface temperature and salinity and metrics described below starting with Ocean Heat Content (OHC). OHC, introduced by Leipper and Volgenau (1972), and used in operational hurricane forecasting is the vertical integral of heat from the 26°C isotherm to the surface calculated as:

$$Q = \rho_o c_p \int_{Z_{26}}^{0} (T - 26) dz$$

Where ρ_o=1025 kg m^{-3} and $c_p = 4 \times 10^3$ J kg^{-1}°C^{-1} and Z_{26} is the depth of the 26°C isotherm. The 26°C isotherm has historically been chosen to represent average subtropical atmospheric boundary layer temperatures, implying that ocean temperatures and associated heat warmer than that value would be available for flux into the relatively cooler atmosphere during a storm event, leading to storm intensification. Mainelli et al. (2008) found that in statistical hurricane intensity predictions, OHC values greater than 60 kJ cm^{-2} were predictive of storm intensification, while OHC below this threshold were predictive of weakening. However, Mainelli et al. (2008) also proposed that the larger OHC was not the direct cause of storm intensification, but rather larger OHC were related to deeper warm temperatures and thus limited SST cooling throughout storms. Other OHC value thresholds have been discussed for intensification (Jaimes et al., 2016), however for simplicity we use 60 kJ cm^{-2} as a reference throughout this work. More recent work (Balaguru et al., 2018; Potter and Rudzin, 2021) has also shown that pre-storm SST and OHC are not always a good predictor of storm intensity, particularly when there are shallow mixed layers present. Price (2009) detailed an alternative upper ocean average temperature metric T_d, where d = 100m over the deep ocean (indicated as a typical depth of mixing for a category 3 tropical cyclone) or d = the water column depth on shallow continental shelves. As NG645 was located off the continental shelf in more than 100m of water for the duration of its deployment we calculate T_d metric to 100m (T100).

Price (2009) briefly discussed necessary modifications of T_d for salinity stratified water columns, where mixing would not reach 100m in deep ocean cases or the bottom on continental shelves, and alternative dynamic temperature metrics (Balaguru et al., 2018) have been used to represent upper ocean temperatures down to the 26°C isotherm. To evaluate the role of salinity stratification in the case of Hurricane Ida we additionally calculate the potential energy anomaly (PEA), ϕ, which is the amount of energy required to vertically redistribute the mass of the water column from stratified to fully mixed (Simpson and Hunter, 1974; Simpson et al., 1981), represented by the equations:

$$\phi = \frac{1}{h} \int_{-h}^{0} (\bar{\rho} - \rho) g z dz; \quad \bar{\rho} = \frac{1}{h} \int_{-h}^{0} \rho dz$$

In this case h is equal to the 100m water depth, ρ is the density measured at a given depth z, and g is the gravitational constant. We limit the PEA to the upper 100m for similar reasons as T100, e.g. we expect TC induced upper ocean mixing to be limited to water shallower than 100m. While PEA is a useful water column metric, we also calculate barrier layer thickness (BLT) as the difference between the isothermal layer depth (ILD) and mixed layer depth (MLD). Each glider profile was evaluated for the presence of a barrier layer where the MLD was defined following de Boyer Montégut et al. (2007) using the potential density:

$$\Delta\sigma_\theta = \sigma_\theta(T_\circ - \Delta T, S_\circ) - \sigma_\theta(T_\circ, S_\circ)$$

where $T_{\circ}$ and $S_{\circ}$ are the 2m temperature and salinity, respectively. ΔT is 0.5°C. We calculated the ILD as the shallowest depth where the temperature is 0.5°C less than the $T_{\circ}$, and the BLT as the distance between the ILD and the MLD. The 0.5°C criterion is larger than that used by de Boyer Montégut et al. (2007) however it is aligned with Rudzin et al. (2017), which adapted the criteria for salinity barrier layers.

2.2 1-D mixed layer experiments

Upper ocean mixing experiments were carried out with twin PWP model simulations at two sites to investigate the role of salinity stratification in shear-driven upper ocean mixing as Ida (2021) approached and made landfall on the Louisiana coastline. The 1-D PWP model has been used extensively to study ocean mixing during hurricane conditions (Zedler et al., 2002; Wang et al., 2011; Rudzin et al., 2018; Yang et al., 2019). The PWP model is initialized from profiles of temperature and salinity and forced with observed or idealized wind stress, freshwater surface flux, and heat flux. The bulk and gradient Richardson numbers determine mixed layer and shear stability, respectively. The model uses boundary conditions to solve a non-advective momentum equation for velocity, temperature, and salinity. During the implementation of forcing at each time-step the model will check both bulk ($R_b \geq 0.65$) and gradient ($R_g \geq 0.25$) Richardson number stability criteria. If there is an instability present the water column will be iteratively mixed until the criteria are satisfied. PWP primarily includes processes and parameterizations that represent shear-induced mixing and buoyancy forcing processes, as well as rotational effects due to Coriolis, and is not designed to evaluate 3-D mixing or advective processes. Considering this limitation, we expect our model results to provide insights on the forced stage sensitivity to barrier layer presence and absence analysis of the model simulations on the ahead-of-eye forced stage and sensitivity to barrier layer presence and absence. We do not expect the PWP model to account for all upper ocean mixing and cooling processes during Ida and expect future studies to investigate those processes more broadly.

We limited external PWP model forcing to surface wind stress as in previous studies (Balaguru et al., 2020) to evaluate the isolated impact of salinity stratification on upper ocean shear-driven mixing processes. The surface wind stress was extracted in real-time from the publicly available High Resolution Rapid Refresh (HRRR) model operated by NOAA via their Operational Model Archive and Distribution System. HRRR is a 3km horizontal resolution implementation of the Weather Research and Forecasting model (Skamarock et al., 2019) updated hourly. We evaluated HRRR with the nearest National Data Buoy Center (NDBC) buoy 42040 to the northeast of Ida's track (Figure 1). Other sites were considered, however available data were either located over land, far away from study sites or experienced data loss ahead-of and during the storm event. Evaluation of the HRRR model 10m wind speeds vs 42040 showed that the wind speed magnitudes mean bias for the longest model forcing duration (08/19 to 08/31) was 0.14 m s^{-1} with a correlation coefficient of 0.92. Maximum HRRR winds were 23.63 m s^{-1} at the buoy site, or 1.24 m s^{-1} faster than observed, occurring an hour and forty minutes earlier.

2.3 Enthalpy flux and dynamic potential intensity

For intercomparison of model experiments we estimate both enthalpy flux and dynamic potential intensity. Our enthalpy flux calculations are based on bulk formula as presented in Jaimes et al. (2015) and derived from numerous observational studies in high winds (Powell et al., 2003; Black et al., 2007; Zhang et al., 2008) with wind speed dependent exchange coefficients of momentum and enthalpy. Ocean properties used in bulk formula are extracted from the PWP model experiments with an assumed 98% saturation state. However, atmospheric parameters such as 10m wind speed (U_{10}), air temperature T_a, and atmospheric specific humidity (q_a) are estimated from HRRR model output with an assumed relative humidity of 95%.

For an additional comparison with the PWP model output we calculate the dynamic potential intensity (DPI) (Balaguru et al., 2015; Rudzin et al., 2020) of our pre-storm glider data with and without the barrier layer included to evaluate how the influence of barrier layer presence and absence could potentially impact storm intensity. The DPI is calculated as:

$$DPI = \quad V_{max}^2 = \frac{T_{dy} - T_0}{T_0} \frac{C_K}{C_D} (k_{T_{dy}} - k)$$

Where T_{dy} is the average temperature of the upper ocean, T_0 is the hurricane outflow temperature at 200mb (assumed to be 221 K), $k_{T_{dy}}$ is the enthalpy of air above an ocean with a temperature of T_{dy}, and k is the specific enthalpy of air near the surface ocean. The ratio of enthalpy and drag coefficients is set to 1 for simplicity as in Rudzin et al. (2020).

$$T_{dy} = \frac{1}{L} \int_0^L T(z) dz$$

$$L = h + \left(\frac{2\rho_0 u_*^3 t}{\kappa g \alpha} \right)^{\frac{1}{3}}$$

Where h is the MLD; ρ_0 is a reference density of 1025 kg m^{-3}; $t$is the mixing time period calculated as the radius of maximum winds of the storm divided by the storm's translation speed (t= R_{max}/U_h = 1.15 hours); u_* is the surface friction velocity calculated using the maximum wind stress from HRRR output during time t, $\kappa$is the von Karman constant of 0.4; g is gravitational acceleration; α is the vertical density stratification below the mixed layer calculated as the density gradient from the MLD to 50m below the MLD. L is the forecasted mixing depth based on the initial profile and storm properties based on the Monin-Obukhov mixing length (Balaguru et al., 2015). T_{dy} is the temperature of the upper ocean if the passing storm homogeneously mixes the ocean down to a depth of L.

2.4 Additional datasets

Sea surface temperature (SST) data from the GOES-16 (Schmit et al., 2017) geostationary satellite are used to show storm SST cooling throughout the Gulf of Mexico. Daily composites of hourly GOES-16 images were extracted from 8/25 and 09/03, the last and first clear composite images before and after the storm respectively. Hurricane Ida (2021) best track information was extracted from the International Best Track Archive for Climate Stewardship (IBTrACS) dataset (Knapp et al., 2010; Knapp et al., 2018) including position and maximum wind speeds at 3 hourly intervals, with additional reported data at landfall times.

3 Results

Hurricane Ida impacted Cuba and entered the GoM late on 08/27 and into 08/28 as a category 1 storm (Figure 1). It began to intensify over the central GoM late on 08/28, and rapidly intensified to a category 4 storm over the northern GoM and continental shelf until landfall at 08/29 16:00, gradually weakening on 08/30 as it moved inland (Figure 1). A zoomed in view of Ida's track and intensity in relation to glider NG645's position and pre-storm *in-situ* SST, salinity, and OHC are shown in Figure 2. These *in-situ* data show that the upper ocean was warm, and a freshwater barrier layer was present to the right of the storm track in the week prior to Ida's passage.

SST imagery ahead of the storm (08/25) showed warm pre-storm SSTs above 30°C along the storm track (Figure 3). The first clear composite image was available approximately 4-days after landfall and showed significant cooling (Figures 3) of more than 1°C over more than 230,000 km^2 of the GoM, a maximum cooling of 3.8°C on the shelf near the landfall location and 2.38°C near the glider station keeping location. Ida's rapid intensification despite this cooling implies that a significant portion of the satellite observed SST cooling occurred after the storm's eye-passage. We use *in-situ* glider data to investigate the specific timing of the cooling further.

Cross-sections (Figure 4) and derived upper ocean metrics (Figure 4) demonstrate pre-storm ocean properties during the cross-track storm survey period (08/17 – 08/27) and the ocean response to the right of the storm track during the station keeping period (08/27 – 08/31). During the pre-storm survey period the glider observed an isothermal warm (>30°C) layer extending to ~30 meters depth to the west and ahead of the storm track. As the glider progressed eastward the isothermal layer shoaled to<20 meters. In contrast, the MLD was found near the surface (<5m) because of a shallow layer of low salinity water (~ 32.5 to 34.5 PSU) aside from a brief salty surface salinity on 08/17.

T100 showed warm average upper ocean temperatures to the west peaking at (28.2°C) and cooler temperatures to the east reaching a minimum of 23.4°C where the glider began its station keeping mission (Figure 5C). Ocean heat content (Figure 5D) had a similar pattern as T100, notably with values above the 60 kJ cm^{-2} threshold identified for hurricane intensification by Mainelli et al. (2008) on the western portion of the track. Observed OHC dropped below that threshold on 08/23 as the glider progressed eastward reaching a minimum of 25 kJ cm^{-2} as the glider started its station keeping mission. Aside from a brief dip to 400 J m^{-3} on 08/21 the PEA remained near 500 J m^{-3} throughout the pre-storm survey (Figure 5E). The consistently high PEA indicates that the water column stability was high, and the SST was not likely to cool to the full T100 value, despite the strength of the storm. For context, later in section 4 we detail the difference in PEA with and without a barrier layer as shown in (Figure 6).

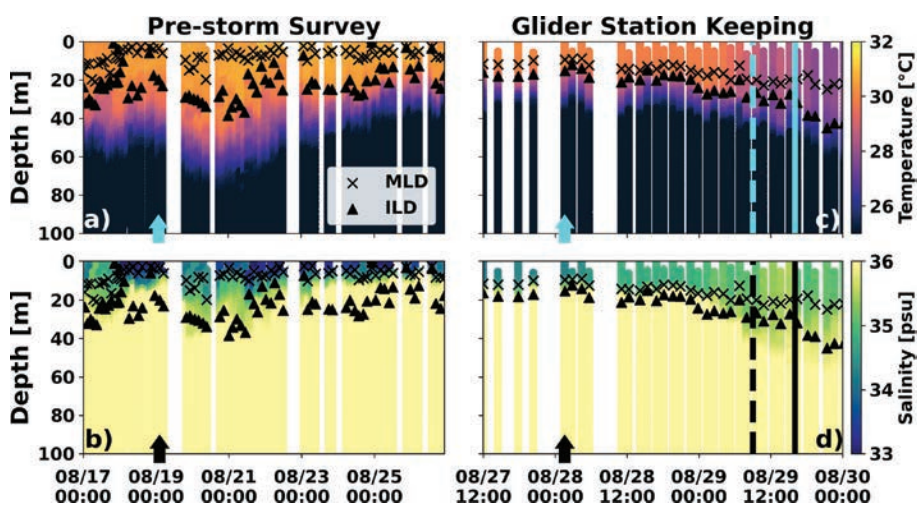

FIGURE 4
Glider NG645 cross-sections of temperature **(A, C)** and salinity **(B, D)** during the pre-storm survey **(A, B)** 8/17 to 8/27 and glider station keeping (c,d) 8/27 to 8/30 0900. MLD and ILD estimates are represented by x's and triangles, respectively in all panels. The arrow in the pre-storm survey **(A, B)** on 8/19 denotes the glider profile used in PWP experiment 1, and the arrow in the glider station keeping **(C, D)** on 8/28 denotes the glider profile used in PWP experiment 2. The vertical lines represent the times that Hurricane Ida passed the glider (dashed line) and made landfall (solid line), respectively.

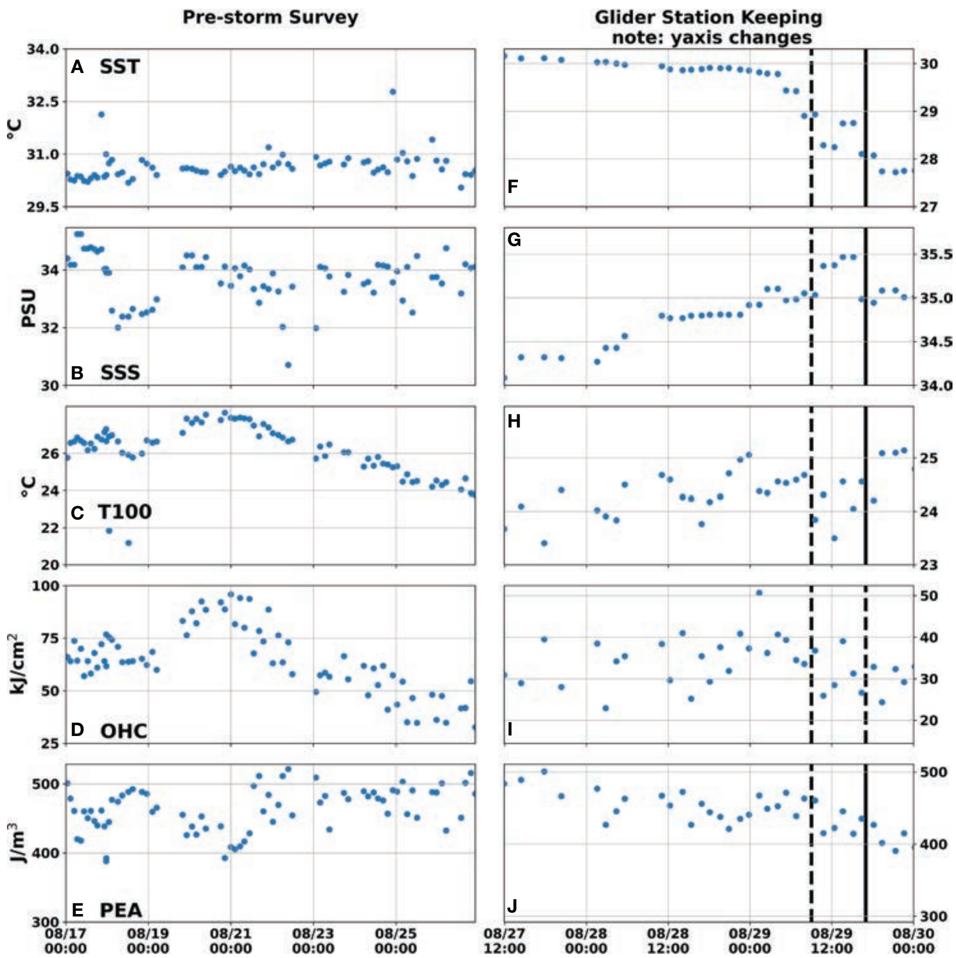

FIGURE 5
Upper ocean metrics derived from NG645 data split into pre-storm survey **(A–E)** 8/17 to 8/27 and glider station keeping **(F–J)** 8/27 to 8/30. SST **(A, F)**, SSS **(B, G)**, T100 **(C, H)**, OHC **(D, I)**, and PEA **(E, J)**. Note the glider station keeping y-axis differs from the pre-storm survey. The vertical lines represent the times when Hurricane Ida passed the glider (dashed line) and made landfall (solid line), respectively.

During the station keeping period the glider showed that the upper ocean cooled, increased in salinity, and both the ILD and MLD deepened throughout and following the storm event (Figures 5F–J). From 8/28 to eye-passage and landfall the SST cooled by 1.1°C and 1.96°C, respectively. This represents less than half of the satellite observed ocean cooling by eye-passage, and 82% by landfall. Sea surface salinity only experienced a small increase of 0.44 PSU for a brief period between eye-passage and landfall (Figure 5G). The MLD and ILD deepened from ~5m to ~20m and ~18m to ~30m. T100 and OHC experienced negligible changes throughout the storm mixing period (Figures 5H, I), while PEA dropped almost 100 J m^{-3} from the station keeping period to landfall and continued to drop to 350 J m^{-3} following landfall (Figure 5J). The minimal changes in T100 and OHC paired with a large drop in PEA suggest ocean mixing processes were first breaking down the upper ocean salinity stratification before accessing deeper cold subsurface waters. We evaluate this with the 1-D PWP model in the following section.

3.1 PWP model simulations

We carry out four 1-D model mixing experiments using the PWP model to evaluate sensitivity of upper ocean temperatures to the presence and absence of the salinity barrier layer. We initialized the PWP model with temperature and salinity profiles extracted from the pre-storm glider data at two locations and times (Figure 6). Specifically, 08/19 ~02:00 where NG645 crossed ahead of Ida's future track, and 08/28 00:00 as NG645 was station keeping to the right of the storm track (Figures 1–3). We selected these two sites to focus on 1) the region of high salinity stratification directly beneath the storms track and 2) the region to the right of the track where the glider was located throughout the storm event.

Twin model experiments for each site included cases with the barrier layer removed at each study site. Initial profiles of temperature and salinity from the glider and calculated ILD and MLDs are presented in Figure 6 at each site. At both sites the initial surface temperatures were >30°C. At the along-track site

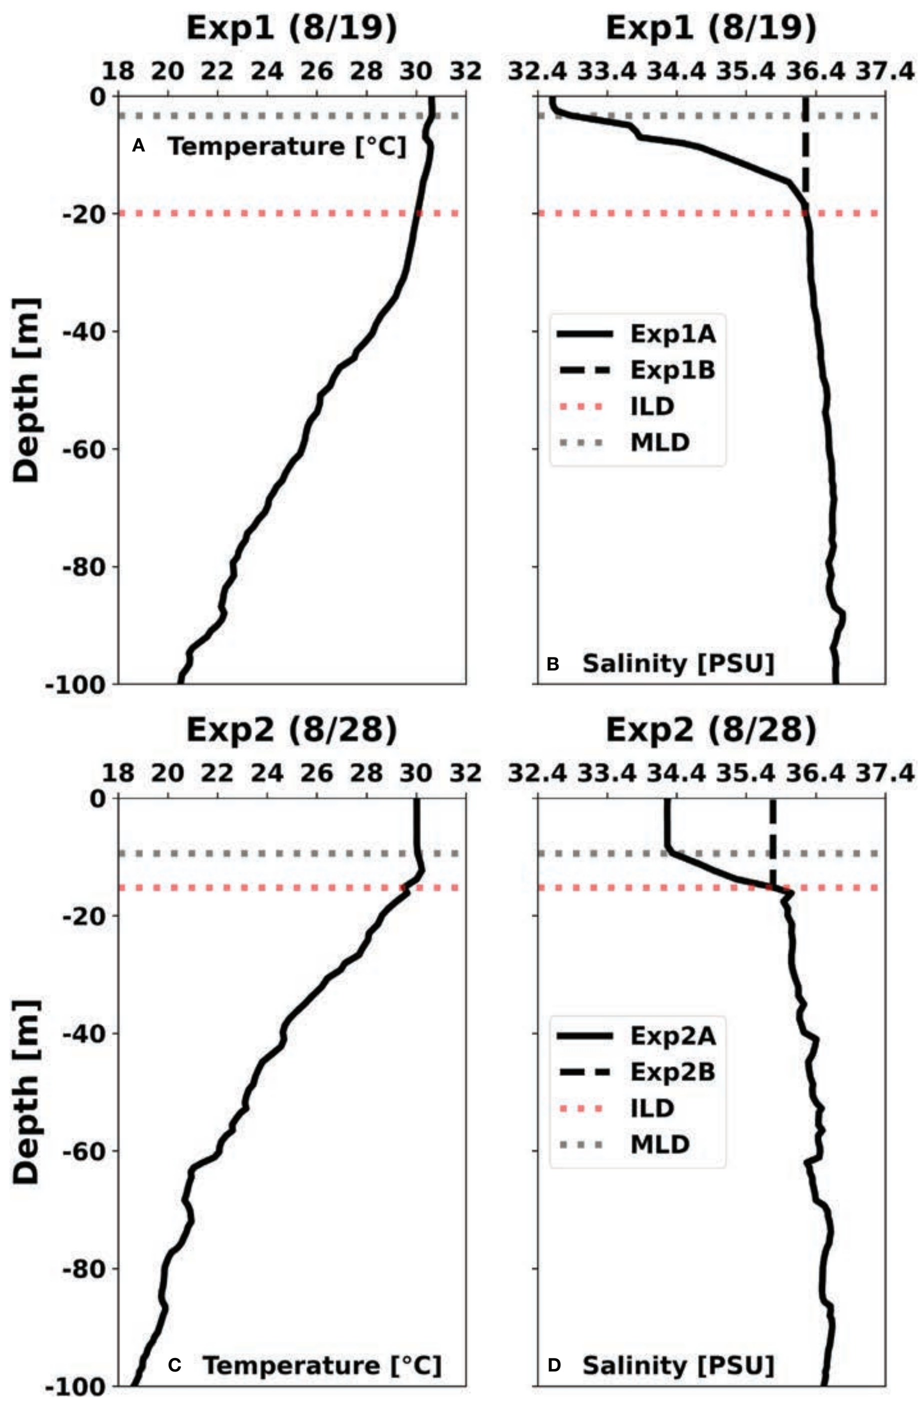

FIGURE 6
Initial profiles of temperature **(A, C)** and salinity **(B, D)** from Glider NG645 on 8/19 and 8/28 used to initalize PWP experiments 1 **(A, B)** and 2 **(B, C)**. Panel a shows the initial temperature profiles from 8/19 for Exp1A and Exp1B. Panel b) shows the initial salinity profiles from 8/19 for Exp1A inclusive of the barrier layer (solid black line) and Exp1B - barrier layer removed (dashed black line). Panel c shows the initial temperature profiles from 8/28 for Exp2A and Exp2B. **(D)** shows the initial salinity profiles from 8/28 for Exp2A inclusive of the barrier layer (solid black line) and Exp2B - barrier layer removed (dashed black line). In all panels, the dashed gray line and dashed red line represent the MLD and ILD, respectively.

(Figures 6A, B) the MLD and ILD were at 3.29m and 19.9m, respectively resulting in a 16.61m BLT. Salinity above the MLD was at 32.5 PSU and increased to 36.3 PSU at the ILD. At the glider station keep location (Figures 6C, D) the initial MLD was deeper at 9.36m and ILD shallower at 15.17m, resulting in a smaller barrier layer of 5.81m. Salinity above the MLD was 34.4 PSU and increased to 35.79 PSU at the ILD. To remove the barrier layer at both sites we extrapolated the salinity from the ILD to the sea surface as in Wang et al. (2011). Experiment 1A (Exp1A) and 1B (Exp1B) were carried out with the initial profiles from the along-track site, while experiment 2A (Exp2A) and 2B (Exp2B) were carried out with initial profiles from NG645's station keeping location. B experiments used extrapolated salinity to artificially remove the barrier layer as shown in Figures 6B, D.

Wind speeds extracted from the HRRR model at each study location are shown in Figure 7. Winds at both locations rapidly increased late on 8/28 and through 8/29 reaching a first peak just ahead of eye-passage at 8/29 08:00. Winds at the glider station-keep location used in Exp2A and Exp2B steadily decreased following this peak, while at the along-track site used in Exp1A and Exp1B winds dropped dramatically as the eye-passed and reached a second, higher, peak of over 30 m s^{-1} from the back side of the storm just before it made landfall. Wind speeds then dramatically weakened as the storm moved inland.

PWP model results for Exp1A and Exp1B are presented in Figures 8, 9. Minimal upper ocean mixing occurred during the first 6 days of the simulation thus we present results starting on 8/25 through when Ida was downgraded to a tropical storm. The upper ocean in Exp1B, with the barrier layer removed, cooled earlier and the ILD and MLD reached deeper depths than Exp1A. In Exp1A SSTs were reduced by 0.19°C at eye-passage and a total of 0.44°C by landfall. ILD and MLD reached 38m and 34m, respectively (Figures 8A, C). In Exp1B SSTs were reduced by 0.4°C at eye-passage and a total of 0.71°C by landfall. The ILD and MLD reached 44m and 41m, respectively (Figures 8B, D). With the barrier layer removed, SST cooled by an additional 0.21°C by eye-passage and 0.27°C by landfall (Figure 9B). Inclusion of the barrier layer resulted in an additional 7% cumulative enthalpy flux to the atmosphere over the 16 hours from 8/29 to landfall (Figure 9D).

For Exp2A and Exp2B presented in Figures 10, 11 we show the period 08/28 00:00 through 08/30 09:00. The upper ocean in Exp2B, with the barrier layer removed, cooled earlier and the ILD and MLD reached deeper depths than Exp2A. In Exp2A SSTs were reduced by 0.44°C at eye-passage and a total of 0.65°C by landfall. ILD and MLD reached 29m and 28m, respectively (Figures 10A, C). In Exp2B SSTs were reduced by 0.73°C at eye-passage and a total of 0.98°C by landfall. ILD and MLD reached 32m and 31m, respectively (Figures 10B, D). Thus, with the barrier layer removed SST cooled by an additional 0.29°C by eye passage and 0.34°C by landfall (Figure 11B). Similar to Exp1, inclusion of the barrier layer resulted in an additional 11% cumulative enthalpy flux over the 16 hours from 8/29 to landfall (Figure 11D).

The Exp2A control run cooled by 0.66°C and 1.31°C less than the glider observed at eye-passage and landfall, respectively. The PWP experiments presented here represent 40% (33%) of the glider observed cooling at eye-passage (landfall). This suggests that PWP captures a significant portion of the cooling and ocean processes ahead of eye-passage but has less utility in the period between eye-passage and landfall. As described previously, we did not expect PWP to capture the full range of 3-D upper ocean mixing processes (advection, Ekman pumping, inertial mixing, waves, and sub-mesoscale stratified upper ocean mixing processes). However, the twin model experiments indicate that for the 1-D shear driven processes represented by PWP the SST cooling during the landfall approach of Hurricane Ida had a large sensitivity to the presence and absence of the barrier layer. This finding agrees with idealized PWP simulations from Rudzin et al. (2019) that showed sensitivity in SST cooling to shear-driven mixing between strong and weak salinity stratification for TC wind forcing.

As an additional comparison we calculate the dynamic potential intensity as described in section 2.3, specifically for the initial conditions extracted from the glider in Exp1A and modified for the removal of the barrier layer in Exp1B at the along-track site. Exp1A initial conditions (Table 1) showed a shallower mixing depth, warmer depth integrated temperature, and higher DPI than Exp1B with the barrier layer removed. The removal of the barrier layer reduced stratification, deepened the initial MLD, resulting in a deeper mixing depth. The enhanced cooling in Exp1B led to a decrease in DPI of 5.01 m s^{-1}, which is approximately the order of the 2022 NHC official intensity error (Cangialosi et al., 2020). These findings along with the PWP model simulations show that there is a demonstrated potential for the freshwater barrier layer to enhance enthalpy flux into the atmosphere by restricting upper ocean cooling, thus contributing to Ida's continued intensification ahead of landfall.

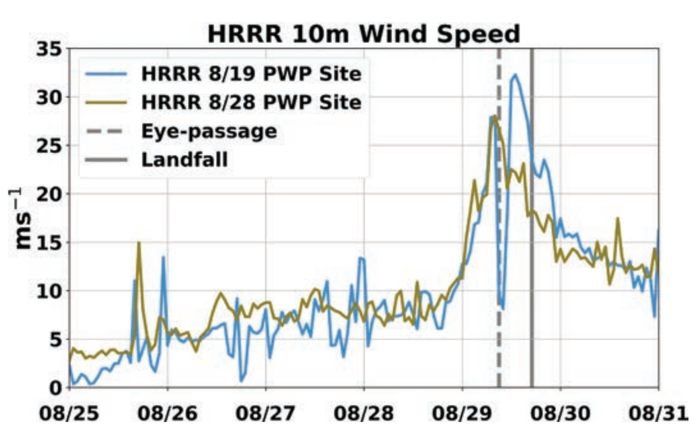

FIGURE 7
10m HRRR windspeeds extracted from the 8/19 Exp1 study-site (blue) and 8/28 Exp2 study-site (brown) used to force PWP simulations. The vertical lines represent the times at which Hurricane Ida's eye-passage (dashed line) and landfall (solid line).

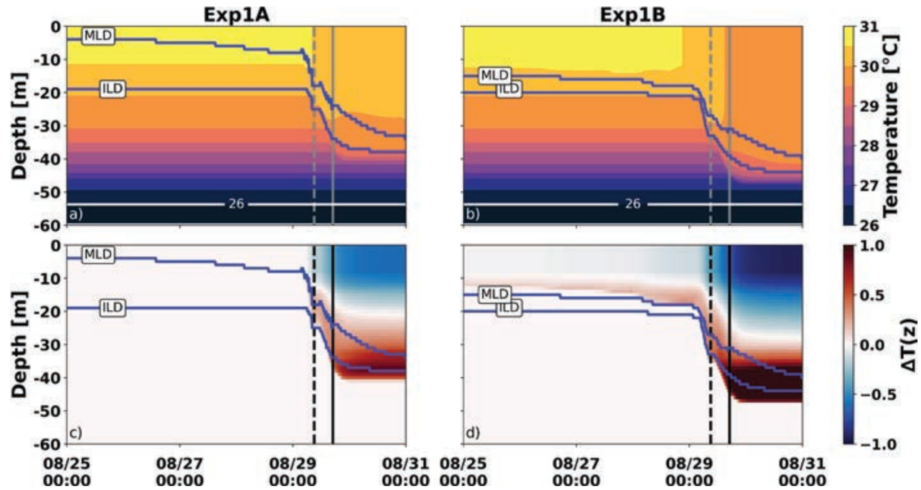

FIGURE 8
PWP model runs initialized using the 8/19 NG645 profile and simulated from 8/19 00:00 to 8/31 00:00. Exp1A **(A, C)** is inclusive of the barrier layer and depicts **(A)** temperature with the 26°C isotherm (white) and **(C)** contoured change in temperature since initialization. The MLD and ILD are labeled and contoured in blue. Panels **(B, D)** are similar but for Exp1B with the barrier layer removed as shown in Figure 6. The vertical lines represent the times at which Hurricane Ida passed the glider (dashed line) and made landfall (solid line). We limit the beginning display period from 8/25 00:00 as limited ocean cooling occurred before that time.

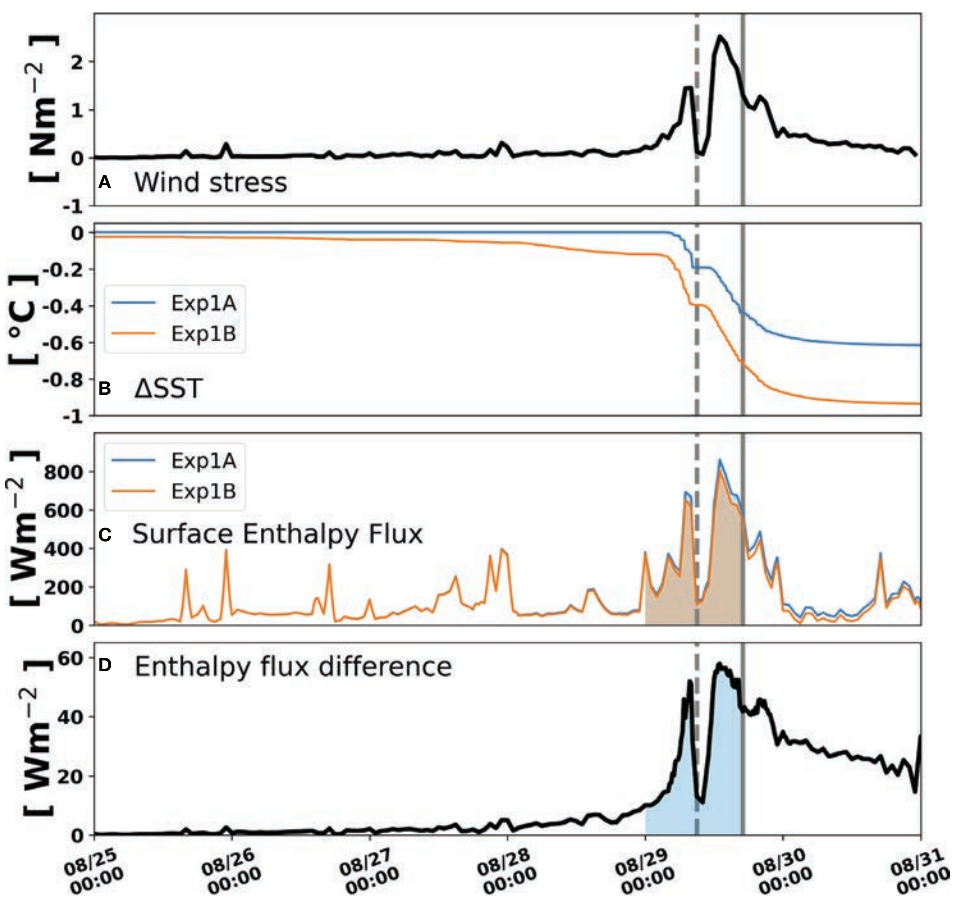

FIGURE 9
Time-series plots from experiment 1 **(A)** wind stress, **(B)** ΔSST from both Exp1A (blue) and Exp1B (orange), **(C)** surface enthalpy flux from both Exp1A (blue) and Exp1B (orange), and **(D)** difference (Exp1A – Exp1B). The shading in c and d represents the period used to calculate the cumulative enthalpy flux. The vertical lines represent the times at which Hurricane Ida passed the glider (dashed line) and made landfall (solid line).

4 Discussion

Observations from Slocum glider NG645 ahead of and beneath Hurricane Ida (2021) in the GoM captured upper ocean cooling ahead of eye-passage and landfall (Figures 4, 5). Despite this cooling, SST at the glider location just prior to landfall remained warm (28.1°C), approximately 3.5°C above T100 (24.6°C) at landfall. This indicates that the standard assumption made in

TABLE 1 A table of dynamic potential intensity parameters showing the difference between Exp1A (Barrier Layer) and Exp1B (No Barrier Layer) initial conditions from the glider location on 08/19.

	L_{pred} [m]	T_{dy} [°C]	DPI [ms^{-1}]
Exp1A (Barrier Layer)	14.51	30.52	84.49
Exp1B (No Barrier Layer)	18.10	30.10	79.48
Difference	3.58	0.42	5.01

Price (2009) that a typical category 3 hurricane will mix to ~100m was not valid for Hurricane Ida (2021) passing over the northern GoM. The freshwater barrier layer located over the deep ocean suggests that the northern GoM could be added to the list of regions where T100 is an unreliable metric such as the Bay of Bengal (McPhaden et al., 2009) or western Tropical Pacific (Price, 2009). Additionally, the glider observed OHC was just above the intensification threshold of 60 kJ cm^{-2} suggested by Mainelli et al. (2008) in its pre-storm survey period (Figure 6) and well below that threshold during the glider station keep period. Despite this relatively low OHC, Ida underwent RI and maintained its status as a Category 4 storm as it passed over the glider sampled region and made landfall. This indicates that OHC in this region was a poor metric for storm intensification, again likely due to salinity stratification as described in Price (2009). In contrast, both in the pre-storm survey and glider station- keep time periods (Figure 5) PEA of the upper 100m suggested the water column was highly stable. For reference, the PEA of the initial profiles used in PWP Exp1A and Exp2A were 460 and 477 J m^{-3}. With the barrier layer removed in Exp1B and Exp2B the initial PEAs were reduced to 327 and 381 J m^{-3}, respectively. This represents a reduction in stability of 29% and 20%, respectively with the largest reduction in the along-track region.

The reduced cooling in PWP experiments at both the along-track and glider locations simulated here due to the barrier layer is consistent with previous studies focused on other regions. In these twin model experiments the salinity barrier layer inhibited SST cooling in Exp1 (and Exp2) by 53% (57%) ahead-of-eye passage, 38% (32%) by landfall. For example, Balaguru et al. (2012) identified a 33% reduction in cooling due to barrier layers in the category 4 hurricane Omar (2008) in the northeastern Caribbean. In the Bay of Bengal Neetu et al. (2012) showed that monsoon generated barrier layers are responsible for a ~40% reduction in cooling by TCs relative to post monsoon seasons. Idealized PWP experiments in Rudzin et al. (2018) were designed to represent a range of ocean features in the eastern Caribbean that showed cooling ranges of 0.4 to 0.8 °C, also consistent with the total cooling presented here. Similarly, an idealized coupled numerical modeling barrier layer sensitivity study (Hlywiak and Nolan, 2019) showed reduced cooling of more than 0.6°C for TCs that were slow moving, strong, and with favorable atmospheric conditions for generation using barrier layer conditions typical of the Amazon-Orinoco River Plume. Balaguru et al. (2020) also carried out extensive PWP model experiments with and without salinity stratification for the Amazon-Orinoco River plume to evaluate the connection between rapid intensification (RI) and salinity barrier layer cooling inhibition. They found for idealized RI cases, salinity barrier layers reduced SST cooling by up to 0.3°C, which is consistent with what we simulated for a rapidly intensifying Hurricane Ida. For non-RI cases in their study, salinity barrier layers were only responsible for inhibiting 0.15°C of cooling, highlighting potential feedbacks between barrier layers and RI. Despite their findings in the Amazon-Orinoco River Plume, they found that barrier layers had limited impact on storm intensity in the GoM. Their study utilized the Navy Global Ocean Forecast System (GOFS) to initialize PWP. The dearth of upper ocean observations to support data assimilation in the northern GoM, and practice of using climatological river inputs in GOFS may have limited their ability to resolve the sharp upper ocean salinity gradients such as those observed by NG645.

One of the few studies (Le Hénaff et al., 2021) of barrier layer and hurricane interactions in the GoM identified a barrier layer ahead of Hurricane Michael (2018). They identified SSS<34 PSU to as far south as 27.5°N, above the 32.6 PSU SSS observed in the pre-storm survey by NG645 (Figure 2) but ~75km further south. However, a study of the intensification of Hurricane Isaac (Jaimes et al., 2016), which followed a similar track to Ida, found no evidence of barrier layers in profiles collected from air-deployed expendables. A recently published study of the ocean conditions ahead of Hurricane Sally (2020) (John et al., 2023) identified similar freshwater salinity barrier layers from the Mississippi River Plume as observed here in Ida, which contributed to continued intensification over the continental shelf. A study investigated the evolution of barrier layers during TCs globally with Argo floats (Steffen and Bourassa, 2018) using a barrier layer potential energy (BLPE) metric with similarities to PEA. They showed Argo floats between 2001 and 2014 with both low BLPE approaching 0 J m^{-2} and high >1200 J m^{-2} near overlapping at our study site. These studies and our findings indicate that barrier layers in the GoM are highly variable and can cover broad areas that hurricanes, such as Isaac (2012), Michael (2018), Sally (2020), and Ida (2021) must pass over before making landfall, and can have an impact on intensity.

The observations from NG645 and the results from the PWP sensitivity study highlight the potential importance of salinity stratification on the deep open ocean region off the continental shelf in the northern GoM, which is clearly influenced by coastal freshwater inputs. In the northern GoM a variety of thermal stratification regimes exist. In the nearshore environment it can be warm throughout the water column or highly thermally stratified. Ahead of Hurricane Michael (2018) subsurface temperatures of 22°C were observed near 10m depth to the northeast of our study-site (Dzwonkowski et al., 2020). This feature was removed during a marine heatwave that dramatically warmed the shelf waters to over 28°C in a few days. Further offshore the presence of LC/LCE waters can lead to warm and salty features that extend throughout the upper 100m and beyond (Elliott, 1982). In contrast, the region between the LC/LCE and continental shelf is typically warm at the sea surface but can have cooler waters beneath the seasonal thermocline in the upper ocean, as evidenced in the glider observations by NG645. In this “gap” region between the LC/LCEs and the continental shelf where the Mississippi River plume can be exported off the continental shelf, our findings suggest that salinity barrier layers can increase stratification and further isolate the subsurface cold water from mixing and cooling the surface. These warm and fresh surface waters would theoretically support storm intensification approaching landfall, or at a minimum reduce the oceans contribution to storm weakening.

5 Conclusion

We have shown that the standard upper ocean metrics OHC and T100 were likely not robust indicators of storm intensity in the deep waters of the northern GoM escarpment ahead of Ida's landfall. An alternative stability metric, PEA, and 1-D upper ocean mixing model experiments indicated that the presence of a freshwater barrier layer likely inhibited additional sea surface cooling and enhanced enthalpy flux under a rapidly intensifying Hurricane Ida (2021). In our experiments the removal of the barrier led to earlier, more rapid, and greater cooling, which resulted in reduced enthalpy flux to the atmosphere, and a greater DPI. This is particularly critical as it highlights an essential ocean feature, a Mississippi River plume freshwater barrier layer, in the "gap" region south of the continental shelf and north of the LC/LCE that landfalling hurricanes must cross before impacting coastal communities. While the limited utility of OHC on continental shelves and T100 in freshwater stratified layers is well-known (McPhaden et al., 2009; Price, 2009; Potter et al., 2019), salinity observations are severely lacking in this region. This study highlights the need and capability of expanded ocean observing assets along the shelf-break of the GoM to identify freshwater barrier layers and improve intensity forecasts of landfalling hurricanes in this vulnerable region.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: NG645 was operated by the Naval Oceanographic Office and coordinated by the Integrated Ocean Observing System (IOOS) Regional Association Gulf of Mexico Coastal Ocean Observing System through the Commercial Engagement Through Ocean Technology Act of 2018. Data sources included glider NG645 (https://gliders.ioos.us/erddap/tabledap/ng645-20210613T0000.html), Buoy 42040 from the National Data Buoy Center (https://www.ndbc.noaa.gov/station_history.php?station=42040). The PWP model was adapted from https://github.com/earlew/pwp_python_00.

Author contributions

TM, SC, and SG designed the initial experiments and carried out analysis. JE generated figures and carried out data analysis. SC, SG, JR, and ST provided scientific guidance and paper edits. TM prepared the manuscript for publication. All authors contributed to the article and approved the submitted version.

Funding

This work included support by the Integrated Ocean Observing System directed funding via the Mid Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) through NOAA Grant NA21NOS0120096.

Acknowledgments

We thank two reviewers for their thoughtful comments that significantly enhanced this paper. NG645 was operated by the Naval Oceanographic Office and coordinated by the Integrated Ocean Observing System (IOOS) Regional Association Gulf of Mexico Coastal Ocean Observing System through the Commercial Engagement Through Ocean Technology Act of 2018. Data sources included glider NG645 (https://gliders.ioos.us/erddap/tabledap/ng645-20210613T0000.html), Buoy 42040 from the National Data Buoy Center (https://www.ndbc.noaa.gov/station_history.php?station=42040). Abstract

The Mid-Atlantic Cold Pool is a seasonal mass of cold bottom water that extends throughout the Mid-Atlantic Bight (MAB). Formed from rapid vernal surface warming, the Cold Pool dissipates in the fall due to mixing events such as storms. The Cold Pool supports a myriad of MAB coastal ecosystems and economically valuable commercial and recreational fisheries. Offshore wind energy has been rapidly developing within the MAB in recent years. Studies in Europe demonstrate that offshore wind farms can impact ocean mixing and hence seasonal stratification; there is, however, limited information on how MAB wind development will affect the Cold Pool. Seasonal overlap between the Cold Pool and pre-construction wind lease areas at varying distances from shore in the MAB was evaluated using output from a data-assimilative ocean model. Results highlight overlap periods as well as a thermal gradient that persists after bottom temperatures warm above the threshold typically used to identify the Cold Pool. These results also demonstrate cross-shelf variability in Cold Pool evolution. This work highlights the need for more focused ocean modeling studies and observations of wind farm effects on the MAB coastal environment.

Keywords: stratification; bottom temperature; Cold Pool; offshore wind; Mid-Atlantic Bight

Introduction

The Mid-Atlantic Cold Pool is a seasonal mass of cold bottom water extending throughout the Mid-Atlantic Bight (MAB) from Nantucket, Massachusetts to Cape Hatteras, North Carolina, resulting in one of the largest thermal gradients in the world. The MAB Cold Pool is present primarily between depths of 20–100 m (Bigelow 1933). This stratification and the associated cold bottom temperatures and nutrient-rich environment support a diverse coastal ecosystem, including economically important recreational and commercial fisheries (Miles et al. 2021). Although defined wind lease areas are in flux, as of 2023, within the MAB, over 2 million acres of the continental shelf have been leased for offshore wind energy projects that are under development, including sites that overlap with the seasonal Cold Pool (Miles et al. 2021, Musial et al. 2022, Methratta et al. 2023). Limited information exists about the extent of this overlap as well as the impact of these future wind turbines on the Cold Pool (Miles et al. 2021).

The Cold Pool develops in the winter as cold water from Nantucket Shoals, north of the MAB, is transported southward to well-mixed MAB water (Houghton et al. 1982, Ou and Houghton 1982). In the spring, as surface water temperature increases and storm frequency decreases, a strong thermocline develops that isolates this cold and relatively fresh bottom water known as the Cold Pool (Bigelow 1933, Houghton et al. 1982). Stratification within the MAB is controlled and stabilized by salinity and temperature (Castelao et al. 2010). The strength of the thermocline, driven primarily by temperature, reaches a seasonal peak between July and August (Castelao et al. 2010). As surface temperatures begin to decrease in the late summer and early fall, the thermocline weakens, and fall storms eventually mix warmed stratified surface waters to the bottom, dissipating the Cold Pool (Bigelow 1933, Houghton et al. 1982, Ou and Houghton 1982, Castelao et al. 2010, Lentz 2017, Chen et al. 2018). The seasonal interannual variability of the Cold Pool can be influenced by annual large-scale climate and oceanic processes such as increased upwelling conditions or more frequent storm events (Houghton et al. 1982, Glenn et al. 2004, Li et al. 2014, Chen et al. 2018; Chen and Curchitser 2020).

There is along-shelf variation of the Cold Pool within the MAB that defines three distinct regions: the northern MAB, the central MAB, and the southern MAB (Bigelow 1933, Castelao et al. 2010, Lentz 2017). The geography of the coastline along the Central MAB enhances the coastal upwelling response to summertime southerly winds (Castelao et al. 2010). The proximity to the Hudson River within the central MAB also changes the salinity within the Cold Pool in this region compared to the northern and southern MABs (Castelao et al. 2010). The Central MAB has the coldest bottom water during peak Cold Pool months (Ou and Houghton 1982, Castelao et al. 2010, Lentz 2017).

Seasonal Cold Pool evolution is integral to MAB ecosystem processes. Upwelling along the MAB occurs each summer, transporting Cold Pool waters further inshore and toward the surface near the coast, which can drive phytoplankton blooms (Glenn and Schofield 2003, Glenn et al. 2004, Xu et al. 2011). The presence of Cold Pool water allows species ranges to extend further south than would be anticipated by latitude, supporting many economically and culturally valuable finfish and shellfish fisheries (Gabriel 1992, Lucey and Nye 2010, Murray 2016, Friedland et al. 2022). The Cold Pool can also impact hurricanes along the MAB by enabling ahead-of-eye center cooling through shear-induced mixing of the stratified water column (Glenn et al. 2016).

The USA is anticipated to become one of the largest offshore energy markets by 2030 with an estimated 2.4 million acres under lease and >2100 turbine foundations to be installed (Musial et al. 2022, Shields et al. 2022, Methratta et al. 2023). The MAB region leads the nation in proposed offshore wind energy projects with current regional offshore wind goals totaling >30 gigawatts (GW) of energy within the next decade (Musial et al. 2022, Methratta et al. 2023). European offshore wind energy has been developed extensively and can provide insight into possible interactions between turbines, physical oceanographic processes, and biological systems within the MAB, although there are key differences between the regions (Methratta et al. 2020). While still applicable, results from European studies are more representative of conditions in the MAB during relatively weakly stratified periods and do not represent Cold Pool conditions (Miles et al. 2021). Likewise, many European lease areas use smaller capacity turbines with different spacing, further adding to uncertainty about how relevant prior research is to MAB conditions (Methratta et al. 2020).

Wind turbines can directly impact hydrodynamics within and around wind farms through their underwater infrastructure and indirectly through changes in both the surface and atmospheric wind fields (van Berkel et al. 2020). Structure-induced friction and blocking from flow past cylindrical structures often form Von Kármán vortex streets, increasing the turbulence directly downstream of the turbine. In the context of the Cold Pool, this could lead to less stratified conditions (Miles et al. 2021). It is unclear what the effects will be on a highly stratified system like the MAB Cold Pool if the area of increased turbulence is expanded (Carpenter et al. 2016, van Berkel et al. 2020). Likewise, the extraction of atmospheric kinetic energy by turbines may be amplified by larger clusters of wind turbines, in turn reducing shear-driven forcing at the sea surface, decreasing horizontal velocities, and turbulent mixing within several kilometers of the wind site (Christiansen et al. 2022, Floeter et al. 2022, Golbazi et al. 2022). This could mean that within the MAB, offshore wind projects overlapping with the Cold Pool could strengthen stratification. However, recent MAB-specific modeling has illustrated a surface cooling effect due to the extreme height of the newer turbines proposed within the MAB wind farms (Golbazi et al. 2022), which could reduce stratification. North Sea-focused modeling studies have attributed lower dissolved oxygen concentrations to the potential strengthening of stratification and decrease in depth of the mixed layer due to wind wake generation and upwelling and downwelling dipoles (Daewel et al. 2022). The implications of offshore wind on the hydrodynamic features of the MAB require further study due to the key differences between the two regions such as the broader spatial extent of wind lease areas (WLAs), the weaker tidal strength, and increased storm frequency within the MAB versus Europe, as well as the technological differences in turbine design (Brunner and Lwiza 2020, Miles et al. 2021). In this paper, we evaluate the extent and cross-shelf variability of spatial overlap between pre-construction MAB WLAs and the Cold Pool. We specifically evaluate the overlap between the Cold Pool and the Bureau of Ocean Energy Management lease area call sites listed in Fig. 1. We evaluate the duration, strength, and variability of stratification where the Cold Pool overlaps with these sites within the MAB using output from a data-assimilative regional ocean model known as Doppio (López et al. 2020).

Methods

Data used in this study was simulated by the Doppio model, a Regional Ocean Modeling System (ROMS) application of the MAB and the Gulf of Maine (López et al. 2020, Wilkin et al. 2022). ROMS is a 3D hydrostatic terrain following a primitive equation model used extensively for coastal applications (Haidvogel et al. 2000, Shchepetkin and McWilliams 2005). Doppio is an implementation of ROMS with a uniform 7 km horizontal grid and 40 vertical sigma layers, covering the period of 2007–2021. It includes atmospheric forcing from National Centers for Environmental Prediction (NCEP) products, namely the North American Regional Reanalysis (NARR) (Mesinger et al. 2006) for the period of 2007–2013 and the North American Mesoscale (NAM) (Janjic et al. 2005) forecast model for 2014 and later. Boundary conditions are based on daily mean data taken from the Mercator Ocean system (Dre´villon et al. 2008) provided by Copernicus Marine Environment Monitoring Service (CMEMS) as well as the Oregon State University Tidal Prediction Software (OTPS) (Egbert and Erofeeva 2002) for harmonic tidal forcing of sea level and depth-average velocity along the open boundaries.

Additionally, Doppio uses 4-dimensional variational data assimilation (4D-Var) to obtain the best state estimate of the ocean within the domain. This includes assimilation of satellite sea surface temperature, sea surface height, HF-radar ocean surface currents, and all available *in situ* observations from the MARACOOS and NERACOOS regional associations of the US Integrated Ocean Observing System (IOOS) among other datasets (Wilkin et al. 2022). The output of Doppio used in this study spans from 2007 to 2021 and was generated by the Rutgers Ocean Modeling Group. Data were accessed in July 2023 from the THREDDS catalog of Doppio ROMS 15-year monthly reanalysis, as described in Wilkin and Levin (2022).

Metrics defining the presence and location of the Cold Pool area where the vertical temperature gradient is 0.2°C/m or greater and the bottom temperature is 10°C or less (Houghton et al. 1982, Mountain 2003, de Boyer Montégut et al. 2004, Brown et al. 2012, Li et al. 2015, Lentz 2017, Miles et al. 2021). The density stratification over the MAB region is primarily thermally controlled during the peak Cold Pool months; thus, stratification is determined by calculating the temperature gradient:

$$0.2^{\circ}C/m \leq \delta T/\delta z \,\&\, T \leq 10^{\circ}C \tag{1}$$

All 25 active WLAs within the MAB were analyzed in this study to determine the seasonal and cross-shelf overlap, more specifically with the Cold Pool. Total surface area of the Cold Pool and the MAB WLAs was extracted using ArcGIS and further analyzed (BOEM 2023). The centroid of each of the 25 MAB WLAs was used as the study location for each WLA (Fig. 1). Single points were used because the size of each WLA is small relative to the resolution of Doppio (7 km). Study locations were divided into three MAB segments based on the physical characteristics of each region: north, central,

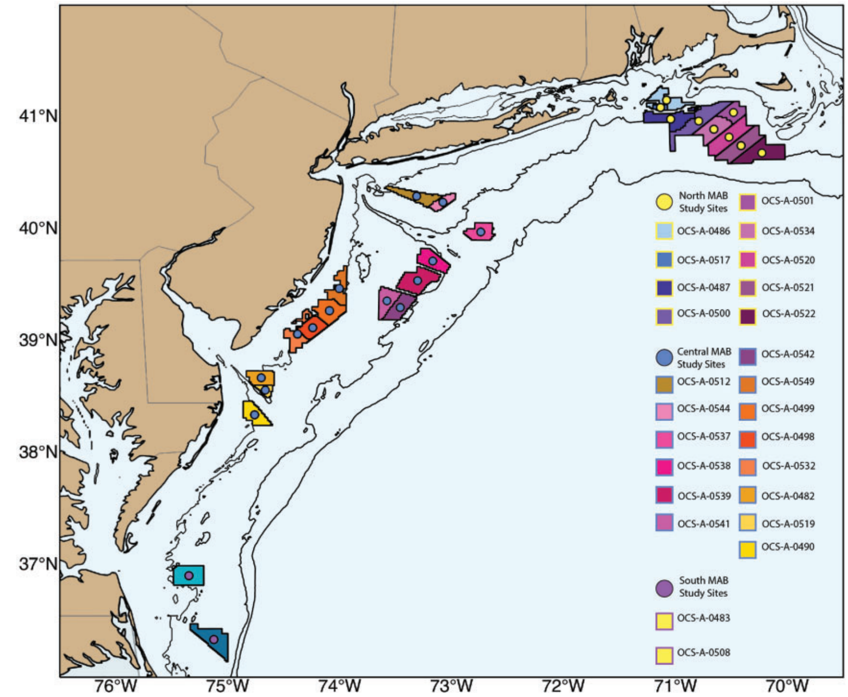

Figure 1. Study locations are depicted with circles and associated wind lease areas (WLAs) are shown as colored blocks, with colors indicating different lease blocks. The 25, 50, and 75 m isobaths are shown in black lines. Northern MAB sites correspond to the yellow circles with the lease blocks outlined in yellow. For northern MAB sites, blue hues represent nearshore sites (<43 m) and purple hues represent offshore sites (<43 m). Central MAB sites correspond to the blue circles with the lease blocks outlined in blue. For central MAB sites, yellow hues represent nearshore sites (<33 m) and pink hues represent offshore sites (<33 m). Southern MAB sites correspond to the purple circles with the lease blocks outlined in purple. The legend is organized from north to south.

and south (Bigelow 1933, Castelao et al. 2010, Lentz 2017). Within the central and northern MAB regions, study sites were further categorized into nearshore and offshore based on the average of the deepest and shallowest depths within each section. For northern MAB WLAs, the defined depth threshold is 43 m, and for central MAB WLAs, the defined depth threshold is 33 m. The southern MAB only has two WLAs, which we evaluate individually; hence, depth categorization was unnecessary. For each of these 25 study locations, the above method was used to determine the 15-year ensemble monthly averages of bottom temperatures and vertical temperature gradients, as well as standard deviations for variability across the 15-year span for each month for both criteria. Thermal gradients for each of the selected study sites were further evaluated by plotting monthly temperature-depth profiles.

Results

The MAB bottom temperatures warm from south to north and inshore to offshore, with the earliest warming along the southern and nearshore MAB regions (Fig. 2). By April, MAB areas south of New Jersey have already reached bottom temperatures above 10°C. Despite a northward bottom temperature warming trend through peak Cold Pool months, the area offshore of the New York Bight, near the Hudson Shelf Valley, remains below 8°C, even when more northern sites reach bottom temperatures close to 12°C (Fig. 2). The setup of the stratification (vertical thermal gradient values above 0.2°C/m) within the MAB is much less uniform (Fig. 3). In contrast to bottom temperature warming, stratification setup initiates in the north; however, the setup is much faster across all depths and latitudes within the MAB (Fig. 3). Reduction of stratification occurs earliest offshore and moves inshore during the later summer months (Fig. 3).

The combined stratification and bottom temperature metrics show that the Cold Pool sets up earliest at the southern edge of the MAB nearshore around North Carolina (Fig. 4). The Cold Pool remains inshore of the 50-m isobath during April and begins to set up in the NY bight at the mouth of the Hudson Shelf Valley and initiation of the Hudson Shelf Valley following stratification setup seen in Fig. 3. By May, the Cold Pool dissipated south of Delaware from warming bottom temperatures but extended northward to Massachusetts and offshore to depths of 100 m (Figs 2 and 4). Following the trend of warming bottom temperatures seen in Fig. 2, the Cold Pool weakens fastest inshore, leaving only a spatial footprint of cold bottom waters along the New York Bight in September (Figs 2 and 4).

For the central MAB WLAs, bottom temperatures within the MAB warm more rapidly nearshore than offshore (Fig. 2). Within the nearshore WLAs, bottom temperatures reach well above 10°C between April and May, while bottom temperatures in the offshore WLAs do not reach 10°C until July (Fig. 2). Nearshore, maximum bottom temperatures exceed 20°C, while the offshore bottom temperatures reach a maximum of 16°C (Fig. 2). A stratified water column (the temperature gradient is above 0.2°C/m) also forms earlier in nearshore WLAs than offshore WLAs, with nearshore values close to 0.6°C/m by April (Fig. 3). However, stratification is sustained for longer in offshore sites, with temperature gradients maintained above 0.2°C/m through September (Fig. 3).

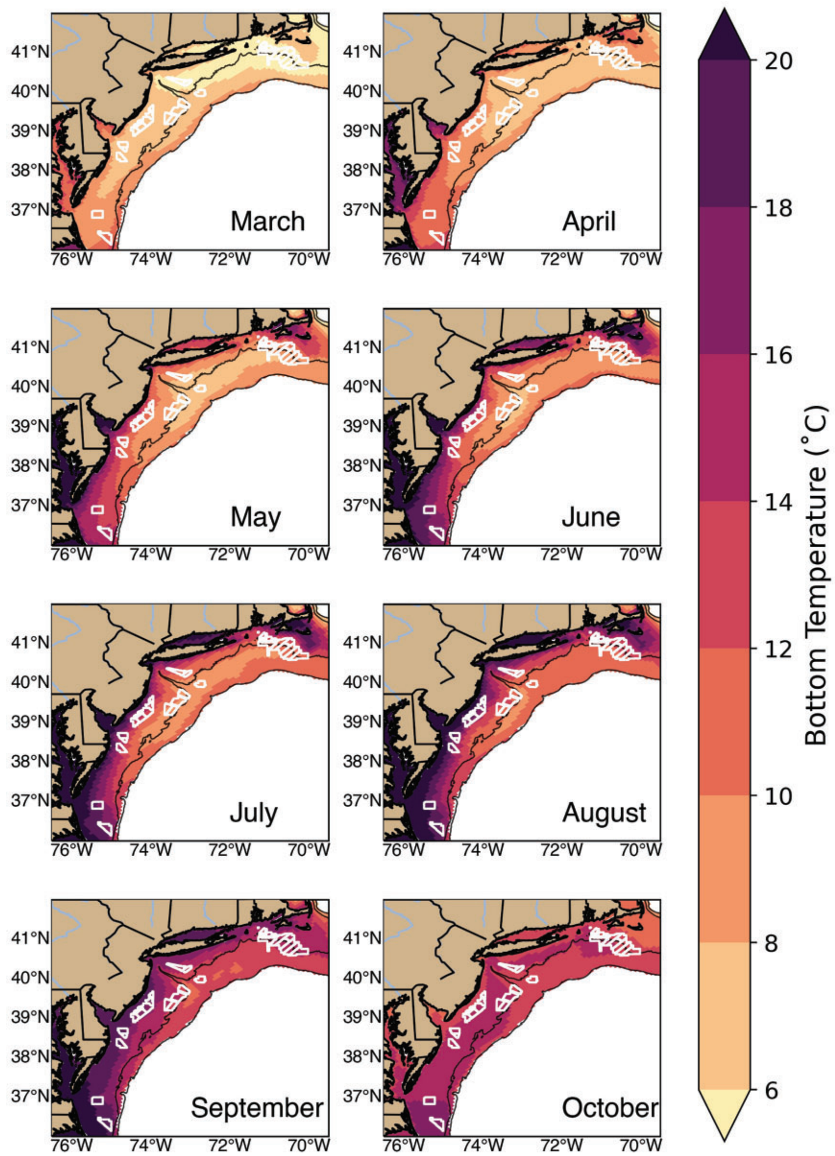

Figure 2. Monthly averaged bottom temperatures based on Doppio simulations spanning 2007 to 2021 within the MAB. Only peak Cold Pool months are included. The Cold Pool bottom temperatures are defined herein as those below the 10°C threshold. WLAs included in this study are outlined in white. The 50 and 100 m isobaths are shown in black.

Throughout peak Cold Pool months, the overlap between MAB WLAs and the Cold Pool varies substantially (Fig. 4). In the month of March, despite the Cold Pool's surface area of 1109 km^2, there is no overlap with the MAB WLAs (Fig. 4). In the month of April, the surface area of the Cold Pool expanded to 19 595 km^2 (Fig. 4). 19% of the MAB WLAs overlapped with the Cold Pool in April, although only 9% of the Cold Pool was covered by MAB WLAs (Fig. 4). In May, the Cold Pool surface area peaked at 56 153 km^2, and the MAB WLAs overlap with the Cold Pool increased to 81%, the highest annual overlap. Despite this large overlap, only 13% of the May Cold Pool was covered by MAB WLAs (Fig. 4). In June, the Cold Pool surface area covered 50 787 km^2, and 62% of the MAB WLAs overlapped (Fig. 4). Only 11% of the June Cold Pool was covered by the MAB WLAs (Fig. 4). In July, the Cold Pool surface area decreased to 36 942 km^2, and 41% of the MAB WLAs overlapped with 10% of the Cold Pool covered by the WLAs (Fig. 4). August is the last month of significant overlap between the Cold Pool and WLAs. The surface area of the August Cold Pool decreased to 19 333 km^2 with only 18% of the Cold Pool covered by WLAs and only 8% of WLAs overlap (Fig. 4). September was the only month that had a larger percentage of WLAs overlap with the Cold Pool (0.3%) than the percentage of the Cold Pool covered by WLAs (0.1%) (Fig. 4).

There are limited latitudinal differences in the duration and strength of the Cold Pool based on both metrics across the nine northern WLAs. Four of the northern MAB sites are nearshore with depths shallower than 43 m. The offshore sites (the remainder of the northern WLAs) are at ∼50 m depth (Fig. 1). All eight northern MAB WLAs had stratification strength reach 0.2°C/m in the month of May while maintaining the bottom temperature below 10°C, signifying the presence of the Cold Pool starting in May (Fig. 5). The four nearshore sites had bottom temperatures warm above 10°C

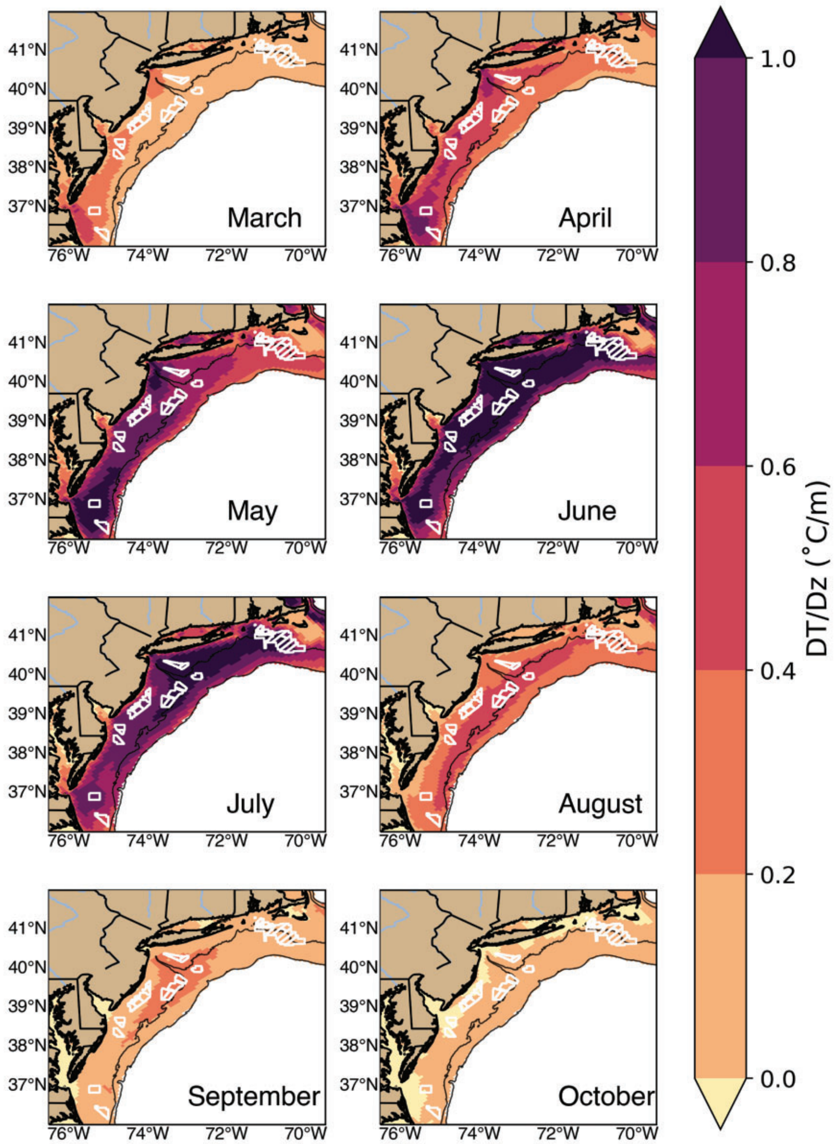

Figure 3. Monthly averaged temperature gradient values (dT/dz [°C/m)] based on Doppio simulations spanning 2007 to 2021 within the MAB. Only peak Cold Pool months are included. Cold Pool stratification is defined herein as dT/dz > 0.2°C/m. WLAs included in this study are outlined in white. The 50 and 100 m isobaths are shown in black.

in the month of June, while the four offshore sites had bottom temperatures warm above the Cold Pool threshold in the month of July (Fig. 5).

Despite the difference in duration of the Cold Pool of one month versus two between the nearshore and offshore sites within the northern MAB, the evolution of the stratification strength and bottom temperatures between the groups was not noticeably different. All eight sites had thermal gradients peak in July at between 1 and 1.5°C/m, despite the faster warming of bottom temperatures within the four nearshore sites (Fig. 5). Even with the rapid warming of the bottom temperature above 10°C, in all eight MAB sites, the stratification strength remained above 0.2°C/m until September (Fig. 5). In all eight northern MAB sites, the minimum bottom temperature occurred well before the stratification strength reached 0.2°C/m in either March or February (Fig. 5). The maximum bottom temperature occurred in October in all eight sites (Fig. 5).

Thermal gradients for each of the northern selected study sites were further evaluated by plotting monthly temperature-depth profiles. In peak Cold Pool months, the vertical temperature gradient is similar between all study sites, despite the differences in depth and distance from shore (Fig. 6). Surface water temperature variability was relatively low across all eight sites with a 2°C difference throughout peak Cold Pool months.

Latitudinal differences can be seen in the duration and strength of the Cold Pool based on both metrics across the 14 central MAB study locations. The six central MAB offshore study locations are below 33 m of water depth, while the eight nearshore sites are <33 m of depth (Fig. 1). All six offshore study locations had bottom water temperatures below 10°C and a thermal gradient >0.2°C/m in the month of May, signifying the presence of the Cold Pool (Fig. 7). The bottom temperature at five of these offshore study points exceeded 10°C in August, meaning the Cold Pool duration there was

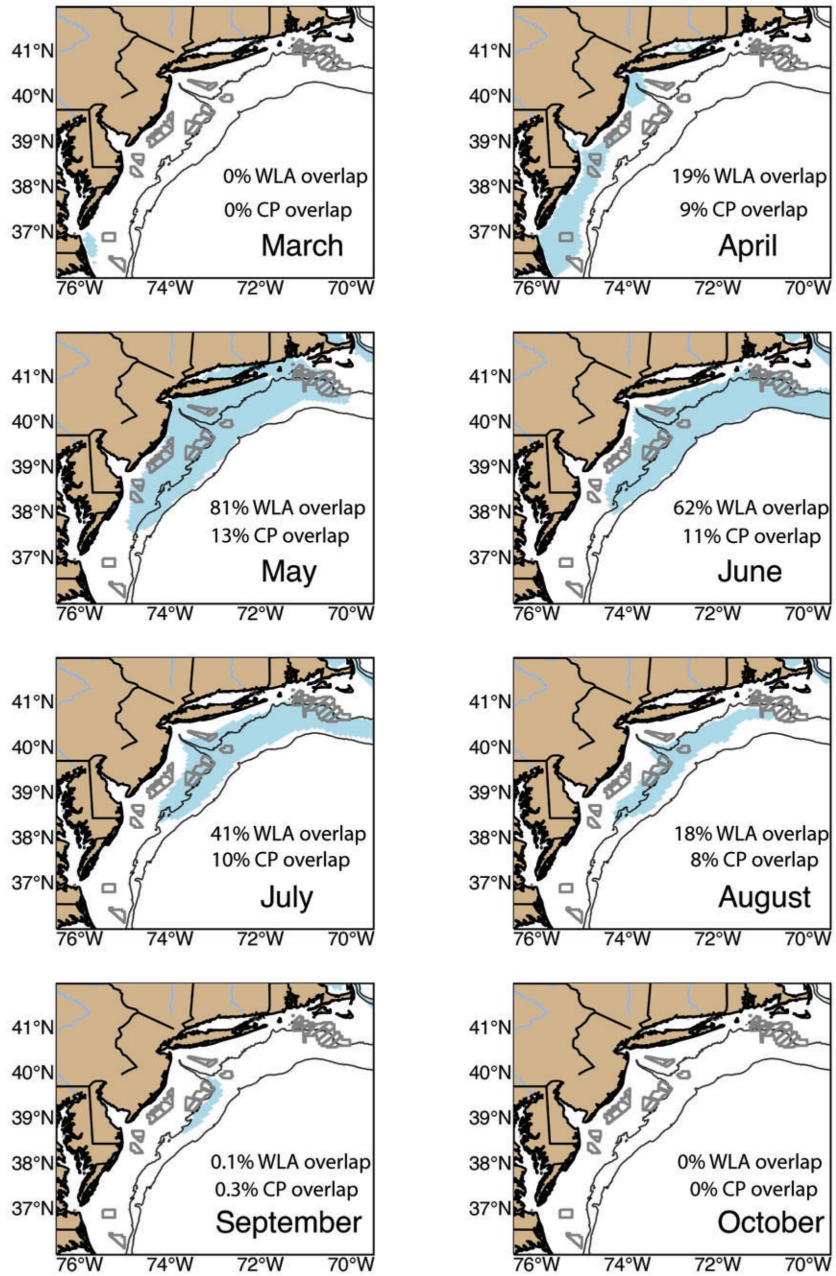

Figure 4. The Cold Pool is present in the areas of the shelf shaded in blue, which represent both bottom temperatures below 10°C and temperature gradients >0.2°C/m. Calculations were made based on Doppio simulations spanning 2007–2021 within the MAB. Only peak Cold Pool months are shown. Wind lease areas included in this study are outlined in gray. The 50- and 100-m isobaths are shown in black. Wind Lease Area Overlap with the Cold Pool (WLA overlap) and Cold Pool Covered by Wind Lease Areas (Cold Pool Overlap) percentages in km^2 are listed for each month in each panel.

approximately three months (Fig. 7). Despite the warming bottom temperatures in all six offshore sites, stratification above 0.2°C/m was maintained for three additional months dissipating in October (Fig. 7). Peak thermal gradient values occurred in July for all six offshore WLAs (Fig. 7). The highest bottom temperatures occurred as stratification broke down around October or November, consistent with downward mixing of warm surface waters due to fall transition storms.

There are notable differences in the Cold Pool evolution between the nearshore and offshore WLAs. In the eight central MAB nearshore, Cold Pool duration was shorter, spanning approximately one month, starting in April with increasing stratification and ending in May when the bottom temperature surpassed 10°C (Fig. 7). Despite the short duration of the Cold Pool, high thermal gradient values (>0.2°C/m) in these eight nearshore sites lasted for six months, dissipating in September (Fig. 7). Like the central MAB offshore WLAs, thermal gradients peaked at the nearshore sites in July. Despite an earlier development of stratification at the nearshore sites, the thermal gradient weakened at approximately the same time as the offshore sites (Fig. 7). Bottom temperatures reached a greater maximum value at the nearshore sites by >3°C (Fig. 7). Peak thermal gradient values were relatively similar between the central MAB nearshore and offshore WLAs.

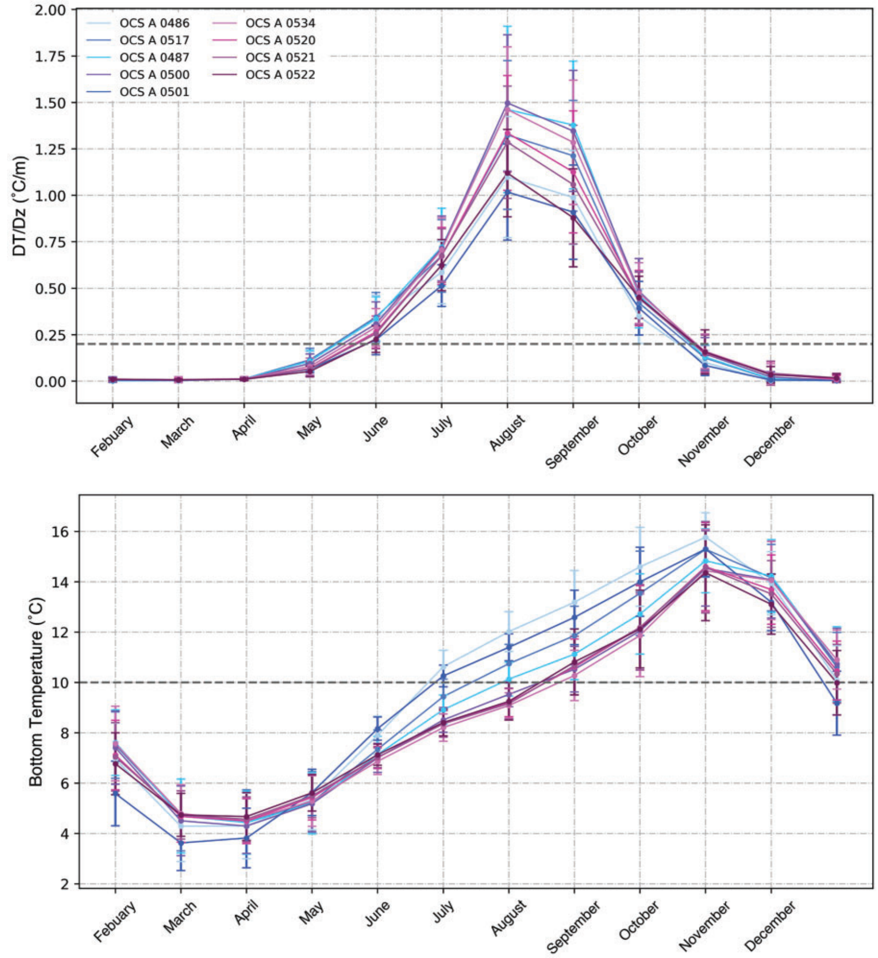

Figure 5. Monthly average bottom temperature (lower panel) and dT/dz values (upper panel) from 2007–2021 for northern MAB study locations based on Doppio simulations. Colors correspond to the specified wind lease area shown in Fig. 1. The Cold Pool exists when bottom temperatures remain below the dashed gray line and dT/dz values are above the above gray dashed line. Error bars show the standard deviation of variability for each month between 2007 and 2022. Blue hues represent nearshore sites (<43 m) and purple hues represent offshore sites (<43 m).

Thermal gradients for each of the selected central MAB study sites were further evaluated by plotting monthly temperature-depth profiles. In peak Cold Pool months, the vertical temperature gradient is similar between all study sites, despite the differences in depth and distance from shore (Fig. 8). Surface temperatures across all six sites differed the most in May and June with 3°C differences among sites. The difference in surface water temperature between sites decreased across Cold Pool months, while the difference in bottom temperatures increased, with a maximum difference in September of around 7°C between nearshore and offshore sites (Fig. 8). During July and August, surface temperatures at the nearshore sites were cooler and bottom temperature warmer than those of the offshore sites. The vertical temperature gradient values at the nearshore and offshore sites were similar, despite differences in depth and bottom temperatures.

Based on bottom temperature and stratification thresholds, the Cold Pool is only present in one of the two southern MAB WLAs, OCS-A-0483. Despite the presence of the Cold Pool according to the thresholds defined, the bottom temperature warms above 10°C within the same month that the stratification reaches 0.2°C/m for OCS-A-0483, meaning the Cold Pool presence is limited to one month (Fig. 9). Even with the warm bottom temperatures for both southern MAB WLAs, the stratification strength does reach 0.2°C/m and remains above the Cold Pool thermal gradient threshold until September for both sites (Fig. 9). Even in the southern MAB site, where the Cold Pool, according to the thresholds given, is not present, the bottom temperature reaches below 10°C. Not, however, simultaneously with the thermal gradient reaching 0.2°C/m. Both sites have peak thermal gradients in the month of June and maximum bottom temperatures warmer than the other two MAB regions. Based on the temperature profiles for the southern MAB WLAs, it is clear that the region does not have the same stratification strength as the northern and central MAB WLAs (Fig. 10).

Discussion

Regional Cold Pool trends offshore of New Jersey in this study are consistent with those of previous studies that discuss the spatial and temporal variability of the Cold Pool (Houghton et al. 1982, Ou and Houghton 1982, Mountain 2003, Castelao et al. 2010, Brown et al. 2012, Lentz 2017, Chen et al. 2018). Our work provides additional

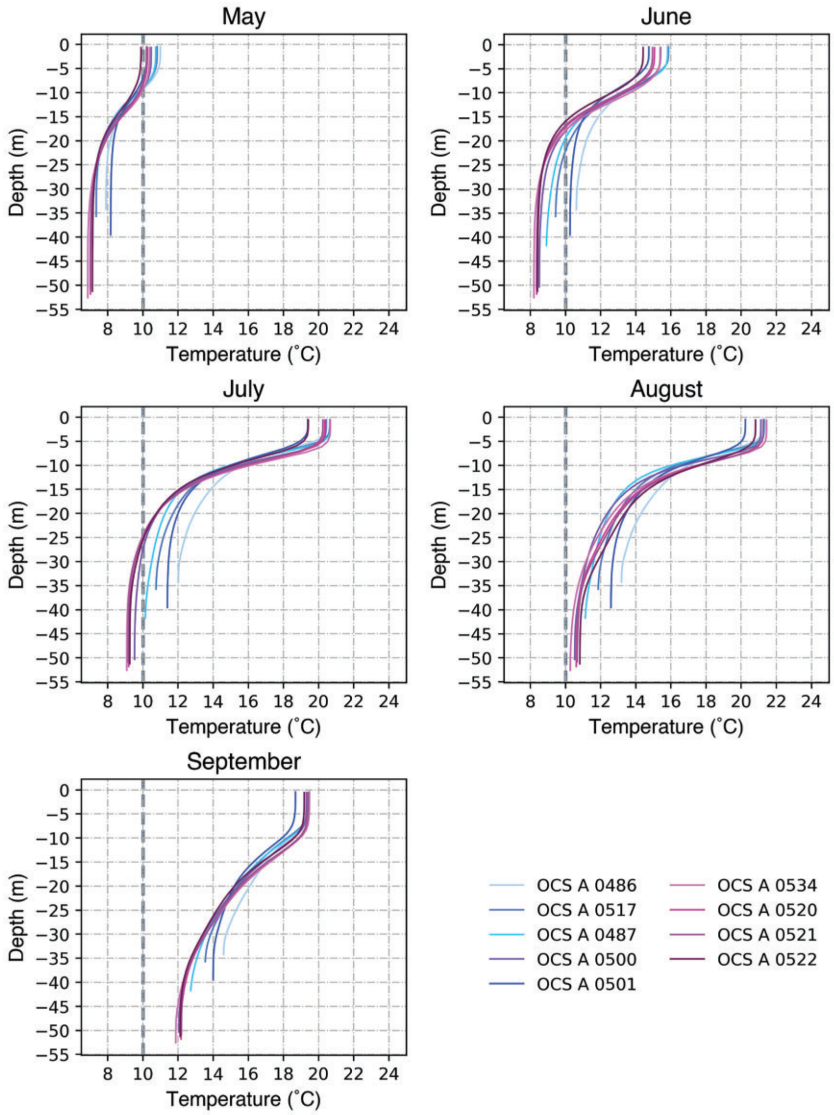

Figure 6. Northern MAB WLAs temperature profiles for Cold Pool months based on monthly averaged Doppio simulations from 2007 to 2021. Cold Pool bottom temperature threshold is depicted with the gray dashed line. The color of each profile corresponds to a study point within the selected wind areas shown in Fig. 1. Blue hues represent nearshore sites (<43 m) and purple hues represent offshore sites (<43 m).

context related to the co-location of this essential ocean feature and WLAs, but we provide some general comparisons with their results. Lentz (2017) utilizes observational data from the National Center for Environmental Information (NCEI) World Ocean Database, generally between 1955 and 2014 (Boyer et al. 2013), while Chen et al. (2018) are based on modeling results from a regional ROMS model that covers 1958–2007. While the DOPPIO model configuration has similarities to Chen et al. (2018), DOPPIO is a data-assimilative ocean model that benefits from both the extensive observations throughout the region and continuous spatial and temporal coverage of a modeling system. Generally, nearshore bottom temperatures warmed more quickly than offshore, which is consistent with previous results (Lentz 2017, Chen et al. 2018). However, we found that the bottom temperatures within the regional MAB were warmer than those reported in previous studies, accompanied by higher temperature gradients (Lentz 2017). Generally, the Cold Pool is shorter in duration at areas of shallower depths (Lentz 2017, Chen et al. 2018). These differences could be a result of the differing time periods between DOPPIO and the observations and models used in Lentz (2017) and Chen et al. (2018), as the Cold Pool has undergone significant warming over the last 40 years (Friedland et al. 2022). Previous studies have defined Cold Pool dissipation as the decrease in stratification strength in early fall from increased mixing by storm events and warming bottom temperatures (Lentz 2017, Chen et al. 2018). While findings in this study support the strengthened thermal gradient extending into the early fall, bottom temperatures at our study locations were consistently above accepted Cold Pool thresholds after May depending on the region. The thermal gradient in the central MAB has been observed to be greater than in other areas of the MAB, which is consistent with previous work (Lentz 2017, Chen et al. 2018). These previous studies indicate the maximum temperature gradients are between 0.5 and 0.8°C/m (Lentz 2017, Chen et al. 2018), while in both offshore and nearshore sites in this study they exceeded 1°C/m.

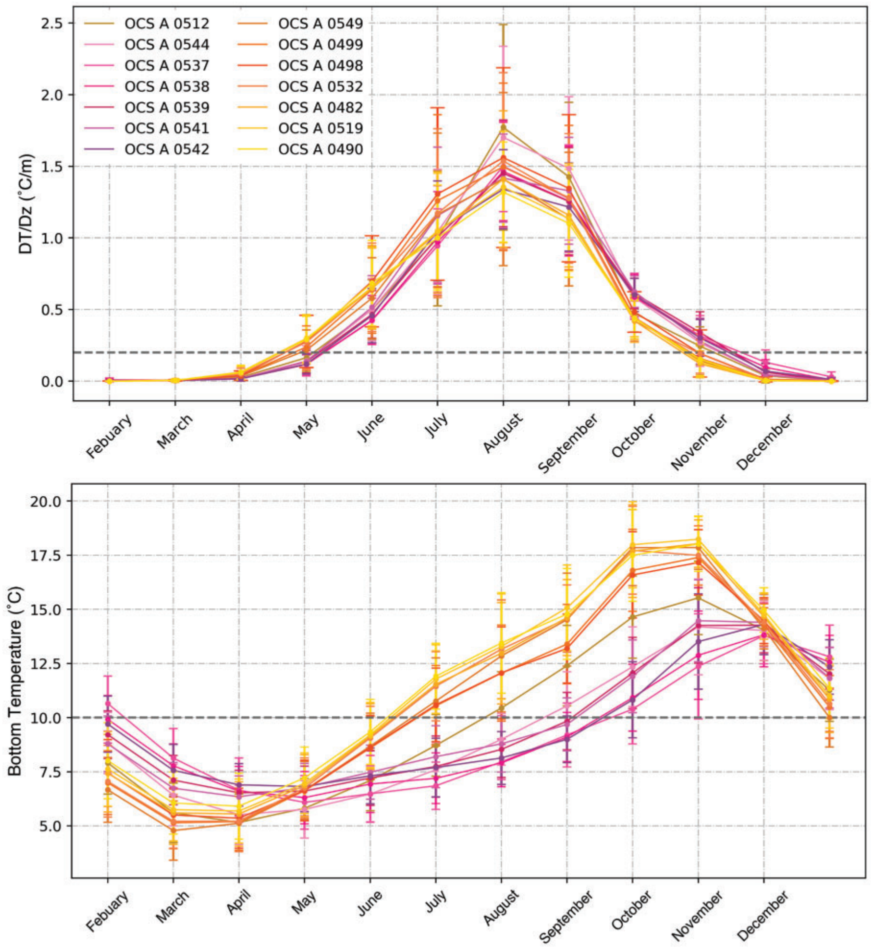

Figure 7. Monthly average bottom temperature (lower panel) and dT/dz values (upper panel) from 2007 to 2021 for central MAB study locations based on Doppio simulations. Colors correspond to the specified wind lease area shown in Fig. 1. Yellow hues represent nearshore sites (<33 m) while pink hues represent offshore sites (<33 m). The Cold Pool exists when bottom temperatures remain below the dashed gray line and dT/dz values are above the above gray dashed line. Error bars show the standard deviation of variability for each month between 2007 and 2022.

Cold Pool breakdown criteria have previously identified as bottom temperatures warming above 10°C and weakening of the thermal gradient below 0.2°C/m (Houghton et al. 1982, Lentz 2017, Chen et al. 2018); however, we found that the vertical thermal gradient remains above 0.2°C/m well beyond the time of bottom temperature warming above 10°C. Even at the nearshore sites where higher maximum vertical thermal gradient values are observed, stratification extends months after the bottom temperature warms. Stratification is the buoyancy force that inhibits mixing by flow past structures such as wind turbines, and it maintains ecologically important habitat (Miles et al. 2021). Atlantic Surf clams, Ocean Quahogs, and Sea Scallops are among the most economically valuable fisheries within the MAB region (Munroe et al. 2016, Powell et al. 2020, Miles et al. 2021, Friedland et al. 2022). These species are thermally sensitive and their distribution is often an indicator of changing bottom temperatures (Powell et al. 2020, Friedland et al. 2022). A 2023 study found that 20% of 177 species of MAB forage fish preferentially used habitat within WLAs (Friedland et al. 2023). Changes in stratification that have the potential to affect primary productivity may heavily impact these ecologically important species (Daewel et al. 2022, Friedland et al. 2023). Other demersal fish, such as the Yellowtail Flounder, use the changing bottom temperatures to trigger important life-stage changes (Sullivan et al. 2005, Sackett et al. 2008). Thermal gradients, changes in bottom temperature, and consequent changes in primary productivity could directly impact these and other commercially and ecologically important species in the region. Climate change has been warming waters within the MAB region in recent years, more specifically bottom temperatures (Wallace et al. 2018, Friedland et al. 2022, Amaya et al. 2023). Despite these warming temperatures, stratification associated with the Cold Pool has maintained values at and above 0.2°C/m. While 10°C is a useful indicator, these warming bottom temperatures may necessitate an updated bottom temperature threshold range. Because of the ecological and environmental importance of the Cold Pool, several metrics, in addition to bottom temperature, should be used to evaluate the Cold Pool.

This study shows a larger spatial and temporal overlap between the Cold Pool and WLAs further offshore versus wind lease areas closer to shore. We observed in this study that the average variation from 2007–2021 in Cold Pool metrics was limited for both bottom temperatures and stratification. Despite limited decadal Cold Pool variation, previous

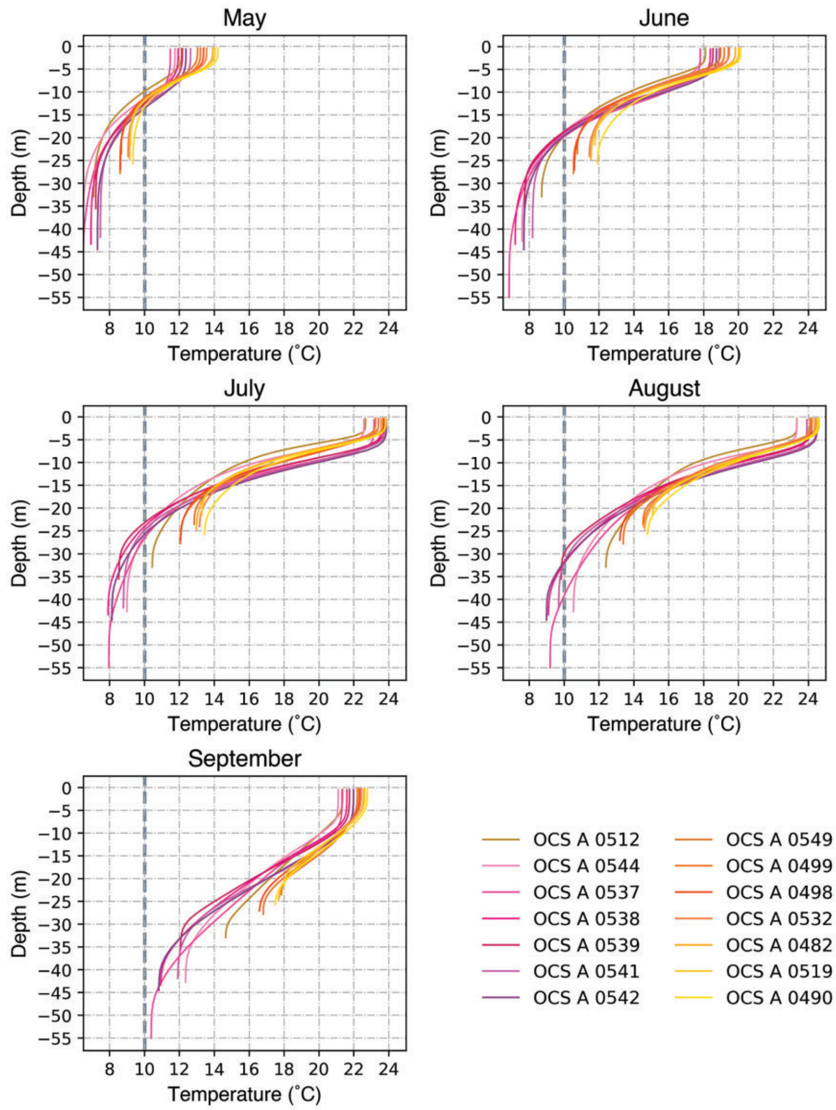

Figure 8. Central MAB WLAs temperature profiles for Cold Pool months based on monthly averaged Doppio simulations from 2007 to 2021. Cold Pool bottom temperature threshold is depicted with the gray dashed line. The color of each profile corresponds to a study point within the selected wind areas shown in Fig. 1. Yellow hues represent nearshore sites (<33 m), while pink hues represent offshore sites (<33 m).

studies have shown that broader ocean processes such as favorable upwelling or downwelling conditions can influence the daily and weekly variability of the Cold Pool (Houghton et al. 1982, Glenn et al. 2004, Li et al. 2014, Chen et al. 2018, Chen and Curchitser 2020). While we observed that there is limited overlap between the Cold Pool and MAB WLAs on a decadal time scale, daily variation in bottom temperatures and stratification can impact this overlap. Future work should evaluate short-term Cold Pool spatial variability to further increase certainty in WLAs overlap with this important regional feature.

Studies focused on European wind farms have shown that wind farms alter the hydrodynamic features of coastal environments (Carpenter et al. 2016, van Berkel et al. 2020, Christiansen et al. 2022, Floeter et al. 2022). These impacts depend heavily on the spatial extent of the wind farms as well as the temporal and spatial variability of stratification and mixing (Carpenter et al. 2016, Christiansen et al. 2022, Daewel et al. 2022). The current WLAs within the German Bight occupy a smaller area of the ocean than those proposed along the MAB. The stratification within the German Bight at depths <50 m is quantified as a 5–10°C difference between surface and bottom water temperatures, and tidal currents in this region can reach near 1.0 m/s (Carpenter et al. 2016, Christiansen et al. 2022). At the peak of thermal stratification in the German Bight during the year 2014, the bottom water temperature along the 40-m isobath only reached 14°C, resulting in a maximum thermal gradient of 0.35°C/m (Carpenter et al. 2016). During the years 2004–2013 along the 35 m isobath within the German Bight, the highest thermal gradient value was 0.37°C/m in July 2009 (Carpenter et al. 2016). The minimum peak thermal gradient value was 0.17°C/m in August 2004 (Carpenter et al. 2016). The maximum MAB thermal gradient value for the nearshore MAB sites, at a depth of ~30 m in the central region was 1.77˚C/m. The maximum stratification within the nearshore MAB sites was close to five times that of the Ger-

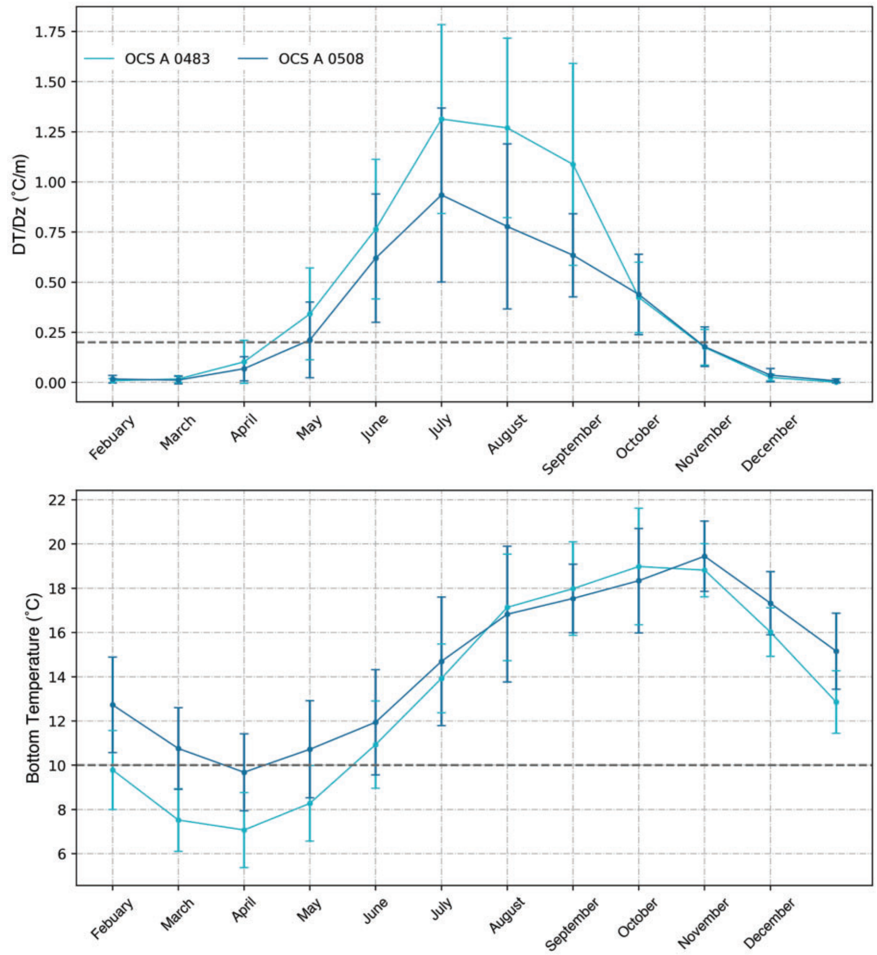

Figure 9. Monthly average bottom temperature (lower panel) and dT/dz values (upper panel) from 2007 to 2021 for southern MAB study locations based on Doppio simulations. Colors correspond to the specified wind lease area shown in Fig. 1. The Cold Pool exists when bottom temperatures remain below the dashed gray line and dT/dz values are above the above gray dashed line. Error bars show the standard deviation of variability for each month between 2007 and 2022.

man Bight. Local tidal forcing within the MAB is much weaker than the German Bight (>0.1 m/s), while storms are more frequent within the MAB (Brunner and Lwiza 2020). The German Bight, consequently, has considerably weaker stratification and stronger currents than the MAB during peak stratification times. Because of the spatial, technological, and environmental differences between the German Bight and the MAB, studies of the hydrodynamic impacts of wind farms in the German Bight cannot be directly extrapolated to the MAB Cold Pool. In November, when storm occurrences become more frequent within the MAB, the weakened stratification might lead to additional impacts from wind farms. The strength of stratification within the MAB and the findings of this study suggest that impacts from turbines on stratification may be less than those found in the German Bight. New studies (Friedland et al. 2023) have indicated that there is significant overlap between MAB forage fish and WLAs; however, the biological responses of the system to changes in habitat from extensive sandy benthic habitats to increased hard structure and intertidal remain unknown. New analyses are currently underway utilizing the methods proposed by Carpenter et al. (2016), but with the MAB stratification conditions. Additionally, more detailed simulations and pre- and post-construction observations should be further explored to fully capture the potential impacts of the turbine structure on the MAB Cold Pool. Our study highlights times and regions of overlap between MAB WLAs and the Cold Pool, which are critical to focus those future studies on.

Conclusion

The MAB Cold Pool is a valuable coastal ocean feature that supports some of the most economically and culturally valuable fisheries in the USA. The Cold Pool influences a variety of oceanographic processes, such as atmospheric and oceanic circulation, coastal primary productivity, and carbon sequestration. Development of offshore wind has been rapidly expanding throughout the MAB. This study found that there is a notable overlap between proposed MAB offshore wind lease areas. In addition, substantial stratification persists past the time at which bottom temperatures warmed above Cold Pool thresholds. Bottom temperatures warm more rapidly in nearshore than offshore, despite stronger thermal gradients in nearshore sites. Although it is evident that MAB WLAs occur

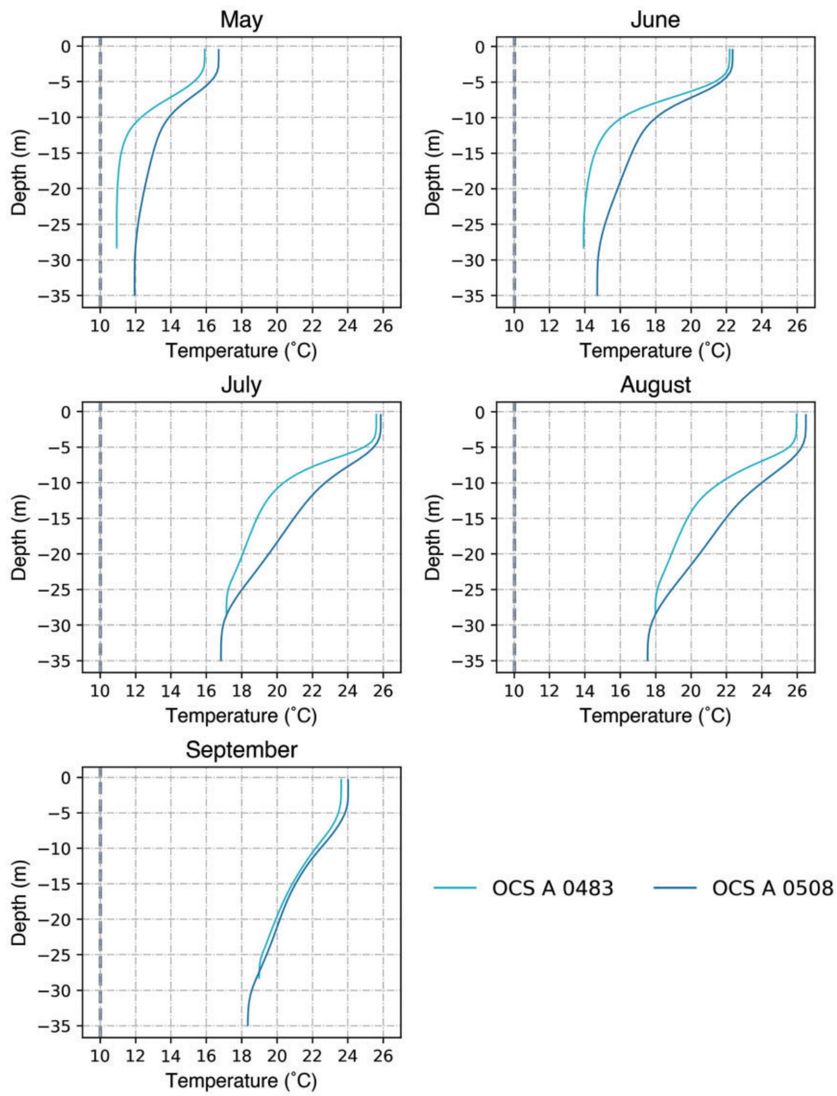

Figure 10. Southern MAB WLAs temperature profiles for Cold Pool months based on monthly averaged Doppio simulations from 2007 to 2021. Cold Pool bottom temperature threshold is depicted with the gray dashed line. The color of each profile corresponds to a study point within the selected wind areas shown in Fig. 1. The x-axis is not consistent with previous like figures (Figs 6 and 8) due to the warmer surface water temperatures within the southern MAB region.

within the Cold Pool, future studies to determine interdecadal trends of Cold Pool evolution and extent are necessary to further evaluate overlap between the Cold Pool and WLAs.

***Abstract*—Advancements in sensor and battery technology over the past two decades have facilitated the integration of complex instruments into autonomous underwater vehicles. The integration of such instruments onto gliders has enabled unprecedented data collection and expanded understanding of ocean processes. Recently, this understanding has been enhanced through the development of a software architecture called "backseat driver" on Slocum gliders, which can increase the efficiency of data collection by increasing the time the glider spends in regions of interest through adaptive mission control. A caveat to this advancement is that sensors that collect large volumes of data cannot efficiently transmit data to shore in real-time, which limits real-time applications (e.g. operational hurricane forecasting, marine mammal detection, water quality monitoring, etc.) and confines shoreside processing to post recovery. This can potentially lead to loss of data in the event of vehicle loss or missions where retrieval is not permissible, resulting in the need to develop a sensor agnostic real-time processing software and hardware architecture. Here, we detail the methodology that will be applied to test a real-time onboard processing algorithm through the use of the backseat driver software on Slocum glider MARACOOS04. An adjunct processor (Raspberry Pi 4) has been integrated into this glider with a data processing algorithm that will parse, process, and compress raw data from an acoustic Doppler current profiler.**

Keywords—Acoustic Doppler Current Profiler, Slocum Glider, Backseat Driver, Real-Time Onboard Processing

I. Introduction

Over the past two decades, advancements in sensor and battery technology have allowed for the integration of a variety of complex sensors into autonomous underwater vehicles (AUV) including but not limited to acoustic doppler current profilers (ADCPs), multi-frequency echo sounders, optical laser diffraction sensors, wave accelerometers, passive acoustics, and turbulence [1]. While integrating these sensors onto platforms such as gliders has led to unprecedented data collection and further understanding of ocean processes, advancement in ocean exploration can be further expanded through the use of a software capability referred to as "backseat driver". This software can increase the glider's working time in regions of high interest through adaptive mission control, which allows the vehicle to change its state (e.g., depth, heading, waypoint, sampling, etc.) based on real-time sensor measurements throughout the duration of the mission [2-3]. Software capabilities like backseat driver are increasingly becoming a necessity as missions become more complex in extreme ocean environments [2,4], and have been implemented on numerous underwater vehicles such as Bluefin SandShark AUV [5], Hydroid REMUS 100 AUV [6], Iver2 AUV [7], Teledyne Gavia AUV [8], Teledyne Webb Research Slocum gliders and many more [2].

The large data volume collected by these sensors during complex missions cannot be transferred to shore efficiently in real-time. As a result, shoreside processing has largely been confined to post recovery, significantly limiting real-time applications. In the event of vehicle loss or missions where retrieval is not immediately permissible, this can lead to an unfortunate loss of data and time. Real-time data processing software is increasingly becoming more important because it can aid in management and scientific applications by increasing data accuracy, preventing data loss, and allowing for adaptive surveys [9]. Recently, some sensors such as the digital acoustic monitoring (DMON) instrument [9], Sequoia Scientific Laser In Situ Scattering and Transmissometry (LISST) sensor [10], and the Fluorescence Induction and Relaxation System (FIRE) [11] have developed self-contained processing algorithms, but they

Funding provided by the Office of Naval Research Project Grant N000142012568.

979-8-218-14218-6 ©2023 MTS

are proprietary to their systems, limited to their internal processing capabilities, and are not easily modifiable [1]. Thus, the development of a sensor agnostic real-time data processing software and hardware architecture is needed for autonomous underwater vehicles.

Although the backseat driver is currently used to autonomously and adaptively modify glider behavior while in mission to efficiently collect data in regions of interest [2], the data processing algorithms are presently only used for adaptive mission control. The resulting data that is telemetered to shore still has to undergo shoreside processing post recovery. We are presently utilizing this software to expand glider real-time data processing capabilities. Here, we detail initial real-time processing experiments focused on ADCP processing via a widely used linear inversion algorithm, first tailored for ship-based surveys [12], then modified for glider platforms to generate depth-binned, absolute ocean velocities [13].

II. Methods

A. Glider

Underwater gliders have been used to monitor and collect data to gain useful information about oceanographic processes [14]. They are considered to be long endurance, low energy, and relatively low cost vehicles [2,14]. Gliders are mobile sensor platforms that are able to collect spatial and temporal data throughout the water column. These vehicles use a change in buoyancy and a set pitch angle to propel itself vertically and horizontally in a sawtooth-like pattern [14-15]. Gliders can be operated in water depths from 5 m to 1000 m and will have a vertical speed of approximately 20 cm/s [14-15]. During glider dives and climbs, the data is sampled every 2 seconds, which results in a robust dataset that can be telemetered to shore via an Iridium satellite phone after decimation [15].

The glider used in this study is a Teledyne Webb Research Generation 3 Slocum glider, MARACOOS04 (MARA04), operated by two STM32 120 MHz processors. This glider is equipped with a standard oceanographic sensor loadout of SeaBird CTD, a 100 m depth-rated buoyancy pump,Wetlabs 3 channel optical sensor, and a 600 kHz Teledyne RD Instruments Pathfinder ADCP. The Pathfinder utilizes a phased array transducer mounted flush to the glider hull with 4-beams in a 30° Janus configuration. Beams 1 and 3 are forward facing and beams 2 and 4 are aft-facing at 22.5° off the glider's center to both starboard and port sides, respectively. The output format of the raw data is configured to be PD0, which is Teledyne RD Instrument's standard binary format. PD0's from an approximately 3-hour long glider segment (time spent underwater between surfacings) result in a file size on the order of thousands of kilobytes which are too large to transfer over an Iridium connection in a timely and cost-effective manner and can only be downloaded post-deployment.

B. Backseat Driver

Prior to the development and implementation of the backseat driver, gliders did not have the capability of adaptive mission control onboard. The pilot sets the initial parameters including but not limited to heading, pitch, target dive depth, and waypoints. These engineering and flight specifications follow the blue (left) pathway shown in Fig. 1A where these parameters are input into the flight computer so that internal calculations can be computed in order to adjust commanded behaviors. The flight computer creates a decimated file (SBD) that is a subset of raw data to be transmitted to shore. Simultaneously, science sensors follow the pink (right) pathway in Fig. 1B where the data collected is then communicated to the science computer to create its decimated file (TBD) that is used to be transmitted onshore. Although the flight and science computers are communicating throughout the duration of the mission, the engineering and flight inputs cannot be dynamically updated. These inputs have to be manually updated by pilots when the glider reaches the surface and establishes communications over iridium.

The development of the backseat driver system by Teledyne Webb Research enhances the glider operation cycle immensely. Gliders equipped with backseat driver follow the same flight and science pathways as Fig. 1A with an additional external processor integrated into the science computer (Fig. 1B). This external processor can receive engineering and science sensor data that enables the system to adaptively update mission parameters. To accomplish the sensor agnostic real-time processing scheme, the external controller is able to receive science sensor data that is both logged to the TBD and data that is logged to a sensor's native data file format. This data is then passed to the external controller, which runs an open-source python processing algorithm (available here: https://github.com/JGradone/Glider_ADCP_Real_Time_Processing) and saves the output to a netCDF file that is able to be efficiently telemetered to shore.

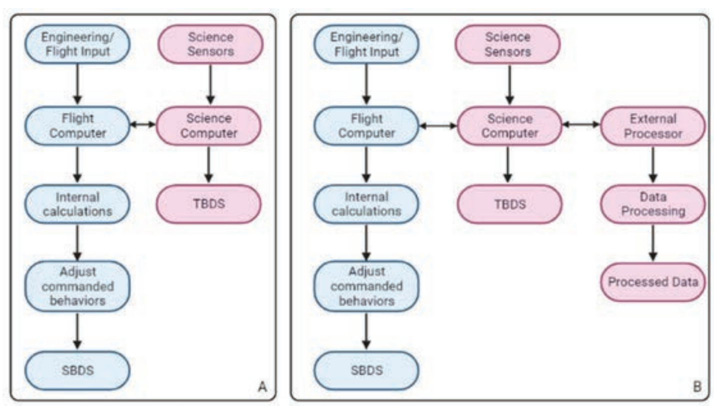

Fig 1. Glider operation cycle (a) without backseat driver and (b) with backseat driver.

a) External Processor Hardware: We are utilizing a Raspberry Pi 4 Model B because it has both sufficient computational power to execute real-time data processing and takes up minimal space within the payload [5]. A Raspberry Pi is a single board computer that is equipped with a 32-bit quad core processor running at 1.8 GHz, standard 40 pin GPIO header, Micro-SD card slot, 2 GB of RAM, 2 USB 3.0 ports, 2 USB 2.0 ports. The Raspberry Pi is being powered through its

5 V USB-C connector by the glider science computer through a USB to serial connector that is equipped with a 12 V to 5 V regulator. This connector utilizes the FTDI chipset and allows communication between the science computer and the Raspberry Pi using RS232 protocol. The Raspberry Pi is running Raspberry Pi OS, a Debian based operating system that has a Linux kernel. Additionally, Python version 3.9.2 is installed which is used to run the external controller script and the linear inversion algorithm. The Raspberry Pi is mounted in the forward section of the glider science payload on the starboard support bar (Fig. 2). The mount pictured, is a UCTRONICS DIN rail mount and is installed with the mounting bracket facing the inside of the payload and the base is fastened to the starboard support bar. Because the mount is made out of 1.2 mm carbon steel, we placed a piece of plastic between the base and the Raspberry Pi so that the pins of the Raspberry Pi do not touch the base of the mount. Additionally, we drilled a large hole into the mounting bracket of the mount so that we can access the power port. The Raspberry Pi is integrated into the science computer using the USB to Serial connector mentioned above. The backseat driver recognizes it through the proglet, but the current version does not include the use of a sensor sample behavior argument to control the power of the Raspberry Pi. This can prove problematic because that means there is a constant power draw throughout the duration of the mission. To address this issue, a new version of backseat driver is under development that will enable sensor sample behavior control over the Raspberry Pi and increase power efficiency for the duration of the mission.

Fig. 2. Raspberry Pi 4 Model B mounted inside glider science payload.

b) External Controller Software: The external controller software is able to communicate with the glider's flight computer through the backseat driver, a software developed by Teledyne Webb Research. This software is able to subscribe state parameters to the backseat driver which enables the subscribed parameter to be processed by an external controller. The external controller can both modify and update the result back to the glider to update desired parameters. In order to facilitate near real-time data transfer, we have developed an enhanced external controller that is a modified version of [1] onboard processing application. When the .PD0 file is read into the script, standard quality control methods are performed to optimize data quality for the final velocity profile derivation [1,16-17]. Data below a correlation threshold of 50%, an echo intensity of 70 dB, and percent good of 80% are discarded. Glider pitch and roll as well as individual beam angles and directions are used to map beam velocity data to depth cells and then transformed to level true depth. Following this transformation, additional QC is performed, where first measurement cells found to be below the seafloor are removed. Velocities relative to the glider exceeding 75 cm/s are also removed [13]. Then, data from the velocity bin closest to the glider are removed to avoid ringing and other contamination and data shallower than 5 m are removed to ensure the glider has achieved a state more typical of glider flight behavior for valid measurements [18]. Lastly, the data goes through a final check to ensure that the inversion can be completed. If the data fails any of the tests included in the final check, the inversion cannot be performed, otherwise the algorithm will continue to the inversion portion. This check includes three steps consisting of a depth range check, missing data check, and if there are two or more non-nan data points. The depth range check looks to see if there is a change in depth. If all depth values are the same, for example 0 m, the error flag is set to 1. The missing data check looks to see if all data is missing, and if it is, the error flag is set to 2. If there are less than two existing data points, then the error flag is set to 3, or if there are two or more existing data points the error flag is set to 4. Two is chosen for the purpose of receiving all possible processed data even if it produces a poor inversion, and may change as testing continues. Once the data has gone through the quality control steps, the data is fed through the linear inversion algorithm that was first developed for ship-based observations [12], modified by [13] to calculate depth-binned absolute ocean velocities on the Spray glider platform, and further modified by [1] for the Slocum glider platform.

III. Testing

To test and optimize the ability of the backseat driver software to initiate real-time processing of the raw data generated from the integrated ADCP. The backseat driver will be implemented via an external controller script, written in Python on the onboard Raspberry Pi computer, which will act as the interface between the backseat driver software and the science computer on the glider. Because it is important to limit the time the glider spends at the surface processing and transmitting data, we are developing precise software triggers to enable the glider to initiate the real-time processing workflow as quickly as possible. The plan is to have the ADCP programmed to sample during dives, climbs, and while hovering (state_to_sample = 7, Fig. 3A). When the glider enters the surface state (m_depth < u_reqd_depth_at_surface), the ADCP closes the .PD0 file and the external controller script is then initiated (Fig. 3B). This enables the processing to begin and, after optimization, finish before the glider is in a state to send data to shore via Iridium. Due to idiosyncrasies of the glider software, we have designed the external controller to start based on the following triggers:

1) ADCP is told to stop samping (c_dvl_on = -1*)*.

2) Glider is physically at the surface (m_depth < u_reqd_depth_at_surface, typically 3 m for shallow gliders and 7 m for deep gliders)

3) Glider's state changes to be at the surface, indicating state_to_sample =7 is no longer fullfilled and the ADCP is no longer sampling (cc_final_behavior_state = 5).

By design, there is overlap in the manner in which these sensors change their state, leading to redundancy in the trigger checks. The external controller script sends the .PD0 from the science computer to the Raspberry Pi and executes the onboard processing linear inversion algorithm, developed by Gradone et al. (2021) (Fig. 3C). This algorithm solves a system of equations for absolute horizontal water velocities using least squares techniques. The resulting velocity profile is exported into a network Common Data Form (netCDF) file that the external controller then sends from the Raspberry Pi to the glider science computer, so that the data can be efficiently transferred onshore in near real-time (Fig. 3C).

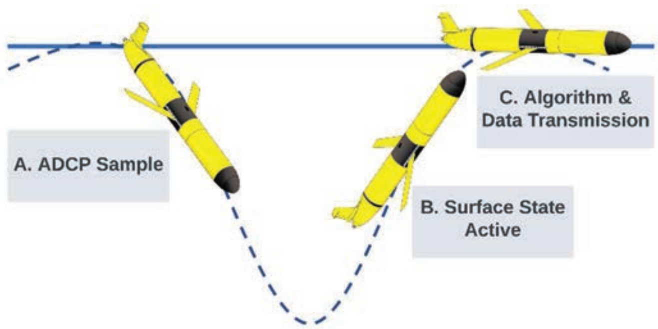

Fig 3. Step by step schematic of near real-time onboard processing.

Additional tests will be conducted to calculate computation time, optimal file size for iridium satellite transmission, and power draw in both simulation mode and the field. Considerations include algorithm constraints, smoothing values, quality control thresholds, and solution vertical resolution among other parameters. We tested the time it took for the Raspberry Pi to execute the linear inversion algorithm on 125 ADCP data files that were a mixture of 30m and 1000m max depth. These files were approximately 4 megabytes each but will be reduced to around 10 kilobytes, making them small enough to transfer over iridium. On average a glider spends 10 to 15 minutes at the surface, processing time would increase surface time by an average of 17.116 seconds, with a minimum of 0.642 seconds and maximum of 28.17 seconds. There will be a myriad of future real-time onboard processing applications once the Raspberry Pi-external controller data processing has been further integrated in the sensor agnostic manner as described here. We achieved our original goals with the resultant short processing time and small processed file sizes in the bench top environment. In the coming weeks we expect to demonstrate this capability in a field environment, including transfer of data to shore via Iridium communications.

Acknowledgment

We thank Rutgers University Center for Ocean Observing Leadership (RUCOOL) glider team for glider preparations. We also thank Eli Hunter and John Kerfoot (RUCOOL) for additional code development. We also acknowledge Teledyne Webb Research staff for technical assistance.

Key Points:

- Total transport and transport of South Atlantic Water through the Anegada Passage (AP) may be larger than previously estimated
- The AP is a pathway for both Atlantic Meridional Overturning Circulation return flow and subtropical gyre recirculation
- Gliders are an effective component of the global ocean observing system, needed for measuring subsurface water mass structure and transport

[1]Center for Ocean Observing Leadership, Department of Marine and Coastal Sciences, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA, [2]Center for Marine and Environmental Studies, University of the Virgin Islands, St. Thomas, VI, USA, [3]Ocean and Coastal Observing—Virgin Islands, Inc, St. Thomas, VI, USA

Abstract Caribbean through-flow accounts for two-thirds of the Florida Current and consequently is an important conduit of heat and salt fluxes in the upper limb of the Atlantic Meridional Overturning Circulation (AMOC). Considering there is evidence that up to one-half of the Florida Current originates as South Atlantic Water (SAW), determining the distribution of SAW throughout the Caribbean Island passages is important as this constitutes the major pathway for cross-equatorial AMOC return flow. The Anegada Passage (AP) is a major pathway for subtropical gyre inflow and suggested to be a potential SAW inflow pathway worth revisiting. Here, we present glider-based observations of temperature, salinity and subsurface velocity that represent the first observations of any type in the AP in nearly 20 years. An isopycnal water mass analysis is conducted to quantify the transport of water masses with South Atlantic or North Atlantic origin. Two potentially new aspects of AP transport are revealed. The total AP transport (−4.8 Sv) is shown to be larger than previously estimated, potentially by up to a factor of two. The transport of SAW through the AP (−1.66 Sv) is also shown to be larger than previously estimated, which represents 35% of the total transport reported here and 28% of the SAW entering the Caribbean north of the Windward Island Passages. These results indicate the AP may be an important pathway for cross-equatorial AMOC return flow. These results also provide evidence that gliders with acoustic doppler profilers are a viable method for measuring island passage transport.

Plain Language Summary The Caribbean Sea through-flow is a major transport pathway for heat and salt in the upper limb of the Atlantic Meridional Overturning Circulation (AMOC). The presence of water masses (bodies of water with distinct temperature and salinity properties) that originated in the South Atlantic (SAW) in the Northern Hemisphere is indicative of cross-equatorial AMOC return flow. Ship-based observations in the 1990's identified major pathways for this AMOC return flow but there is still a substantial amount of SAW that is taking an unknown, alternate route northward. This study presents the first observations in nearly 20 years of temperature, salinity, and subsurface velocity in the Anegada Passage (AP). Here, we perform a water mass analysis that suggests the total transport and SAW transport through the AP is larger than previously estimated. This result is significant as the AP may be an important pathway for AMOC return flow. This study also shows that autonomous underwater gliders are a viable method for measuring island passage transport.

1. Introduction

To maintain Earth's radiative balance, both the atmosphere and the ocean drive a net poleward heat flux. However, the net heat flux in the Atlantic Ocean is northward, even in the southern hemisphere. The Atlantic Meridional Overturning Circulation (AMOC) is responsible for this heat flux as warm surface waters are carried northward which is ultimately balanced by cold deep waters returning southward. Increases in anthropogenic atmospheric carbon dioxide (CO_2) leading to a greenhouse warming effect are expected to impact the AMOC in several ways. A reduction in the heat loss from the ocean to the atmosphere and an increase in the input of freshwater at higher latitudes are expected to lower water mass density in the deep-water formation regions (Gregory et al., 2005). Currently, there is evidence for and uncertainty around a slowdown in the AMOC (Caesar et al., 2018; Praetorius, 2018; Thornalley et al., 2018). It is vital to better understand the dynamics of this circulation as variations in the strength of the AMOC have been linked with significant changes in global climate (dos Santos et al., 2010; Schmidt et al., 2004). These AMOC variations have induced changes in global temperature, wind fields, and the hydrologic cycle (Rahmstorf, 2002).

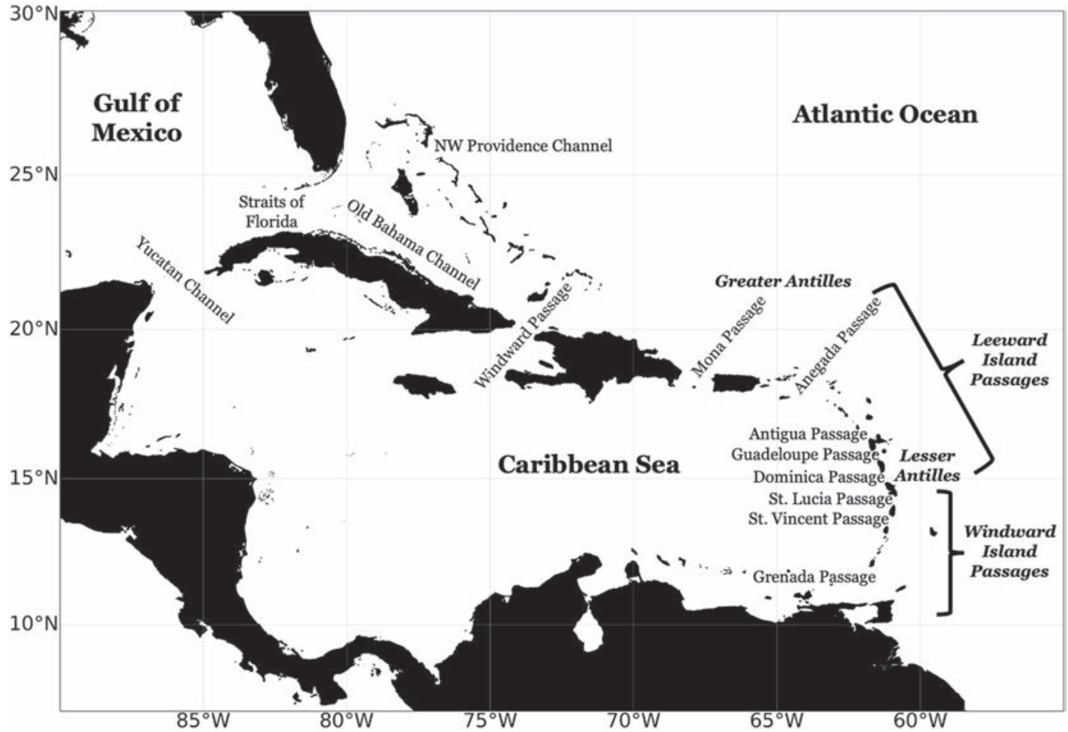

Figure 1. The Caribbean Sea with the major passages between the Atlantic Ocean and Caribbean Sea labeled.

Toward the beginning of the upper-limb of the AMOC's crossing into the North Atlantic lies the complex Caribbean Sea. This semi-enclosed basin is connected to the tropical Atlantic Ocean through a series of passages between the islands of the Greater and Lesser Antilles (Figure 1). The complex bathymetry of the eastern Caribbean passages effectively acts as a sieve for the inflow of Atlantic water due to the average sill depth being approximately 800 m (Johns et al., 2002). The inflow through these passages is highly dynamic. There is variability on synoptic, seasonal, annual, and decadal timescales and forcing from both winds and thermohaline circulation (Johns et al., 1999). Previous studies have found the net inflow to the Caribbean Sea of 28 Sv (1 Sverdrup = 10^6 m^3 s^{-1}) to be nearly equally geographically distributed in thirds: ∼10 Sv through the Greater Antilles passages, ∼8 Sv through the Leeward Island Passages, and ∼10 Sv through the Windward Island Passages (Johns et al., 2002). Throughout the remainder of this analysis, we discuss transport in units of Sverdrups, referring to transport into the Caribbean with a negative sign convention or using the term "inflow." Through a series of modeling experiments Johns et al. (2002) determined that the ∼10 Sv inflow through the Windward Island Passages to the south is almost entirely thermohaline forced as the wind-driven component is essentially zero. The ∼18 Sv inflow through the Greater Antilles and Leeward Islands Passages to the north was found to be driven by the large-scale subtropical gyre circulation. This inflow directly feeds into the dominant surface current, the Caribbean Current, which can account for up to two-thirds of the flow into the Gulf Stream at the Straits of Florida and consequently is an important conduit of mass, heat, salt, and freshwater fluxes in the AMOC (Johns et al., 2002).

While high-latitude sinking and interior mixing processes have a first order control on the magnitude of the AMOC, low-latitude wind-driven processes determine and modify the subsurface density structure of the water masses flowing through the Caribbean Sea, Gulf of Mexico, and eventually the Gulf Stream (Fratantoni et al., 2000). This linkage between upper ocean water mass conditions in the Caribbean and Gulf Stream activity is significant enough to be identifiable in paleoceanographic sediment core records. Planktonic foraminifera assemblages have linked high sea surface temperatures in the Caribbean with diminished Gulf Stream activity (Fischel et al., 2017; Reißig et al., 2019). This connection suggests that the inter-hemispheric atmospheric energy balance ultimately controls the large-scale circulation in this region through its influence on the position of the Intertropical Convergence Zone, which constitutes the main forcing for the North Atlantic Subtropical Gyre (STG) variability (Fischel et al., 2017; Nürnberg et al., 2021; Reißig et al., 2019).

In addition to forcing from STG variability, the modification of the subsurface density structure of the water masses flowing through the Caribbean Sea is also substantially impacted by upstream water mass origin. Historically, 45% (13 Sv) of the Florida Current transport has been considered to be of South Atlantic origin (Schmitz & Richardson, 1991; hereafter SR91), thus there is considerable interest in determining the distribution of South Atlantic Water (SAW) throughout the Caribbean Passages as this constitutes a major pathway for cross-equatorial AMOC return flow (Johns et al., 2002; Kirchner et al., 2009; Tuchen et al., 2022; Wilson & Johns, 1997). However, there are several significant inconsistencies recent publications have raised with the assumptions made by SR91 (Szuts & Meinen, 2017; hereafter SM17):

1. The accepted AMOC value at the time of the SR91's analysis was 13 Sv, whereas recent literature finds a mean value closer to 17 Sv in the Florida Straits at 26°N (Frajka-Williams et al., 2019; Szuts & Meinen, 2017).
2. SR91 consider the transport of all surface waters >24°C to be of South Atlantic origin in their formulation of a 13 Sv AMOC, whereas recent literature has found that surface waters that flow through the Florida Straits do not leave the subtropical gyre and thus potentially do not contribute to the strength of the AMOC (Brambilla & Talley, 2006).
3. SR91 ignore strong mid-depth horizontal gradients in eastern and western Salinity Max Waters and Central Waters in the Florida Current, which suggests these waters are not entirely North Atlantic Water (NAW) as SR91 assume.

In addition to the results from these recent publications, water mass analysis and transport estimates have shown a maximum of 11 ± 2.22 Sv of SAW flows in through the Windward Island Passages and approximately 5.3 ± 0.7 Sv of SAW flows northward from Guadeloupe to the Atlantic across 16°N (Rhein et al., 2005). When these SAW transport estimates are combined, a total SAW inflow of 16.3 Sv is in much better agreement with the accepted AMOC strength of 17 Sv. Therefore, we frame this analysis with an AMOC strength of 17 Sv but continue to reference the pioneering work by SR91 throughout the discussion while acknowledging both the limitations of several of their assumptions as well as the new understandings from more recent literature. With the pathway for a maximum of 11 Sv of SAW constrained to the Windward Island Passages, the route the remaining 6 Sv of SAW take northwards remains largely unresolved. There are uncertainties and consequences for projected changes in the AMOC (Frajka-Williams et al., 2019) and recent evidence that the Caribbean Sea is warming (Antuña-Marrero et al., 2015; Glenn et al., 2015; Jury, 2017), surface waters are freshening (Jury & Gouirand, 2011), and the through-flow is slowing (Jury, 2020). These factors combined with the lack of recent coordinated, sustained ocean observations in this region motivate a reassessment of transport through the Caribbean Passages.

The Anegada Passage (AP), located in the northeast corner of the Caribbean, is the largest and deepest of the Caribbean Passages (sill depth 1915 m, (Fratantoni et al., 1997)). Anegada Passage transport has been shown to be a major pathway for STG inflow in the form of NAW (Johns et al., 2002) and suggested to be an alternate pathway for SAW into the Caribbean (Johns et al., 1999; Wajsowicz, 2002; Wilson & Johns, 1997). Flow through the AP is predominately southwestward into the Caribbean where velocity profiles have shown a subsurface velocity maximum in the center of the passage and weak flow reversals found at times at the surface along both the eastern and western sides of the passage (Johns et al., 1999). There can also be strong eastward components over the western half of the passage and westward components over the eastern half of the passage, leading to strongly convergent flow (Johns et al., 1999).

The eastern Caribbean has been a historically under-sampled region until recently. Ship-based campaigns to collect direct transport observations throughout the Caribbean Passages during the 1990's and early 2000's (Johns et al., 1999, 2002; Kirchner et al., 2009; Rhein et al., 2005; Wilson & Johns, 1997) progressed the state of knowledge immensely. However, ship-based sampling is extremely expensive and limited by weather conditions. The development of autonomous underwater vehicles (gliders) has contributed to filling this data gap in the Caribbean Sea and other regions by providing high quality observations in a novel yet economical manner. Since 2020, gliders equipped with acoustic Doppler profilers (ADP) have been deployed throughout the AP region four separate times covering over ~2,700 km over ~150 days (Figure 2). While ADPs have been integrated onto gliders for over a decade (Miles et al., 2015; Todd et al., 2011, 2017), these field campaigns have served as a unique proof-of-concept that glider deployments can consistently observe passage transport variability at the same, if not better, quality and at comparatively lower cost than traditional ship-based campaigns (Schofield et al., 2007).

The present work builds upon previous Caribbean Passage transport research in several ways. Four glider deployments are utilized to both validate the methodology of using gliders to measure passage transport as well as develop further understandings of the transport dynamics in this region. In 2021, two glider deployments

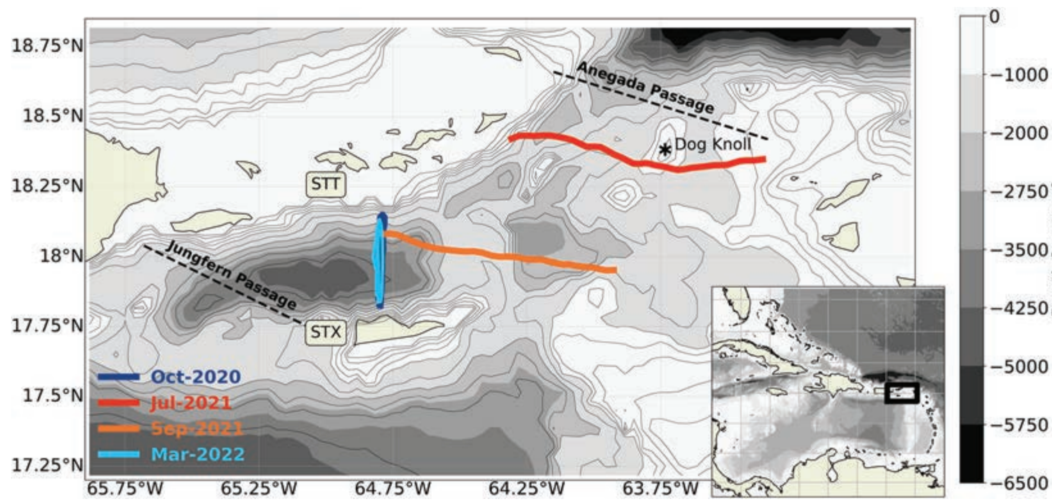

Figure 2. Glider tracks in the Anegada Passage region from 2020 to 2022 glider deployments.

ventured eastward across the AP on a path intentionally similar to historical ship-based transects to allow for a more direct comparison (Johns et al., 1999). In 2020 and 2022, single glider deployments were conducted on a repeating transect line between St. Thomas (STT) and St. Croix (STX) (15 transects in 2020, 6 transects in 2022) to allow for the calculation of a transport time-series from which additional details of the transport dynamics could be gathered. The high resolution, co-located glider observations of temperature, salinity, and subsurface velocity also allow for a detailed isopycnal water mass analysis to quantify the transport of water masses with South Atlantic or North Atlantic origin in the AP transport. To our best knowledge, the results presented in this study are the first published, detailed in-situ analysis of transport below 200 m in the AP region.

2. Observations and Methods

2.1. Transport From Glider-Mounted Acoustic Current Profiler Derived Horizontal Water Velocity

The observations used in this study were collected using Teledyne Webb Research Slocum gliders (Schofield et al., 2007). Gliders are buoyancy-driven, autonomous underwater vehicles that use a combination of changes in their pitch angle and internal volume to move vertically and horizontally in a sawtooth-like pattern. Gliders are modular platforms that can be instrumented with a growing variety of complex sensors. Two deep (1,000 m rated) Slocum gliders, RU29 and RU36, were used in this study. RU29 is a second-generation Slocum glider (G2) equipped with a Sea-Bird Scientific pumped conductivity, temperature, and depth (CTD) sensor and a 1-MHz Nortek AD2CP. RU36 is a third generation Slocum glider (G3) equipped with an RBR *legato*³ inductive cell CTD sensor, a 600-kHz Teledyne RD Instruments (TRDI) Pathfinder ADP, and an Aanderaa Oxygen Optode 4831. The Nortek AD2CP is a four-beam system that was configured to sample 8 pings per second in beam coordinates with a 0.2-m blanking distance in 0.5-m bins. The TRDI Pathfinder is also a four-beam system that was configured to sample one 10-ping ensemble average every second in beam coordinates with a 0.8-m blanking distance in 1-m bins. These configurations were chosen for a variety of reasons. Both instruments were configured to sample as quickly as possible, whereas the other configuration choices were a combination of power consumption capabilities and optimization testing. Data from both current profilers were logged internally and downloaded after the deployment. A summary of glider deployment details and specific configurations is provided in Table 1.

While two different types of current profilers were used in this study, measurements of water velocity relative to the glider were obtained using similar system configurations and processing techniques. The major data processing steps for both current profilers are quality control, correcting the beam velocities to level true-depth, mapping the beam velocities to vertical bins relative to the glider, performing a coordinate transformation to convert from beam to East-North-Up (ENU), and derivation of absolute horizontal water velocities. Raw beam velocity data are quality controlled first through several data screening filters. For the Nortek AD2CP, data below a correlation of 50% or above a high return amplitude of 75 dB are discarded (Todd et al., 2017). For the TRDI Pathfinder, data below a correlation threshold of 50%, an echo intensity of 70 dB, and percent good of 80% are discarded (Haines

Table 1
Glider Deployment Information, Configurations, and Summary of Transport Results

Deployment	October-2020	July-2021	September-2021	March-2022
Duration (days)	24	5.5	4.5	11
Location	St. Thomas-St. Croix	Outer AP	Outer AP	St. Thomas-St. Croix
Number of Transects	15	1	1	6
Current Profiler	Nortek AD2CP	Nortek AD2CP	Nortek AD2CP	TRDI Pathfinder
Absolute Transport from ADP Inversion Method	−2.27 ± 0.66 Sv	−4.43 Sv	−5.24 Sv	−2.47 ± 0.8 Sv
Geostrophic Transport from Thermal Wind	−2.29 ± 0.7 Sv	−4.74 Sv	−4.97 Sv	−3.49 ± 0.35 Sv
SAW Transport	−0.70 Sv	−1.21 Sv	−1.33 Sv	−0.84 Sv

et al., 2011; Taylor & Jonas, 2008). For both current profilers, glider pitch and roll as well as individual beam angles and directions are used to map beam velocity data to depth cells and then transformed to level true depth.

The Nortek AD2CP is mounted in a Janus configuration with beams 1 and 3 oriented forward and aft and slanted 47.5° off vertical and beams 2 and 4 oriented port and starboard and slanted 25° off vertical. A typical dive angle for Slocum gliders is 24–27° so either the forward or aft beams will be nearly horizontal on a climb or a dive for the Nortek system. Because of this configuration, only 3 beams are used in the transformation from beam to ENU velocity (beams 1, 2, and 4 on a dive and beams 2,3 and 4 on a climb). The TRDI Pathfinder is a phased array system also mounted in a Janus configuration where the four beams are angled 30° off vertical but rotated along the central axis of the glider so that beams 1 and 3 are oriented forward and beams 4 and 2 are oriented aft but 22.5° off the central axis of the glider to the port and starboard, respectively. Because of this configuration, all four beams can be used in the transformation from beam to ENU velocity. For both systems, an instrument specific transformation matrix based on the transducer face geometry is used to convert from beam to XYZ velocity (i.e., velocity relative to the glider). Next, another transformation matrix that incorporates the glider magnetic heading is used to convert from XYZ velocity to ENU (i.e., East-North-Up). A final round of quality control is then applied to the ENU velocity. Following Todd et al. (2017), velocities relative to the glider exceeding 75 cm s^{-1} are excluded as the glider's speed through water is ~25 cm s^{-1} and larger relative velocities are not expected over the sampling range of the current profilers (maximum 20 m). Data from the velocity bin closest to the glider are also excluded as this bin can exhibit ringing or other frequent contamination. Lastly, data shallower than 5 m are discarded as the glider typically must travel several body lengths before it achieves a dive angle that is more closely representative of its typical flight behavior as compared to when it is on the surface.

Measurements made by glider-mounted current profilers combine the true water velocity, the velocity of the glider's motion, and noise:

$$U_{\text{adcp}} = U_{\text{ocean}} + U_{\text{glider}} + U_{\text{noise}} \tag{1}$$

There are several methods that can be used to derive absolute horizontal water velocities (U_{ocean}). Fundamentally, they either decompose the different components measured by glider-mounted current profilers or rely on assumptions to ignore them. The inversion method was originally developed for ship-based lowered current profilers (Visbeck, 2002) but has been adapted for use on gliders and used extensively (Ellis et al., 2015; Gradone et al., 2021; Heiderich & Todd, 2020; Ma et al., 2019; Miles et al., 2015; Todd et al., 2011, 2017). This method solves a system of equations for both unknown glider velocities and absolute horizontal water velocities using least squares techniques. An advantage of this method is that constraints (glider estimated depth-average currents, surface drift, bottom-track, etc.) can easily be applied to yield better estimates of the true horizontal water velocities. Additional constraints such as a curvature-minimizing smoothness constraint assist in reducing the noise from missing data (Visbeck, 2002). These constraints can be applied with different weights to determine the degree to which individual constraints should be considered. We follow Todd et al. (2011) by applying weights of 5 and 1 to our glider dead-reckoned depth-average current (DAC) and curvature-minimizing smoothness constraints, respectively. Figure 3 shows example DAC vectors from transects between St. Thomas and St. Croix during the October 2020 deployment. The inversion method is applied with a final solution vertical resolution of 10 m for the Nortek system and 20 m for the RDI system. A coarser vertical resolution was needed for the RDI system to include a larger number of quality data points in each final solution bin. Data from the RDI system

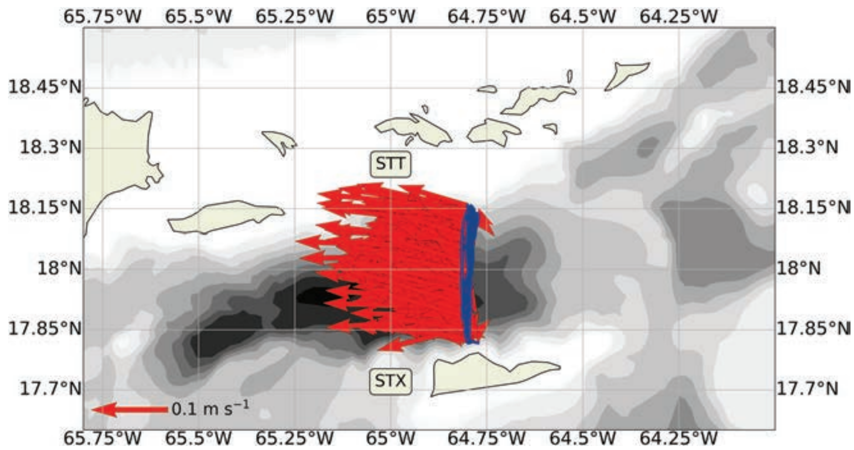

Figure 3. Glider transect track (blue) and segment depth-average current vectors (red) from the October-2020 St. Thomas-St. Croix, Anegada Passage deployment.

experienced degraded data quality with depth likely due to less energy being emitted into the water column and thus a poorer return, especially with decreased scatterers with depth.

The DAC estimate is an integral constraint on the inversion method derivation of absolute horizontal water velocity. DACs can be impacted by a variety of factors such as errors in the internal compass and attitude sensors, accuracy of the hydrodynamic flight model, internal waves, and biofouling (Rudnick et al., 2018). Despite these potential sources of error, DAC root-mean-square accuracy is estimated to be approximately 0.01–0.02 m s^{-1} (Rudnick et al., 2018). This uncertainty is minimal compared to the magnitude of the bulk transport estimates reported here. Furthermore, Todd et al. (2017) apply a quality control step for correcting an instrumental heading bias, which are typically observed in individual velocity profiles as an erroneous heading-dependent shear. Following this correction, substantially smaller heading bias' were found for each deployment presented here to the extent that corrections were not necessary.

For the 2020 and 2022 deployments, horizontal water velocity profiles derived for each glider segment are interpolated onto a regular depth, longitude, and latitude grid representing the mean position of the glider transects between St. Thomas and St. Croix. Glider drift in the E/W direction was minimal so a constant longitude of 64.80° W was chosen. The N/S extent of the transect lines is approximately 30 km. Glider speed over ground for these deployments was consistently ~1 km/hr where a single 1000-m segment (dive and climb) transited ~3 km. Six equally spaced latitude bins (roughly 5 km apart) were chosen so that 2–3 glider segment would be included in the interpolation. This grid interpolation effectively smoothes the absolute velocities. After the velocity profiles are interpolated onto the regular grid, E/W velocity is integrated over the full water column and transect length to produce transport in units of Sverdrups (where 1 Sv = 10^6 m^3/s). Deployment average transport and standard deviation are obtained by calculating transport mean and standard deviation over the total number of transects. E/W transports reported here are effectively cross-passage transport due to the orientation of the transects. There was no attempt to remove tidal variability from the observations. Tides have low spatial variability in this region and are either diurnal or semidiurnal with a relatively small amplitude, typically less than 10-cm (Kjerfve, 1981; Wilson & Johns, 1997). Averaging over the spatial (3-km glider segments, 30-km transects) and temporal (1-hr glider segments, ~36-hr transects) length scales of these observations is assumed to remove tidal variability.

For the 2021 deployments, horizontal water velocity profiles are derived for each glider segment but are not interpolated onto a regular depth, longitude, and latitude grid as there is only one transect per deployment. Because the deployment tracks were designed to travel in a cross-passage direction, the 2021 absolute velocity data are rotated by the orientation of the passage opening (~18°). This rotation transforms the E/W velocity into cross-passage velocity, which enables a more direct comparison with the cross-glider track geostrophic velocities detailed in the following section. This rotation is not needed for the 2020 and 2022 deployments because these tracks were in an approximately N/S direction, so the cross-glider track geostrophic velocities are approximately in a cross-passage direction. Transport is derived for the 2021 deployments by using the start and end locations of each segment to calculate distance in meters and then cross-passage velocity is integrated over the full water column and transect length to produce transport in units of Sverdrups.

10.1029/2022JC019608

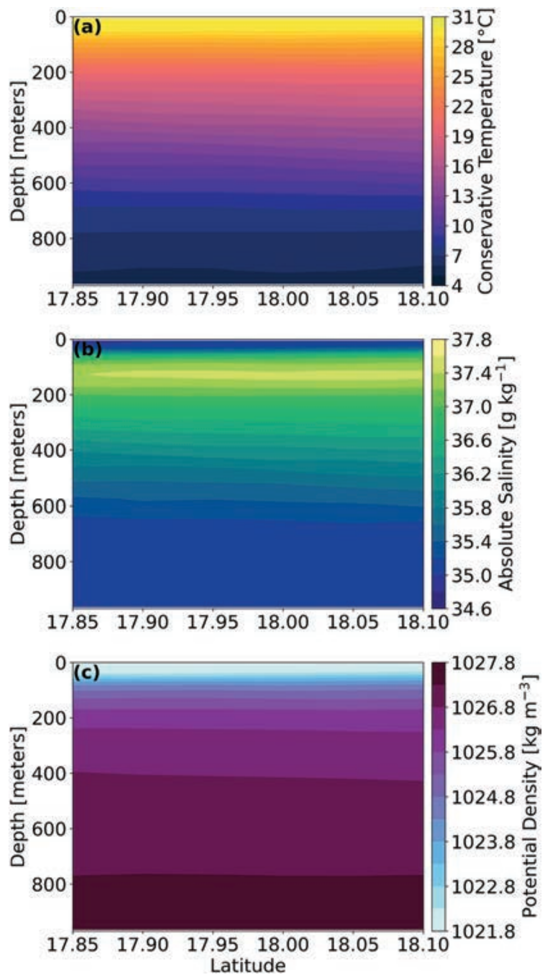

Figure 4. Example conservative temperature (a), absolute salinity (b), and potential density (c) transects in the STT-STX section of the Anegada Passage interpolated onto the regular depth-latitude-longitude grid for thermal wind geostrophic velocity calculation.

2.2. Transport From Geostrophic Velocity

Geostrophic velocity is estimated via the thermal wind relationship following the methodology by Høydalsvik et al. (2013). The CTDs on both gliders were sampled every 2 s throughout full dives and climbs. Potential density (σ_θ, from here on: density) is calculated from conservative temperature (Θ, from here on: temperature) and absolute salinity (S_A, from here on: salinity) measurements using the TEOS-10 standard (Roquet et al., 2015). For the 2020 and 2022 deployments, measurements from dives and climbs were averaged in 2-m vertical bins and interpolated onto the same depth, longitude, and latitude grid used for calculating transport from the current profiler data both to reduce noise and facilitate comparisons. For the 2021 deployments, measurements from dives and climbs were also averaged in 2-m vertical bins but no interpolation onto a regular grid was needed because these deployments were on their own unique tracks. Figure 4 shows an example of temperature, salinity, and density on this grid for the 2020 deployment. Density measurements are then used in the thermal wind relationship to calculate the cross-glider track component of the geostrophic vertical shear:

$$\frac{\partial u}{\partial z} = \frac{g}{\rho_o f}\frac{\partial \rho}{\partial y} \tag{2}$$

where u is the cross-glider track velocity, z is the vertical coordinate, g is the acceleration due to gravity, ρ_o is a reference density (1,027 kg/m^3), f is the Coriolis parameter, ρ is density, and y is the along-track distance. Along-track distance is taken to be the distance between the latitude bin edges for the 2020 and 2022 deployments, roughly 5 km, and true along-track distance for the two 2021 deployments. Relative cross-glider track geostrophic velocity (U_{relative}) is obtained by integrating the previous equation with respect to z:

$$U_{\text{relative}} = \int_{-H}^{0} \frac{g}{\rho_o f}\frac{\Delta \rho}{\Delta y} \tag{3}$$

where H is the maximum dive depth of the glider. Glider dead-reckoned, depth-average currents (U_{DAC}) used to constrain the ADP velocity profiles are also interpolated onto the latitude grid used here. Interpolating the depth-average currents onto this grid effectively results in one representative DAC to be used as a constraint for each latitude point a given transect. For the 2021 deployments, the true DAC is used as a constraint for each glider segment. The depth-average currents are used to reference the relative cross-glider track velocity to absolute geostrophic velocity ($U_{\text{geostrophic}}$) by:

$$U_{\text{geostrophic}}(y,z) = U_{\text{relative}}(y,z) + U_{\text{reference}}(y) \tag{4}$$

The reference velocity is calculated from the DAC as:

$$U_{\text{reference}}(y) = U_{\text{DAC}} - \frac{1}{H}\int_{-H}^{0} U_{\text{relative}}(y,z)\,dz \tag{5}$$

In smaller passages in the southern Caribbean where the flow is expected to have a stronger ageostrophic component, Wilson and Johns (1997) found that smoothing of geostrophic velocity estimates greatly improved comparisons with measured velocities. It was necessary to interpolate the density fields onto the regular grid for the 2020 and 2022 deployments due to the repeating transects, which effectively smoothed these geostrophic velocity estimates. The geostrophic velocity estimates from the 2021 deployments were smoothed using a local least-squares fit by a third degree polynomial in an approximately 30 km rolling filter window similar to Todd et al. (2011). After geostrophic velocity profiles are calculated they are integrated over the full water column and transect length to produce transport in units of Sverdrups. Deployment average transport and standard deviation are calculated in the same manner as was done for the ADP directly measured velocities.

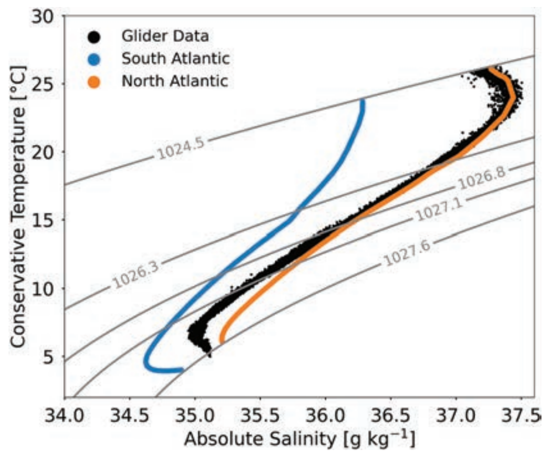

Figure 5. Representative source water mass profiles obtained using mean temperature and salinity profiles from World Ocean Atlas 2018 following Rhein et al. (2005) for the South Atlantic (blue) and North Atlantic (orange). Temperature and salinity data from all four glider deployments shown in black.

2.3. Water Mass Analysis

Water mass analyses using temperature and salinity have been used widely throughout the Atlantic in the past (Poole & Tomczak, 1999; Schmitz & McCartney, 1993; Schmitz & Richardson, 1991) and can applied in a manner to distinguish SAW from NAW in the Caribbean inflow (Garraffo et al., 2003; Johns et al., 2003; Kirchner et al., 2008; Mertens et al., 2009; Rhein et al., 2005). Here, a water mass analysis is conducted following Rhein et al. (2005) by taking an isopycnal mixing approach and expanded through the use of least-squares fitting. Temperature and salinity data are used as constraints in the following system of equations to solve for the mixing fraction of NAW or SAW that is necessary for the observed data to be derived from two distinct source waters.

$$x_{\mathrm{SA}} T_{\mathrm{SA}} + x_{\mathrm{NA}} T_{\mathrm{NA}} - T_{\mathrm{obs}} = R_T \tag{6}$$

$$x_{\mathrm{SA}} S_{\mathrm{SA}} + x_{\mathrm{NA}} S_{\mathrm{NA}} - S_{\mathrm{obs}} = R_S \tag{7}$$

$$x_{\mathrm{SA}} + x_{\mathrm{NA}} - 1 = R_{\mathrm{MC}} \tag{8}$$

Here, (T_{SA}, S_{SA}, T_{NA}, S_{NA}) represent the temperature and salinity definitions for the distinct source water types from the South Atlantic and North Atlantic; (T_{obs}, S_{obs}) represent the observations; (x_{SA}, x_{NA}) represent the fractional relative contributions; and (R_{T}, R_{S}, R_{MC}) represent the residuals which are minimized through a least squares fitting. This method is similar to the optimum multiparameter (OMP) analysis but is limited in the number of source water masses (two) than can be used to still have a determined system of equations. Poole and Tomczak (1999) used OMP analysis to distinguish six source water mass endpoints from three linear T/S relationships in the Atlantic Central Waters (one northern type and two southern types) and constrained this resulting system of equations by including oxygen, silicate, nitrate, and phosphate data along with temperature and salinity. Here, we follow Rhein et al. (2005) and refrain from separating the two South Atlantic source water types which allows for the calculation of fractions of SAW and NAW by T/S data alone. The Python package PYOMPA (version 0.3) is adapted for this analysis (Shrikumar et al., 2021).

The isopycnal mixing analysis is applied from $\sigma_\theta = 24.5$ (~110 m) to $\sigma_\theta = 27.5$ (~1,000 m) which is the glider's maximum operational depth. Representative source water mass profiles are obtained using mean temperature and salinity profiles from World Ocean Atlas 2018 (WOA18; Locarini et al., 2018; Zweng et al., 2018) following the locations of the hydrographic data used by Rhein et al. (2005). The in-situ temperature and salinity profiles from WOA18 are converted to conservative temperature and absolute salinity using the TEOS-10 standard that was applied to the glider data (Roquet et al., 2015). Figure 5 shows these profiles along with all glider temperature and salinity observations below the surface layer analyzed here. The isopycnal water mass analysis is conducted at each depth interval (steps of 2-m vertically) from the respective glider deployments discussed above. At these depth intervals, the T/S properties from the two source water masses along the same isopycnal are used to compute the fraction of each endmember needed to obtain the properties of the observed data. We follow the water mass density ranges and naming conventions of Stramma and Schott (1999) and Rhein et al. (2005) where SW is $\sigma_\theta < 24.5$, salinity maximum water (SMW) is $24.5 \geq \sigma_\theta < 26.3$, upper central water (uCW) is $26.3 \geq \sigma_\theta < 26.8$, lower central water (lCW) is $26.8 \geq \sigma_\theta < 27.1$, and intermediate water is (IW) $27.1 \geq \sigma_\theta < 27.6$. Details regarding differences between the respective North Atlantic and South Atlantic component of each water mass are outlined further in the discussion. The fractional contributions of each source water mass (x_{SA}, x_{NA}) are multiplied by the absolute velocity derived transport at each depth interval to obtain SAW and NAW transport.

The implications of the choices for these source water types have been detailed extensively (Kirchner et al., 2008, 2009; Mertens et al., 2009; Rhein et al., 2005), however we emphasize again that the South Atlantic SMW source water used here is a fresher endmember from the eastern South Atlantic. The more saline SMW from the western South Atlantic is nearly indistinguishable from the North Atlantic SMW. We acknowledge that this choice neglects the contribution of high salinity SAW to the total SAW transport in the SMW layer and estimate potential contributions from this water mass using mass balance assumptions in the discussion (Kirchner et al., 2008; Rhein et al., 2005; Zhang et al., 2003).

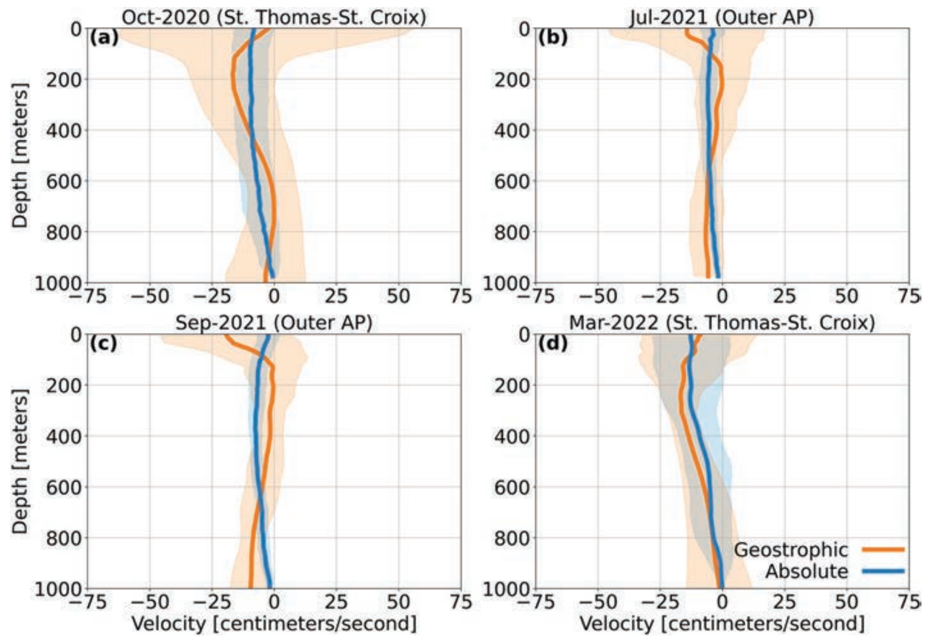

Figure 6. Mean thermal wind derived geostrophic velocity (orange) and acoustic doppler profilers derived absolute velocity (blue) shaded by one standard deviation for all four deployments. Profiles for the 2020 and 2022 deployments represents E(+)/W(−) velocity and cross passage (- into/+ out of passage) velocity for the 2021 deployments.

The isopycnal water mass analysis cannot be applied to the surface layer. Therefore, we follow the assumptions made by SR91, Schott et al. (1998), Hellweger and Gordon (2002), and Rhein et al. (2005) and the subsequent studies that have since adopted the methodology used by Rhein et al. (2005) for this layer. These studies have found that the tropical surface waters warmer than 24°C ranging from the equatorial Atlantic to the Florida Straits are of South Atlantic origin. Thus, here we assign all transport in the $\sigma_\theta < 24.5$ layer as SAW.

3. Results

3.1. Current Structure and Transport

Figure 6 shows mean velocity profiles with a one standard deviation shading for both geostrophic velocity and ADP derived absolute velocity for all four deployments. These mean velocity profiles show the flow is largely barotropic. There is an overall agreement on the mean velocity direction into the Caribbean with larger variability in the geostrophic velocity estimates. Differences between geostrophic and absolute velocity estimates will be discussed further in the following section.

The two 2021 deployments occupied somewhat different transect lengths and orientations, but both generally sampled the entire AP (Figure 2). The first 2021 AP transect, located in the furthest northeast corner of the study area, was occupied from July 4-9, 2021. The ADP derived absolute velocities observed during this glider deployment were also predominately into the Caribbean (Figure 7a). The flow had a slight along passage component, roughly aligned with the shelves on both edges of the transect (Figure 7c). The flow was mainly barotropic, with a slight shearing of the along passage component of the flow occurring near the bathymetric feature Dog Knoll. The average transport was −4.43 Sv into the Caribbean.

The second AP transect, traveling from the area of the St. Thomas-St. Croix transects to approximately 50 km south of Dog Knoll, was occupied from September 14-18, 2021. The ADP derived absolute velocities observed during this glider deployment were predominately into the Caribbean, with a weak reversal in the middle of the transect (Figure 7b). There was more variability in the along passage component of the flow during this deployment, though the magnitude was substantially less than the first deployment (Figure 7d). Again, the flow was mainly barotropic, with a slight shearing of the along passage component of the flow over the entire transect. The average transport was −5.24 Sv into the Caribbean. The mean cross passage velocity for both transects was

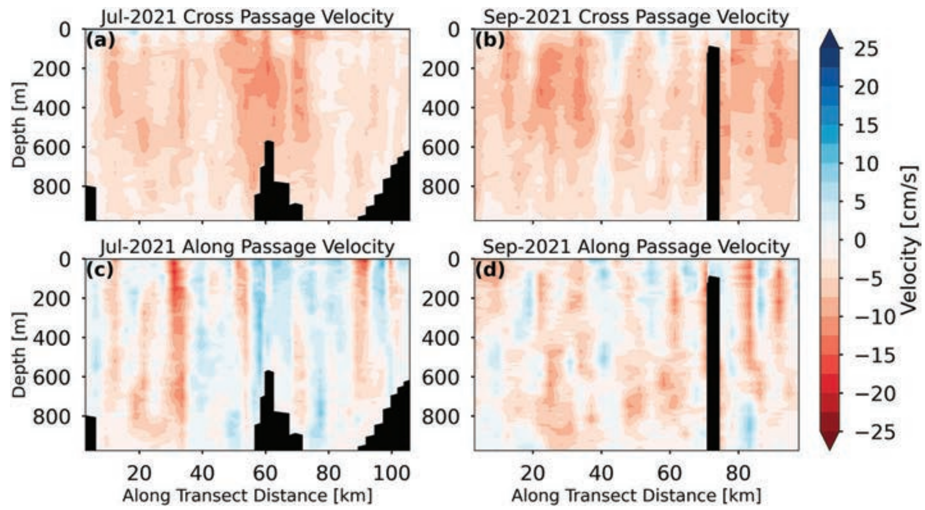

Figure 7. Anegada Passage velocity derived from glider mounted acoustic doppler profilers for the first 2021 deployment (left column) and second 2021 deployment (right column) in the cross passage (- into passage/into Caribbean, + out of passage/into Atlantic) direction (top row) and along passage (- toward bottom of passage/south, + toward top of passage/north) direction (bottom row). Both transects started on the E/NE side of the passage and traveled to the W/SW side of the passage. The duration of the July-2021 deployment was approximately 5.5 days and the duration of the September-2021 deployment was approximately 4.5 days.

approximately -5 cm s^{-1} with a maximum around -20 cm s^{-1} and little to no reversal of the flow. The mean along passage velocity for both transects was approximately zero with a maximum around ± 15 cm s^{-1}. If values for both transects are averaged, the averaged transport observed here is -4.84 Sv into the Caribbean.

Transport time-series' were calculated from the ADP derived absolute velocities collected on the repeat transect lines between St. Thomas and St. Croix during the 2020 and 2022 glider deployments (Figure 8). Mean transport values for the 2020 and 2022 deployments are within each other's error bars, despite more than double the number of transects being occupied in 2020 compared to 2022 (15 vs. 6). Within a deployment and comparing the two deployments, there is very little variability about the mean transport value, suggesting these means are relatively robust. As with the 2021 deployments, the flow here is predominately westward into the Caribbean, with little to no northward component. If values for the 2020 and 2022 deployments are averaged together, the mean transport observed here is -2.33 ± 0.71 Sv into the Caribbean.

Transport values were also derived for each transect from cross-glider track geostrophic water velocities and then averaged for each deployment (Table 1). The mean geostrophic transport for the 2020 deployment is within the error bars of the 2020 deployment absolute velocity transport value. While no standard deviation estimates are available for the 2021 deployments, there is a general agreement on transport into the Caribbean. Furthermore,

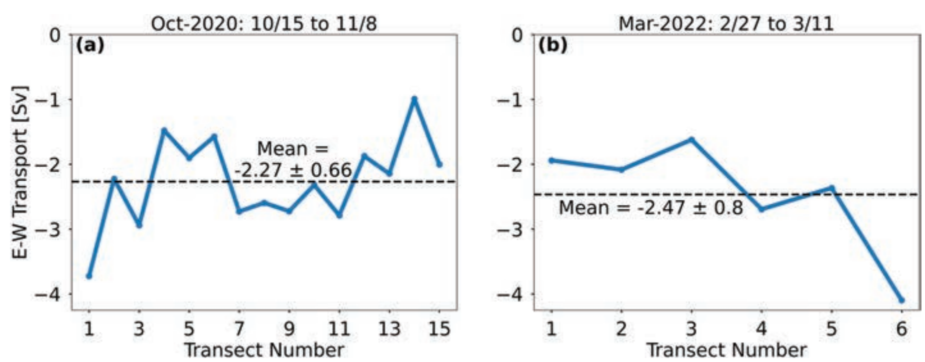

Figure 8. Acoustic doppler profilers derived absolute E(+)/W(−) transport time-series' calculated from the repeat transect lines between St. Thomas and St. Croix for the RU29 October 2020 deployment (a) and RU36 March 2022 deployment (b). Black dashed line represents the deployment mean transport. A single transect consistently took approximately 36 hr.

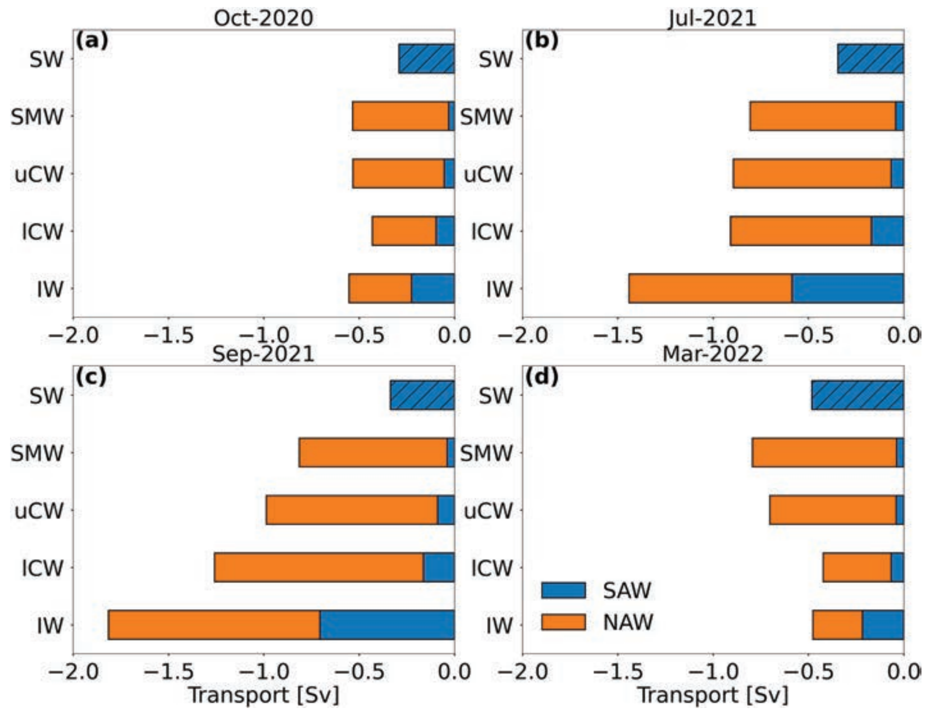

Figure 9. Transport of South Atlantic Water (blue) and North Atlantic Water (orange) in the major water masses from the isopycnal water mass analysis for the four glider deployments. The surface water is hatched blue as it was not included in the water mass analysis. The October-2020 and March-2022 data represent means of the repeat STT-STX transects.

the mean geostrophic transport for the 2022 deployment is outside the error bars of the 2022 absolute velocity transport value, though there is general agreement on transport into the Caribbean here as well.

3.2. Water Mass Analysis and Transport

Following the isopycnal water mass analysis, NAW and SAW transport is calculated per water mass for each deployment (Figure 9). The uncertainties provided below are due to the formulation of a single representative property value (e.g., SAW transport, percentage of SAW in each water mass layer, etc.) for the AP from all four deployments. Including the surface layer, the total SAW transport for each deployment is October-2020: −0.70 Sv, July-2021: −1.21 Sv, September-2021: −1.33 Sv, and March-2022: −0.84 Sv (mean = −1.02 ± 0.26 Sv), which represents 25%–34% of the respective deployment transports (Table 1, mean = 29 ± 3%). The surface layer accounts for the transport of −0.29 to −0.48 Sv of SAW, which represent 8%–20% of the total transport (mean = 11 ± 5%) and 25%–57% of the total SAW transport (mean = 38 ± 13%) for the respective deployment transports.

Excluding the surface layer, the relative percentage of SAW versus NAW gradually increases moving from SMW down to IW. For clarity, only the percentage of SAW is reported here as the percentage of NAW simply reflects the remaining percentage. The SMW is overwhelmingly dominated by NAW, with SAW representing 5 ± 0.4% of the total transport in this layer across all four deployments. The uCW layer is also dominated by NAW. SAW represents 8 ± 1.6% of the total transport in this layer across all four deployments. The percentage of SAW in each respective water mass continues to increase into the lCW layer and below. In the lCW layer, SAW represents 17 ± 3.4% of the total transport in this layer across all four deployments. The IW layer has a much more even split between SAW and NAW. SAW represents 41 ± 2.4% of the total transport in this layer across all four deployments. The relative percentage of SAW or NAW in each water mass is largely consistent across deployments indicated by the low standard deviations. Differences in SAW or NAW transport in these water masses across the deployments can be attributed to the differences in the bulk water mass transport from deployment to deployment.

Characteristic temperature and salinity profiles for this region show dominant features such as freshwater barrier layers and high upper ocean heat content and the approximate ranges of the major water masses (Figure 10). The

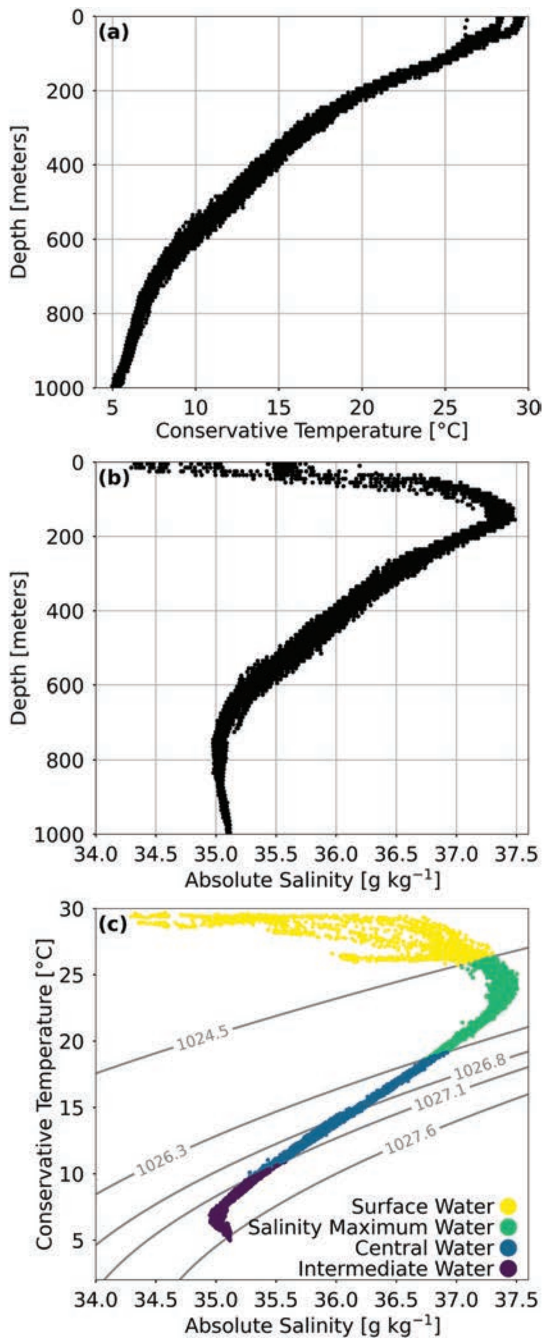

Figure 10. Temperature (a) and salinity (b) profiles in the Anegada Passage region, as well as approximate ranges of the major water masses (c) from all four glider deployments combined.

transport of specific water masses with unique source water types that distinguish their hemisphere of origin within the ranges highlighted in Figure 10 likely play an important role in determining the subsurface density structure of the upper limb of the AMOC. The implications of this balance, the transport of SAW and NAW in these different water masses, are discussed in the following section.

4. Discussion

4.1. Current Structure and Transport

In this study we present glider-based observations of subsurface velocity and integrated transport in the AP that have remarkable similarities with ship-based observations from previous literature. This comparison provides compelling evidence for glider mounted ADPs as a viable alternative to ship-based measurements from ship-mounted ADPs (Johns et al., 1999; Kirchner et al., 2008), lowered-ADPs (Johns et al., 2002), and geostrophic estimates (Metcalf, 1976; Morrison & Nowlin, 1982). While the two 2021 deployments in the AP were single passage crossings, they were intended to be more exploratory in nature, following intentionally similar transects to the two transects in Johns et al. (1999) and consequently provide a particularly valuable comparison point. The magnitude of the subsurface velocity observations from the 2021 deployments agrees well with the magnitude of the observations from the second transect presented in Johns et al. (1999). The 2021 deployments also showed similar structure as subsurface velocity maxima and weak counterflows were common. The magnitude of the subsurface velocity observations from the 2021 deployments were noticeably smaller than the first transect presented in Johns et al. (1999). This difference is likely due to the extremely high velocities in excess of 1.1 m s^{-1} that were highlighted as potentially skewing the observations in Johns et al. (1999).

The observations presented in this study bring to light both potentially new dynamics as well as upper and lower bounds in terms of transport magnitude. Table 1 from Johns et al. (2002) summarized the available transport values and a mean of -2.5 ± 1.4 Sv into the Caribbean was determined for the AP. This value is similar to the -1.8 ± 1.5 Sv mean later reported by Kirchner et al. (2008) but noticeably less than the maximum -8.4 Sv transport observed by Johns et al. (1999) during October 1986. This range in transport estimates and the potential role this flow plays in the pathways and balance of meridional overturning circulation warrant this revisitation of the AP with sustained observations using improved technology. Mean transport values from the St. Thomas-St. Croix transects (-2.27 ± 0.66 Sv and -2.47 ± 0.8 Sv) agree well with the -2.5 ± 1.4 Sv estimate from Johns et al. (2002). However, considering these estimates are more representative of what is historically referred to as the Anegada-Jungfern Passage, or a subset of the greater AP, it is reasonable to expect these values actually represent an underestimation of the total AP transport.

Though these transport estimates may be an underestimate, the repeating St. Thomas-St. Croix transects provide a time-series that sheds light on the variability of this inflow. The means and standard deviations of E/W transport are similar between the October and March deployments. A single transect takes approximately 1.5 days, which suggests the AP transport is stable on weekly time scales. In both the 2020 and 2022 deployments, there is one transect that has a transport value approximately -4 Sv. Though these transport values are greater than one standard deviation from their respective deployment mean transports, they are due to a larger barotropic E/W transport as the N/S component of the glider estimated DAC from these transects are essentially zero. It is also noteworthy that the standard deviation for the glider-based transport estimates (0.66 and 0.8 Sv) are approximately half of the ship-based estimates (1.4 Sv). Part of the reason the standard deviations are likely smaller is because there are 2–3 times more glider-based transport values used for these calculations when compared with the ship-based estimates. The large number of glider observations further highlights gliders with ADPs as a viable, if not potentially more accurate, method for measuring island passage transport.

To place the glider-based transport estimates presented in this study into the context of prior transport estimates in the region, it is important to understand how these observations were collected. First, it is noteworthy that the transport estimates from Johns et al. (1999) were derived from ship mounted ADPs with a range of only 200 m Kirchner et al. (2008) occupied the AP using a ship-mounted ADP with a range of 1400 m. However, this occupation was only for one transect and resulted in a near-zero transport estimate. The -1.8 ± 1.5 Sv mean transport values for the AP was derived by Kirchner et al. (2008) from combining this single, near-zero transport measurement with the five occupations detailed by Johns et al. (2002). Full-depth, lowered-ADPs were only used by Johns et al. (2002), however they only reported transport estimates per deployment and provided no additional details of the flow. The subsurface velocity data presented in this study then represent the first detailed, published observations of AP inflow below the 200-m profiles reported by Johns et al. (1999). This result is noteworthy because transport below 200 m accounts for anywhere from 20% to 50% of this study's 1,000-m transport estimates.

Previous literature has shown there is a common baroclinic velocity structure in Caribbean passage transports, where the upper 200 m contains approximately half of the respective full passage transport (Johns et al., 1999; Wilson & Johns, 1997). With this observation, Johns et al. (1999) applied a factor of 2 to their upper 200-m transport to estimate total passage transport. To better compare our 1000-m transport estimates, we can therefore multiply the 200-m, −2.4 Sv transport value reported by Johns et al. (1999) by a factor of two. This exercise leads to a −4.8 Sv transport estimate that is in much better agreement with the −4.43 and −5.24 Sv transport estimates (mean = −4.84 Sv) for the two 2021 outer AP deployments reported here. A total AP transport of −4.84 Sv for the outer AP also implies that roughly one-half of the transport is split to the north and south of St. Croix as the mean transport north of St. Croix is −2.33 Sv. Therefore, while the two 2021 transport values are only from one occupation, potentially more influenced by tidal and/or spatial impacts, there is reason to believe the actual bulk, mean AP transport is closer to −4.8 Sv. If the St. Thomas-St. Croix deployment transports are taken to be roughly ½ of the total transport and thus multiplied by a factor of 2 (October-2020 = −4.54 Sv, March-2022 = −4.94 Sv), the mean AP transport across all four deployments can be approximated to be -4.8 ± 0.32 Sv. This implies that the AP transport is larger than previously estimated (−2.5 Sv) and, if confirmed through additional transects across the greater AP, would represent close to 20% of the total Caribbean inflow (−28 Sv). The implications of a potentially larger transport and the transport depth structure in relation to different water masses is discussed in further details in the subsequent section.

There is a general agreement in velocity profiles and transport magnitude between the cross-glider track geostrophic velocities and the ADP derived absolute velocities for all four deployments. This is likely due to the flow being largely barotropic and the glider's DAC being used as a constraint for both the geostrophic and absolute velocity estimates. Ageostrophic effects expected in Caribbean passages (friction, curvature, confluence, internal waves, etc.) are less important in the AP as it is the largest passage. Regardless, averaging the repeat transects serves to smooth some of this variability, which is desired when discussing a bulk representation of the flow as we present here. In smaller passages, where these ageostrophic effects have caused disagreement between geostrophic and absolute velocities, averaging repeat transects and smoothing both the absolute velocities and density fields used to calculate geostrophic velocities has led to improvements (Wilson & Johns, 1997).

4.2. Contributions From the Surface Waters to the SAW Transport

In the results presented here for the surface layer, we follow the assumption that the tropical SW is entirely of South Atlantic origin (Hellweger & Gordon, 2002; Kirchner et al., 2008, 2009; Mertens et al., 2009; Rhein et al., 2005; Schmitz & Richardson, 1991; Schott et al., 1998). In their analysis of the sources of the Florida Current, SR91 were the first to consider tropical surface waters warmer than 24°C and waters in the 7–12°C range to be of South Atlantic origin. They used these temperature ranges in their analysis to estimate that ∼45% of the Florida Current transport may originate in the South Atlantic. While a more detailed and accurate water mass analysis using temperature and salinity data is now conducted for the water masses below the surface layer, we adopted the assumption made by SR91 for the surface layer as the isopycnal water mass analysis cannot be applied here. The following interpretation of the results depends only partially on this assumption as the surface layer here accounts for the transport of −0.29 to −0.48 Sv of SAW (mean = −0.36 ± 0.07 Sv), which represents a mean of only 12 ± 5% of the total transport and 38 ± 13% of the total SAW transport reported here. The surface layer contributing 38% of the transport of SAW in the AP is less than the over 50% contribution from the surface layer to the total SAW transport in the passages south of Guadeloupe from Rhein et al. (2005).

4.3. Contributions From the Saline South Atlantic SMW to the SAW Transport

In the SMW layer, the low salinity endmember from the eastern South Atlantic contributes 5 ± 0.4% which is noticeably smaller than the 30%–37% found by Rhein et al. (2005) in the passages south of Guadeloupe. As the isopycnal water mass analysis only permits two source water masses, the saline SMW from the western South Atlantic cannot be distinguished from the North Atlantic SMW and is consequently unaccounted for. Several methods have been applied to estimate contributions from the western South Atlantic SMW source. Zhang et al. (2003) used potential vorticity, salinity, and geostrophic flow maps to determine the transport pathways for waters with densities between $\sigma_\theta = 23.2$ and $\sigma_\theta = 26.0$ between the Subtropical and Tropical Atlantic in both hemispheres. Transports of 2–3 Sv and 4–6 Sv were determined for the saline North Atlantic and saline South Atlantic SMW, respectively. Using this mass balance and converting it to a fraction, Rhein et al. (2005) proposed that the saline western South Atlantic SMW could contribute 47%–54% of the North Atlantic SMW transport. Kirchner et al. (2008) expanded on the approximation made by Rhein et al. (2005) by conducting an isopycnal water mass analysis off the Brazilian coast to 40°W and between 5°S and 7°N. They determined that the fraction of the transport of the low salinity eastern South Atlantic endmember is on the order of 70%–75%, leaving a maximum of 25%–30% from the saline western South Atlantic. Using these estimations, a factor of 25%–54% could reasonably be applied to the NAW component of the SMW transport to account for the saline western South Atlantic source. With these ranges from prior literature, the potential total SAW fraction from both sources, with the 5% observed in this analysis for the fresh endmember, would then sum to 30%–59%. However, using both hydrographic and model data, Kirchner et al. (2009) determined that the low salinity endmember from the eastern South Atlantic dominates the equatorial region and prevents the saline western South Atlantic SMW from spreading northward. Therefore, it is expected that contributions from the saline western South Atlantic SMW in the AP are toward the lower end of this estimate range. Taking the minimum from this range (25%), applying it to the North Atlantic component of the SMW for the respective deployments, and including this additional SAW contribution would increase the total SAW transport for each deployment to October-2020: −0.83 Sv, July-2021: −1.40 Sv, September-2021: −1.52 Sv, and March-2022: −1.03 Sv (mean = −1.20 ± 0.28 Sv).

4.4. Total Transport of SAW Into the Caribbean

If a conceptual box model is applied to the greater Caribbean Sea, there are constraints on the through-flow that reveal unresolved aspects of the AMOC return flow here. Figure 1 may be helpful to geographically guide the reader through this section. The presence of SAW in the northern hemisphere represents AMOC return flow. Through the use of the isopycnal water mass analysis used in this analysis, Rhein et al. (2005) estimated that a maximum of 11 Sv of SAW is flowing into the Windward Island Passages of the southern Caribbean. At 26°N, it is accepted that the strength of the AMOC is 17 Sv (Frajka-Williams et al., 2019). This implies that there are 17 Sv of SAW flowing northward through the Florida Straits at 26°N. With these values as the input and output for this conceptual box model, the pathways for the remaining 6 Sv of SAW entering the Caribbean north of the Windward Island Passages and exiting through the Florida Straits are highlighted as largely unresolved.

If the mean value of −1.20 ± 0.28 Sv from the proposed addition of the saline western South Atlantic SMW is taken as the estimate for the total SAW transport through the AP, this would represent 20% of the 6 Sv of SAW entering the Caribbean north of the Windward Island Passages. However, if the St. Thomas-St. Croix transects are again considered to be representative of ½ of the total AP transport as proposed in Section 4.1, the SAW transports for those deployments would increase the October-2020 deployment to −1.66 Sv and the March-2022 deployment to −2.06 Sv. These values are in much better agreement with the −1.40 Sv for the July-2021 and −1.52 Sv for September-2021. This would bring the mean total SAW transport through the AP up to −1.66 ± 0.25 Sv which would represent 35% of the mean total AP transport reported here (−4.8 Sv) and 28% of the −6 Sv of SAW entering the Caribbean north of the Windward Island Passages.

We show here that the AP is of a larger importance for the inflow of SAW into the Caribbean than previously considered. While transport in the 5–12°C range has historically been attributed largely to the AP due to its deep sill depth (Schmitz, 1995; Schmitz & McCartney, 1993; Wilson & Johns, 1997), Kirchner et al. (2008) is the only reference to consider SAW transport throughout the entire AP through a detailed water mass analysis with co-located transport measurements. This analysis found 0 Sv of SAW transport in observational data and −0.4 Sv of SAW transport in modeled data, both of which are significantly less than the SAW transport values reported here. This difference is likely due to two factors. First, these authors reported a total AP transport of −1.8 ± 1.5 Sv that is lower than the previously accepted value of −2.5 ± 1.5 Sv (Johns et al., 2002) and considerably lower than −4.8 ± 0.32 Sv proposed in this analysis. Second, Kirchner et al. (2008) reported the fraction of SAW in the IW layer to be 21% in their observational data and 38% in their modeled data, both of which are lower than the mean of 41% proposed in this analysis.

4.5. Transport of NAW Into the Caribbean

NAW that recirculates in the North Atlantic subtropical gyre and does not represent any part of the cross-equatorial AMOC return flow still makes up a substantial portion of the transport of the Florida Current and thus must be entering the Caribbean through either the Greater Antilles, Leeward Island, or Windward Island Passages. Following SM17, the water mass with the highest respective transport in the Florida Current is found in what they refer to as intermediate water east (IWE; 14.8 ± 0.2 Sv) water mass class. IWE is comprised of NAW SMW, eighteen-degree water (EDW; Worthington, 1958), and North Atlantic Central Water, all of which have origins in the North Atlantic. This water mass class is considered to be mid-depth waters $24 \geq \sigma_\theta < 27$, above the IW layer and encompassing the SMW, uCW, and lCW layers discussed here. If NAW transport in the SMW, uCW, and lCW layers is summed for each deployment, here considering the entirety of North Atlantic SMW as to formulate an upper limit, the IWE transport in the AP could account for −1.32 Sv for October-2020, −2.33 Sv for July-2021, −2.77 Sv for September-2021, and −1.77 Sv for March-2022 (mean = −2.05 ± 0.55 Sv). A mean of −2.05 Sv would represent 14% of the IWE in the Florida Current. If the St. Thomas-St. Croix transects are again considered to be representative of ½ of the total AP transport as proposed in Section 4.1, the IWE transports for those deployments would increase the October-2020 deployment to −2.64 Sv and the March-2022 deployment to −3.54 Sv. These values are in much better agreement with the −2.33 Sv for the July-2021 and −2.77 Sv for September-2021. This would bring the mean total IWE transport through the AP up to −2.82 ± 0.45 Sv which would represent almost 19% of the IWE in the Florida Current.

4.6. Implications for Water Mass Transport Into the Caribbean

Given the uncertainties and consequences for projected changes in the AMOC (Caesar et al., 2018; Frajka-Williams et al., 2019; Praetorius, 2018; Rahmstorf, 2002; Thornalley et al., 2018) and the fact that the time-series length of our observing systems is just entering the "detection window" for determining statistically significant trends (Lobelle et al., 2020), it is vital to work toward a better understanding of the dynamics of this system. SM17 recently determined that the source of the AMOC flow through the Florida Straits is controlled potentially twice as much by NAW than by SAW. This is further significant as these authors determined decadal changes in salt transport through the Florida Straits may be impacted more by actual salinity changes rather than changes in the transport itself. That is, the Florida Current water mass structure determines the northward transport of salt more than the transport of the Florida Current itself. For example, SM17 found that both NAW and Antarctic Intermediate Water (SAW) have salinified in recent decades which increased the salinity anomaly transport without corresponding changes in the volume transport. Therefore, the transport of SAW and NAW through the Caribbean Island Passages and into the Florida Straits has substantial implications for AMOC heat and salt transport and analyses focused on determining potential upstream changes in the transport of these water masses are needed.

If the −1.66 Sv of SAW transport through the AP are considered with the 11 Sv of SAW transport thought to be flowing in through the Windward Island Passages (Rhein et al., 2005), 12.66 Sv out of the 17 Sv (74%) of cross-equatorial AMOC return flow through the Caribbean are now accounted for. While this leaves the pathways for the approximately 4.34 Sv or 26% of the remaining SAW transport unaccounted for, model analysis from Kirchner et al. (2009) suggests it may enter the Caribbean through either Mona Passage or Windward Passage (between Cuba and Hispaniola, Figure 1). This is further supported by the inconsistencies and potential corrections SM17 raise on the assumptions SR91 make on SAW transport. If we follow SM17 by not including SW transport as part of the AMOC, the 11 Sv of SAW transported through the Windward Island Passages determined by Rhein et al. (2005) would be closer to 5.5 Sv. The 50% of SAW in the SW layer relative to the total transport through the Windward Island Passages is larger than the 38% found here in the AP. If SW transport is excluded from both the 11 Sv Windward Island Passage inflow and 1.66 Sv AP inflow of SAW (5.5 and ~0.63 Sv respectively) the inflow of only 6.53 Sv or 38% of the 17 Sv SAW entering the Caribbean and exiting the Florida Straits can be accounted for. This highlights that there may be more uncertainty and unknowns in the cross-equatorial AMOC return flow pathways than previously considered.

With these results, we have shown that SAW transport in the IW layer is larger in the AP compared to other known passage transports for this layer. IW transport occurs almost entirely below 600 m and thus the deep sill depths of the AP (1,915 m) (Fratantoni et al., 1997) and Windward Passage (1,560 m) (Metcalf, 1976) highlight these passages as likely important IW transport pathways.

SM17 distinguish IWW (Intermediate Water West) as potentially contributing a large percentage of the unaccounted for AMOC transport, however the origin of IWW is noted as difficult to determine based on temperature and salinity alone. It is important to note IWW water mass class used by SM17 consists of the SMW, uCW, and lCW reported here and is distinctly different than IW discussed in this water mass analysis. SM17's IWW has been discussed as originating in the Gulf of Mexico (Schmitz & McCartney, 1993), Caribbean (Schmidt et al., 2004), or the tropical or South Atlantic (Rhein et al., 2005). Measurements of additional parameters such as dissolved oxygen and at least one nutrient parameter, depending on the number of unique source waters, that covaries with respiration/remineralization as a water mass is transported and ages could potentially shed light on water mass origin uncertainty through the use of optimum multiparameter (OMP) water mass analysis (Poole & Tomczak, 1999; Tomczak & Large, 1989). If SW transport is excluded from the SAW transport, a revisitation of all Caribbean passages to measure these additional parameters along with subsurface velocity could help to better constrain this uncertainty. Regardless, the results presented here suggest that a major finding of this analysis is the likely non-negligible transport of SAW at mid-depths in the AP.

5. Conclusion

This study presents glider-based observations of upper ocean temperature, salinity, and subsurface velocity in the AP region of the northeastern Caribbean Sea. The glider observations analyzed in this study represent a proof-of-concept for using gliders as a means for measuring island passage transport. These observations of co-located temperature, salinity, and subsurface velocity also represent the first measurements of this kind in this region in nearly two decades. Four glider deployments were conducted in the AP region, two conducting repeat transects between St. Thomas and St. Croix and two conducting single transects across the wider AP. A detailed isopycnal water mass analysis was conducted to quantify the transport of water masses with South Atlantic or North Atlantic origin in the passage transport. We interpret the transport observations collected during these deployments as showing two potentially new aspects of AP transport. The total transport (-4.8 ± 0.32 Sv) and the transport of SAW (-1.66 ± 0.25 Sv) in the AP may be larger than previously estimated, potentially by up to a factor of two for total transport. An AP SAW transport of -1.66 Sv would represent 35% of the mean total AP transport reported here and 28% of the 6 Sv of SAW entering the Caribbean north of the Windward Island Passages. These results also show gliders with ADPs are a viable method for measuring island passage transport.

Sustained observations of Essential Ocean Variables (EOVs; Lindstrom et al., 2012) improve our ability to understand, predict, and assess components of the climate system. EOVs like sea surface temperature and salinity, subsurface temperature and salinity, temperature and salinity anomaly transport, sea level anomaly, and deep density gradients have been linked to changes in the strength of the AMOC (Frajka-Williams et al., 2019; Szuts & Meinen, 2017). In the Caribbean, EOVs are also impacted by variations in the transport of water masses with differing sources and in the variations of the source waters themselves. In light of the uncertainties surrounding the AMOC, as well as the recent evidence of climate change induced impacts on the Caribbean Sea, sustained and expanded observations of these metrics are needed in this region. Observations of EOVs specifically relevant to the dynamic features of this region (heat content, heat transport, freshwater content, freshwater transport, freshwater barrier layer thickness, depth, and magnitude of salinity maximum, etc.) are especially needed.

This study has added to the growing body of literature supporting the use of gliders as an effective component of the global ocean observing system. In the three decades since Henry Stommel's 1989 vision of the Slocum Mission, the depth and endurance range of gliders have advanced, and a growing number of complex instruments are now being integrated regularly. The maturity glider platforms have now reached make them uniquely well suited to collect the "evolving maps of subsurface variables" needed for sustained climate monitoring developed in the original vision of Stommel (1989).

Data Availability Statement

Glider data used in this analysis can be found at https://gliders.ioos.us/ under the following dataset ID's: ru29-20200908T1623, ru29-20210630T1343, ru29-20210908T1943, and ru36-20220223T1807. The acoustic current profiler data collected during these deployments can be found at https://doi.org/10.5281/zenodo.7468695 (Gradone et al., 2022a). The code used for this analysis can be found at https://doi.org/10.5281/zenodo.7473774 (Gradone et al., 2022b).

Acknowledgments

We are grateful for support from the G. Unger Vetlesen Foundation for the 2020 and 2021 deployments and the Office of Naval Research (N00014-20-1-2568) for the 2022 deployment. We thank Dave Aragon, Nicole Waite, and Chip Haldeman from the RUCOOL glider team and Antonio Farchette from OCOVI for assistance preparing, piloting, deploying, and recovering the gliders used in this analysis. J.C. Gradone acknowledges support from the Department of Defense National Defense Science and Engineering Graduate Fellowship. W.D. Wilson acknowledges support from VI-EPSCoR NSF award OIA# 1946412. This is contribution #268 from the Center for Marine and Environmental Studies, University of the Virgin Islands. We thank Eli Hunter and Sam Coakley for assistance with development of the processing codes used in this analysis, Eleanor Frajka-Williams, Rebecca Jackson, and Johannes Karstensen for insightful discussion that guided the water mass analysis, and the anonymous reviewers whose comments helped greatly.

***Abstract*—Rutgers University's accelerated master's degree program in Operational Oceanography (MOO) was established in 2019 to fulfill the workforce gap of the New Blue Economy (NBE), which includes satisfying renewable energy demands as the global population approaches 9 billion by 2050. The MOO program provides students experiential learning opportunities throughout the entire 12-month curriculum, often intersecting with the various technology and data teams that operate a state-of-art ocean observing network and comprise RU COOL (Rutgers University's Center for Ocean Observing Leadership), an internationally oceanographic center of excellence developing new technologies, research, outreach, and educational paradigms for working in the ocean. Students collaborate as a cohort on hands-on activities and assignments involving operational oceanographic equipment, specifically the large fleet of Slocum gliders and expansive network of High-Frequency Radar, both of which are key data pillars for RU COOL. Students work independently on data analysis, learning to analyze, synthesize, and visualize large datasets of real-time oceanographic data and numerical ocean model output on Rutgers University's High-Performance Computing (HPC) cluster, all using the versatile and transferable Python programming language. These were the tenets with which the program was initialized.**

In the past 4 years, the MOO program has evolved considerably. The first 2 years saw the students mostly remote due to the COVID-19 global pandemic, with limited experiential learning opportunities either in the lab or in the field. The program was pivoted to a strong focus on data processing during this time, such that the graduates would still be both competitive and capable upon degree completion. As those restrictions lifted in the third year and the program returned to the original intent, focus was redistributed across both tenets. Internalizing both student feedback and performance after each course and year, as well as industry feedback on desired skills, the program curriculum shifted significantly for the fourth year. Students were tasked to collaboratively run two quarterly glider deployments. This included coordination with our glider staff team for preparation, and real-time marine weather-based decision making for the operation and piloting, as well as extensive subsequent data analysis. This unique learning opportunity came with significant student responsibility, but the cohort collaboration and tapered support from the glider staff team ultimately allowed for great student successes. The endeavor realized the student-led glider transect offshore of New Jersey, originally conceptualized at the creation of the program. This element of the ocean observatory of RU COOL now enables applied, operational experience for subsequent cohorts in the MOO program.

The program's goal has been to capitalize on the unique ocean observing lab resources and capabilities of RU COOL and Rutgers to meet the NBE workforce needs with the accelerated, experiential learning of a new generation of operational oceanography graduate students. Through the continual evolution of the program towards this goal, all MOO graduates have received employment in an oceanography-related career. The program curriculum continues to refine and adapt with each cohort, both to enhance the applied, experiential learning opportunities and to ensure skill proficiency that continually aligns with industry and government workforce needs. And while these global needs exceed the capacity of the MOO program to solely meet, our program may serve as a model for other universities to begin developing their own NBE pipelines.

Keywords—education, ocean observing systems, marine technology

I. Introduction

A. Motivation

The New Blue Economy (NBE) presents a paradigm shift in how humanity interacts with the ocean, requiring a skilled workforce to harness its vast potential while ensuring sustainable practices [1]. Graduates of marine science programs hold the key to powering the NBE's multidisciplinary teams, as they are entrusted with the task of unlocking the value hidden within observational data streams. By transforming ocean data into actionable information, these professionals play a critical role in the broader NBE data hierarchy. As the global population continues to concentrate along coastlines, and the effects of climate change, sea level rise, ocean acidification, and extreme weather events intensify, the need for operational oceanographers becomes increasingly urgent. To meet these evolving demands, Rutgers University established in 2019 an innovative master’s degree program in Operational Oceanography (MOO), aimed at providing students with comprehensive training and hands-on experience in the latest ocean observing technologies and methodologies [2][3].

B. Program Overview

The Rutgers University master’s degree in Operational Oceanography is a comprehensive and dynamic program designed to address the increasing demand for skilled professionals in NBE. The NBE represents a paradigm shift in how society interacts with the ocean, requiring a workforce capable of unlocking the vast potential of oceanic resources while ensuring sustainable practices. This cutting-edge program equips marine science graduates with the expertise and hands-on experience needed to excel in operational oceanography, where they play a crucial role in harnessing vast oceanic observational and forecast data streams.

The program's curriculum revolves around four fundamental pillars, carefully tailored to provide students with the necessary knowledge and skills for success in the NBE. First and foremost, students acquire foundational oceanographic knowledge in physical and biological oceanography courses. Delving into the intricacies of ocean dynamics, ecosystem interactions, and environmental changes, this foundational knowledge is essential for interpreting and analyzing data collected through advanced observing systems. Graduates emerge with a thorough understanding of the marine environment, enabling them to contribute effectively to decision-making processes within the NBE.

Secondly, the program places a strong emphasis on observing systems technology expertise through many operational oceanography courses. Hands-on training in hardware units enables students to become familiar with deploying and managing cutting-edge instruments, such as Slocum gliders and High-Frequency Radar. Immersed in authentic, real-world scenarios, students gain practical experience in data acquisition, quality assurance, and real-time data stream management, fostering confidence in handling complex ocean observing systems. This hands-on approach ensures that graduates are well-prepared to tackle the challenges posed by the dynamic marine environment.

To thrive in the era of big data, operational oceanographers must develop data literacy and ocean model proficiency. Through a combination of coursework and hands-on experiences, students acquire the skills to access, manipulate, and analyze large datasets, including real-time data streams from observations and models. Additionally, the program provides comprehensive training in ocean modeling, enabling graduates to work with numerical ocean models like ROMS [4] and WRF [5]. Armed with these essential data literacy and modeling capabilities, graduates can contribute effectively to advanced forecasting and predictive modeling efforts within the NBE.

Finally, the program recognizes the multidisciplinary nature of the NBE and fosters collaborative skills among its students. Team-building exercises and collaborative class projects cultivate students' abilities to work cohesively with diverse groups, mirroring real-world scenarios within the marine industry. The program provides students these operational oceanography challenges, such as operating climate glider surveys and assisting in regional HF radar networks. This emphasis on collaboration ensures that graduates are well-prepared to address complex oceanographic issues within the context of multidisciplinary teams, facilitating their seamless integration into the workforce.

C. Program Goals

The primary goal of the Rutgers master’s degree in Operational Oceanography is to address the critical workforce needs of the NBE. To achieve this, the program maintains close collaboration with industry stakeholders and conducts ongoing workforce assessments. This adaptive approach ensures that the program's curriculum remains responsive and relevant, continually aligning with the demands of the rapidly evolving marine industry. By receiving training that aligns with current and emerging needs, graduates emerge as highly desirable candidates for employment within the NBE, ready to contribute their skills and knowledge to tackle the pressing challenges faced by the marine sector.

Experiential learning is a hallmark of the program, setting it apart as a transformative educational experience. The integration of real-world training within the operational ocean observatory at RUCOOL allows students to gain unparalleled experiences that mirror the challenges and excitement of operational oceanography. Guided by experienced faculty and operational personnel, students actively participate in glider deployments, High-Frequency Radar operations, and software boot camps. These hands-on experiences foster a strong sense of camaraderie within the student cohort and create a supportive learning environment where students can apply their skills in practical settings. This immersion in real-world scenarios develops their adaptability, confidence, and resilience, nurturing a new generation of operational oceanographers who are well-prepared to make immediate contributions to the NBE upon graduation.

The program places a strong emphasis on the integration and synthesis of knowledge, fostering graduates' critical thinking and problem-solving abilities. Graduates develop the capacity to connect data, concepts, and theories into a coherent whole, enabling them to contribute effectively to higher-order functions within the workplace. By understanding the entire marine data life cycle, from data collection and quality assurance to management, interpretation, and knowledge production, students emerge as well-rounded operational oceanographers. Equipped with the ability to make informed decisions and provide valuable insights, graduates are poised to contribute significantly to the sustainable and productive use of ocean resources within the dynamic landscape of the New Blue Economy.

The compact 12-month structure of the program ensures timely graduation and industry readiness, a unique feature known as the "4+1" model. This accelerated pathway efficiently provides marine science undergraduates with the opportunity to earn a master's degree, swiftly transitioning them from their undergraduate studies to advanced training in operational oceanography. The program culminates with a thesis defense during the second summer, where students focus on skill-building for marine industries. This emphasis on practical training and industry-relevant projects ensures that graduates are not only equipped with theoretical knowledge but also possess the hands-on skills demanded by employers in the marine sector. As job-ready professionals, graduates confidently step into the NBE workforce, contributing to innovative solutions and advancements in operational oceanography.

II. Updates

A. Post-COVID-19 Changes

In Summer 2021, Rutgers University returned to in-person classes after the COVID-19 pandemic. This was crucial to the long-term success of the MOO program, as one of the core pillars is the experiential learning opportunities the program provides in an operational oceanography lab, distinguishing it from classical research-focused MS programs. The return to this style allowed for the original intention of the program to be realized, with the students participating in Slocum glider missions, High Frequency Radar services, and various unique research grant opportunities, including prolonged missions at sea. All these experiences allow for the students to interface with colleagues beyond our own operational oceanography lab as well, connecting them with potential future employers. This in-person shift led to an increase in peer collaboration as well, improving the overall teamwork dynamic amongst each cohort. Students learn to interact with one another as peer experts, building camaraderie and support across assignments and experiences.

B. Curriculum Changes

Several curriculum changes have been made since the program's creation in 2019. One of the most fundamental is the program duration. Originally conceptualized and run as a 15-month program, the program was condensed further in 2022 to be strictly 12-months. The difference is predominantly in terms of faculty support for the students, as the program start date of approximately early August remains unchanged. However, in the past, students continued beyond the following August with finalizing their research, as the university deadline was early October for a degree completion date. This allowed for a few months of overlap between separate cohorts of students, as the incoming cohort was getting setup while the exiting cohort was trying to finish their research and defend their theses. This both divided the faculty time and led to the exiting cohort becoming disjointed in the final months. In 2022, we opted to advance the program deadline to the start of August. This shift has had numerous benefits. It allows for better faculty support for the students, as the attention is not split across cohorts. Additionally, it allows for the incoming cohort of students to attend the exiting students' thesis defenses, so they immediately understand their goal for the program in the first week. To compensate for the potential loss of research time, the research component of their degrees was initialized earlier on, in the Fall semester.

Multiple changes have been made to the curriculum as a response to student feedback, as well as industry suggestions. The first of these is an incorporation of a course in Geographic Information Systems (GIS). Only some previous alumni have had experience in their undergraduate or professional careers using GIS. In attending various offshore wind conferences, the industry has voiced proficiency in GIS as a highly desirable skill. The Department of Geography department at Rutgers University offers two courses in GIS, and introductory course and an advanced course. We've since incorporated the introductory course to the MOO curriculum. This will allow the students to learn this valuable skill to make themselves more marketable and to better the NBE workforce.

The second feedback-driven curriculum change is an increase in experiential opportunities for glider piloting. Using the CPU "brain" of a glider, it is possible to simulate a functioning glider as a zero-risk, slow-paced learning environment. This is a remarkable capability, as it allows for scaffolded, authentic assessment opportunities that emulate challenges the students may face as they move to early career. Additionally, the no-risk environment encourages an inclusive space, fostering a classroom culture that focuses on individual growth. This is important in classrooms in general, and especially important to t1he MOO program, which has always strived to facilitate NBE workforce development from varied undergraduate careers.

The third feedback-driven curriculum change is the implementation of situational judgment tests (SJTs) across the program. These psychometric assessments pose authentic challenges faced by the operational workforce, with various responses to each challenge. The students then rank the various responses and justify their decisions in short-answer form. This methodology allows insight into how each student thinks and processes challenges, enabling adaptive instruction. The SJTs are implemented as individual then group assessments, comprising a Team Based Learning (TBL) exercise. TBLs are useful authentic instructional tools that strengthen soft skills such as adaptability, communication, and conflict management, all crucial components to working as part of a team.

All these curriculum changes are subject to review after implementation, to assess their viability and influence, and are continually adapted. The MOO program is meant to meet the needs of the employers, so we are constantly interfacing with the community and soliciting further ideas and changes.

C. Endurance Line Introduction

Originally conceptualized at the creation of the program, this past year saw the first implementation of the MOO Climate

Endurance Line. This transect runs from the Rutgers University Marine Field Station in Tuckerton, NJ out to the Shelfbreak, approximately 140 km, and back, every Fall and Spring. This is segment is run using a Slocum glider and is predominantly operated by the program students, with more support from the RUCOOL operational team in the Fall semester, in line with the program's 12-month experiential scaffolding. The students prepare the glider for the shelf conditions as well as the piloting files. As mentioned previously, the scaffolded glider simulation exercises will better the students' performance with this step, compensating for instructional shortcomings in the original plan. The glider collects water parameters, such as temperature, salinity, and density. This data is collected at two times of year when seasonal dynamics in the shelf waters lead to interesting dynamics, namely the setup and breakdown of shelf stratification. Additionally, the students then have two assessments with data analysis and visualization using the data collected from these transects. This multifaceted exercise serves as two summative TBL assessments, one per program semester, that are used to gauge the students' progression.

D. Thesis Format & Defenses

One of the main shifts this past year was the reformatting of thesis defense expectations. This was done to streamline faculty advising time, bolster cohesion between the students, and aid in the students' successes. The new thesis format consists of faculty-outlined succinct research projects that culminate is a communal thesis defense poster symposium, with a public and committee-only section,. This streamlines faculty time by ensuring each project is both accomplishable in the accelerated time frame of the program, and that each project is finalized by the same deadline. This is important as the deadline is within the first week of the newer cohort of students, so the two cohorts of students only overlap by approximately 1 week, minimizing the advising load on the faculty and program advisor. By having the defenses as a collective symposium, the nature of that deadline builds camaraderie to complete their research by the same date. Students empathize with one another over progress checkpoints and support each other with data analysis and visualization. Lastly, students have a firm deadline established at the start of the program; this enables them while applying for employment, as they know their availability date from the beginning. This helps for career negotiating, life planning, employment relocation.

III. FUTURE WORK

A. Enrollment

A strong component of the MOO program are the small class sizes, allowing for adaptive pacing to ensure comprehension, instructor support, and experiential learning opportunities. From 2019 to 2023, enrollment was 2, 2, 4, 6, and then 8 students. Due to the nature of the program, enrollment will likely be capped at 15 students. As seen in Figure 1, the enrollment has been predominantly white individuals, with slightly more women than men. Figure 2 shows that most of program students are from NJ, specifically Rutgers alumni, indicating both the strong presence and the need for more diverse backgrounds.

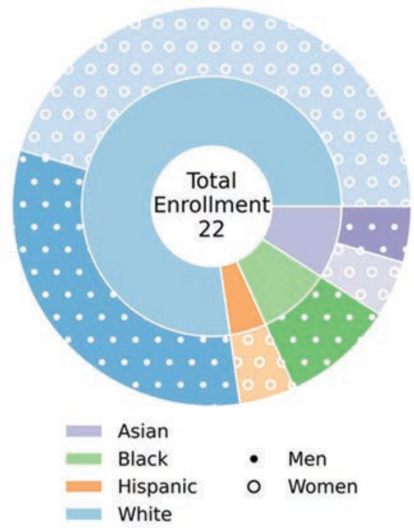

Figure 1. Enrollment demographics for the program.

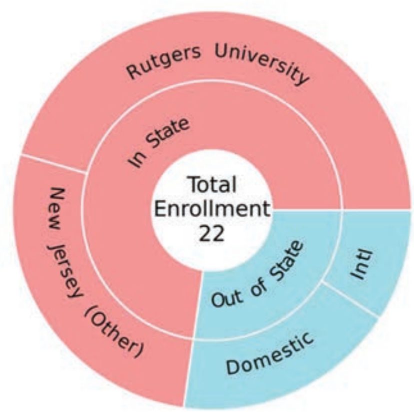

Figure 2. Student residency at time of program enrollment.

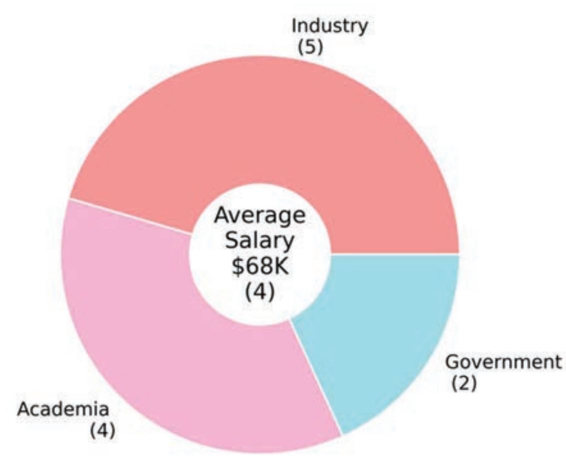

Figure 3. Volunteered career information from graduates.

B. Advisory Board

Another planned addition to the MOO program is the incorporation of an advisory board, comprised of representatives from industry, government, and academia. This board would meet semiannually to discuss the overall program trajectory and ensure that the students are learning the most sought-after skills and information for the NBE workforce. This is meant to be initialized this (2023 – 2024) academic year, and gradually expanded with student enrollment.

C. Career Internships

In line with the Advisory Board, we hope to connect our students with potential employers during the program in a more official capacity, securing internships with these employers. This would provide the students the opportunity to work alongside potential employers and for both sides to determine if each other is a good fit. It could expedite students finding gainful employment in the NBE and raise awareness within the community of the MOO program and the rigorous education the students undergo.

D. Program Certification

The final planned change to note in this program status update is the intention to have the program and its graduates certified. The program curriculum has been developed and maintained alongside individuals from the Marine Technological Society (MTS), with the plan of introducing a suite of micro-credentials, or digital badges, that professionally certify the students' expertise after having completed the program. Consideration has also been made for program certification with Institute of Marine Engineering, Science & Technology (IMarEST), specifically for Marine Technologist (MarTech). Certification from these two organizations, MTS and IMarEST, would further raise awareness within the community about the program while also improving our graduates' competitiveness.

CONCLUSION

In conclusion, the Rutgers master's degree in Operational Oceanography stands at the forefront of workforce development for the New Blue Economy. With its bespoke curriculum, experiential learning opportunities, and emphasis on the integration and synthesis of knowledge, the program produces graduates who are poised to thrive in operational oceanography and contribute significantly to the sustainable and productive use of ocean resources in the ever-changing landscape of the NBE. By inspiring and empowering future generations of operational oceanographers, the program plays a pivotal role in shaping the workforce that will drive advancements in the dynamic and promising era of the New Blue Economy.

***Abstract*— As of March 2023, the U.S. Department of Energy announced the nationwide renewable energy goal of 30 gigawatts (GW) of renewable offshore wind energy by 2030 and setting the standard of 110 GW by 2050. The location of these offshore wind energy areas (WEAs) span along the Mid-Atlantic Bight (MAB) and overlap with the seasonally occurring Cold Pool. The Mid-Atlantic Cold Pool is an economically and environmentally important feature of the northeastern seaboard that supports benthic fauna and commercial fisheries. Monitoring and understanding the stratification strength of the Cold Pool in specified areas along the coast is critical for determining possible future implications caused by offshore wind farm construction. Remote satellite images of existing European wind farms have shown turbulent wakes generated by turbine monopiles in tidal flows, yet the effects of these wakes on Mid-Atlantic stratification are still unclear. In this paper, *in situ* observational data from Slocum gliders provide high-resolution observations of the seasonally occurring thermocline and pycnocline off the southern coast of New Jersey along a commonly sampled transect known as the Rutgers University Glider Endurance Line. Calculations of water column stability using buoyancy frequency are conducted for the summer months of each year between 2016 and 2021 when the Cold Pool is at its peak to evaluate the strength of stratification. Results indicate nearshore regions are more stable than offshore regions based on higher buoyancy frequency values and a higher density gradient.**

Keywords—Cold Pool, stratification, offshore wind, Mid-Atlantic Bight, buoyancy frequency

I. Introduction

Advancements in oceanographic technology in recent decades has allowed for new and improved methods of data collection and observations. Automated underwater vehicles (AUVs) enable oceanographers to collect high-resolution, *in situ* observational data from the water column over time scales from seconds to months [1]. With an abundance of oceanographic data collected off the NJ coast, we have the ability to understand the conditions of the water column in any given time, location, or season. However, despite the increase in instrument deployments in recent years (Fig. 1), the ability to aggregate and analyze raw data has not kept up with the demand for data collection. By creating tools that can widely import, process and analyze data, these products can be used for better understanding of ocean processes and dynamics. With New Jersey's renewable energy goal of 11,000 MW by 2040 on the horizon [2], knowing what the current ocean conditions are off the coast of NJ is essential for assessing the normal amount of mixing and the previous stratification conditions as a basis for future studies on the building of offshore wind farms. In this study, Teledyne Slocum glider AUVs are the primary resource for data collection to determine the baseline state of the water column off the southern coast of NJ. This data is publicly available from the Rutger's ERDDAP data server, which provides quality controlled and assured data from various oceanographic instruments. In this section, a background of the Cold Pool will be discussed as well as the existing research on offshore wind farm impacts on ocean stratification.

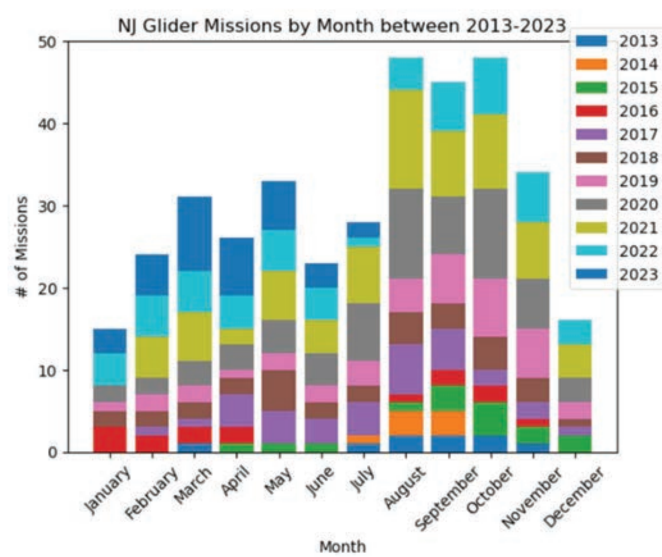

Figure 1: Number of active glider missions by month between January 2013 (bottom dark blue) to July 2023 (top dark blue) off the southern coast of NJ [-74.4 W, 38.0 N, -73.0 W, 39.3 N]. Colors indicate the year in each month. Note the increase in color height in more recent years indicating an increasing number of deployments with each year.

At the time this paper is being written, New Jersey is headed towards a renewable energy goal of 11,000 MW of offshore wind energy by 2040 [2]. Preliminary studies of the area are necessary to determine the baseline state of the water column in areas where turbines will be placed as well as gather information for future studies that analyze the impacts of the turbines on the Cold Pool. The Mid-Atlantic Bight undergoes a unique seasonal transformation, from vertically uniform in temperature, salinity, and density during the winter months, to extreme stratification in the spring and summer, becoming one of the strongest top to bottom ocean temperature differences in the world [3]. The Cold Pool experiences an onset-peak-decline life cycle, with stratification setting up in the spring, reaching its peak stability in the summer and then breaking down in the fall. As a primary feature of the MAB, the annual evolution of the Cold Pool is tightly correlated to that of the MAB shelf water [4]. The cycle of Mid-Atlantic stratification begins in the spring, when remnant winter water becomes cut off from the surface as warmer weather and increased solar radiation at the surface increases stratification. Longer days and less storm activity causes stratification to dominate the water column along the New Jersey shelf during the summer months, allowing cold bottom water to persist throughout the summer months. The Cold Pool reaches its maximum spatial extent in the early summer and breaks down in the fall with the seasonal erosion of the thermocline [4].

Existing literature on the effects of offshore wind farms on ocean stratification yield varying results, as the geographical differences between study locations and the difference in wind farm scale make it difficult to predict how turbine structures may influence the MAB. With most offshore wind farm studies based in Europe around existing wind farms, several modeling studies have found there to be an increase in turbulence around monopile structure that may influence the water column. Vanhellemont and Ruddick [5] used Landsat 8 satellite data to analyze offshore wind farm turbid wakes on sediment suspension. They found turbid wakes scaling 30-150 m wide and length scales exceeding 10 km depending on tidal speed and direction. They also noted the possible ecological impacts of the turbid wakes and their effects on primary productivity. Similarly, an unstructured grid modeling study on the impacts of offshore wind turbines on the structure of seasonally stratified seas found monopile induced mixing that extended several kilometers away, enhancing localized mixing in seasonally stratified regions [6].

Conversely, a hydrodynamic modelling study on atmospheric offshore wind farm (OWF) wakes saw a reduction in wind forcing near clusters of wind farms in the German Bight that resulted in a decline in vertical momentum transfer and less turbulent mixing near wind farms [7]. This resulted in stronger stratification during periods of weak stratification, such as the fall breakdown, as well as changes in temperature and salinity distributions that may affect the shallow water mixed layer. Another study conducted on North Sea stratification stated the current capacity of wind turbines occupying the shelf region would not have an effect on large scale stratification, but could have a significant impact on stratification if wind farms occupied an extensive area of the shelf [8]. The contradictory results of several European OWF studies indicate that additional research is needed to understand the relationship between turbine structures and the surrounding water column.

Most existing offshore wind farm research has used modeling to understand the effects of monopile structure on water column stability. While modeling is useful for studying large swath areas of coastal regions, gliders provide high-resolution and spatially-diverse profiles that give insight into the state of the water column [9]. With this in mind, the raw data obtained from gliders is valuable, but also difficult to aggregate and analyze. The lack of tools for aggregating and processing large volumes of AUV data is a challenge that must be addressed with the rising demand for coastal and offshore research. This case study aims to provide tools for processing raw glider data and utilizing the products for research applicable to various topics including offshore wind development, water column stability or stratification, and potential future environmental and ecological impacts. We also aim to determine the existing stratification strength and conditions of a section of the Mid-Atlantic Cold Pool that may provide background information for future research on the impacts of offshore wind farm development on the physical and biological components of our study region.

Due to its large size and seasonal evolution, the Cold Pool is an essential feature of the MAB thermal structure and influences the seasonal dynamics of primary productivity and species migrations. During its seasonal migration down the Mid-Atlantic Bight, the Cold Pool provides feeding and spawning grounds for various benthic fauna and migratory fish species, including Atlantic surf clams, sea scallops, ocean quahog, black sea bass, monkfish, and several species of flounder and skate [4,10]. This region also supports some of the most lucrative shellfisheries in the country, supporting local and commercial fisheries all along the eastern coast and supporting nearly 80% of the fisheries revenue in the Mid-Atlantic [11]. Some of these vital economic species like Atlantic surf clams and sea scallops are ranked high in climate change vulnerability by the National Marine Fisheries Service from changing ocean conditions like increasing temperatures and ocean acidification [11]. Due to their reliance on benthos conditions, these species are also highly vulnerable to offshore wind farm construction. Additionally, the overlap of wind energy areas with areas of highly valued harvest species rank New Jersey the most exposed state to potential economic impact from WEAs [12]. Analyzing existing stratification properties of the Mid-Atlantic Cold Pool will give insight into possible ecological impacts from offshore wind development. Furthermore, the methods of processing raw data in the MAB region may become helpful in future research not only along the eastern seaboard, but also in stratified seas with leased offshore wind farm areas. The results found in this paper will contribute to national ocean observing systems and improve coordination among observing platforms.

II. Methods

The purpose of this case study is to provide a set of tools for aggregating and analyzing multiple glider datasets to evaluate upper ocean stratification across the continental shelf of New Jersey between 2016 and 2021. The focus area of this study was a cross shelf transect in southern New Jersey approximately 39.4°N, 74.2°W to 38.8°N, 73.0°W along the Rutgers

University Glider Endurance Line (Fig. 2). This transect was chosen for its history of frequent glider sampling, its location in regards to leased offshore wind farms, and its swath of nearshore and offshore profiles. The E-Line has been the site of frequent Rutgers glider observations since the early 2000s as the basis of previous NJ shelf studies [13,9]. Its location crosses the Atlantic Shores North (OCS-A 0549) and Atlantic Shores South (OCS-A 0499) commercial wind lease areas [14]. Sampling depths ranged from the surface to 137 m deep, with 3 missions strictly nearshore and 4 cross shore missions. Teledyne Slocum gliders were the primary source of data collection for this case study. Gliders have a wide range of vertical motion spanning from the surface to 1000's of meters deep, allowing a full visualization of the water column and sub-meter scale observations. The data utilized in this study was pulled from the Rutgers ERDDAP Glider TableDap page, a publicly available network of ocean observational data and tools. A specified latitude, longitude, and time constraint were used to narrow the data field down.

Using Jupyter Python notebook, specified glider data was pulled by selecting glider ID's from the ERDDAP Advanced search page. A spatial extent of 39.6°N, 74.5°W to 38.5°N, 72.8°W and a limited time window of July and August when peak stratification occurs [4] were selected for the years 2016-2021. The selected glider missions were further trimmed to only include data within 15 km from the E-Line. This was done by calculating the bearing of the E-Line, then finding the latitude and longitude of 10 points on the map. The 10 points selected were bearings of 0°, 45°, and 90° from the E-Line, creating a decagon around the E-Line. Each dataset was then trimmed to contain profiles within the polygon around the E-Line. This was done by determining if each latitude and longitude point in the dataset was within the bounds of the polygon. Further in-depth methodology for this section may be referenced in the Data Availability section.

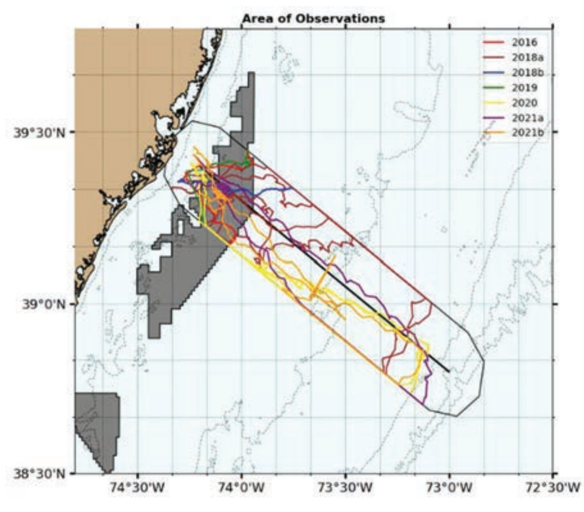

Figure 2: Map of area of observations off the southern coast of New Jersey. The black line represents the E-Line, a frequently sampled transect across the continental shelf. The length of the E-Line is approximately 123 km long, with the 50 m isobath approximately 70 km from the beginning of the E-Line. Each colored track corresponds to an individual glider mission active in July or August between 2016 and 2021. Separate glider missions active in the same year were distinguished with an (a) or (b). The gray areas represent leased offshore wind areas.

Glider missions along the E-Line in the months of July and August between 2016 and 2021, a total of seven individual missions, were included in the case study. Datasets were then separated into nearshore and offshore subcomponents (Fig. 3), with nearshore profiles being defined as profiles inshore of the 50 m isobath and offshore profiles defined as being deeper than the 50 m isobath. This was done by checking the nearest bathymetric value for each latitude and longitude location in the trimmed dataset. The value of the nearest bathymetric point for each row in the dataset was saved to the dataset to then reorganize the data based on the bathymetry value being greater or less than 50 m. Once separated, the maximum density gradient ($\frac{d\rho}{dz}$) and buoyancy frequency (N^2) for each individual or 'unique' profile was calculated. This step was achieved by creating a function that groups or 'bins' the data by a specified depth and averages the data into those specified bin depths. For this study the bin values used were 1m depths from 0 to 150 m. Differences in temperature and density were found with difference in depth across the binned data frame and added back into the dataset. A new subset was then created to find the maximum change in temperature or maximum change in density of each unique profile. The subset with the maximum ($\frac{d\rho}{dz}$) values was then used to calculate N^2 for each unique profile in the subset using Equation (1).

$$Equation\ 1: N^2 = \left(\frac{-g}{\rho} \cdot \frac{d\rho}{dz}\right) \quad (1)$$

Where N^2 is buoyancy frequency, g is gravity, ρ is our reference density value of 1020 kg/m³, and $\frac{d\rho}{dz}$ was the change in density with depth of each profile. The buoyancy frequency measurement determines the strength of stability, defined as the vertical frequency at which a water parcel is vertically displaced [15]. The maximum buoyancy frequency of each unique profile was recorded and added back to the dataset. Boxplots were then created to visualize the distribution of N^2 values for all nearshore and offshore profiles as well as determine the average maximum N^2 for each glider mission.

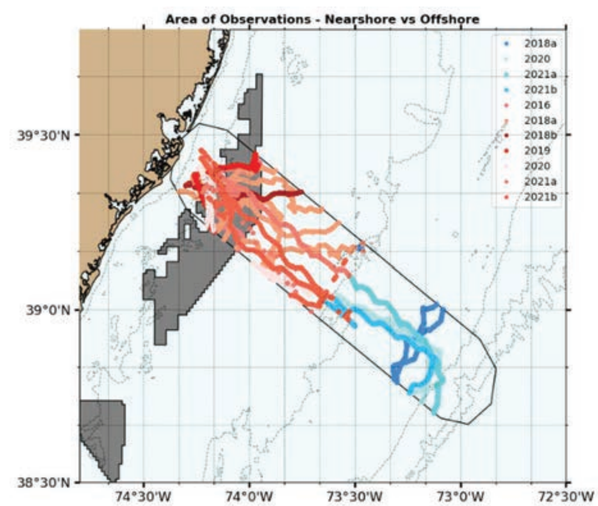

Figure 3: Separation of nearshore (red) and offshore (blue) glider observations separated across the 50 m isobath. Data is limited to within 15 km radii of the historic glider E-Line. Different shades of red and blues correspond to separated glider missions. Gray outlined figures represent wind energy areas.

III. Results

The aim of this case study is to analyze the stratification strength along a transect across the Mid-Atlantic Cold Pool during the summer months July and August between 2016 and 2021. While we focus on this limited 5 year window, future analyses could easily expand and contract the spatial and temporal subset based on study preference. Maximum change in density with depth and the associated maximum buoyancy frequency were calculated for individual profiles of each glider mission to determine the time and location of peak stability. Boxplots were constructed for all profiles across all years separated into nearshore profiles and offshore profiles to visualize and compare the distribution of buoyancy frequencies (Fig. 4, 5, 6). The boxplots show the median N^2 value, the interquartile range (IQR) and the maximum and minimum[1] N^2 value for each year and each region.

The mean buoyancy frequency for nearshore profiles was 0.011 s^{-2} with an IQR between 0.007 s^{-2} and 0.014 s^{-2}. The mean buoyancy frequency values for each year of nearshore profiles were: 0.007 s^{-2} for 2016, 0.012 s^{-2} for 2018a, 0.012 s^{-2} for 2018b, 0.014 s^{-2} for 2019, 0.008 s^{-2} for 2020, 0.010 s^{-2} for 2021a, and 0.010 s^{-2} for 2021b. The interquartile range was largest for 2019, from 0.010 s^{-2} to 0.017 s^{-2} and also had the highest average N^2 value. The mean for offshore profiles was slightly lower at 0.008 s^{-2} with an IQR of 0.006 to 0.010 s^{-2}. Average buoyancy frequencies per year for the offshore regions were 0.007 s^{-2} for 2018a, 0.007 s^{-2} for 2020, 0.009 s^{-2} for 2021a, and 0.009 s^{-2} for 2021b. The widest distribution of N^2 values for the offshore region was in 2021b, with an IQR of 0.007 - 0.011 s^{-2}. The mean buoyancy frequency across the E-Line for all years was 0.010 s^{-2} and the interquartile range of all profiles was 0.007 to 0.013 s^{-2}, with the median buoyancy frequency value being 0.010 s^{-2}. There were outliers for the calculated values stated above, but they were not included in the figures to reduce the scale of the boxplot range.

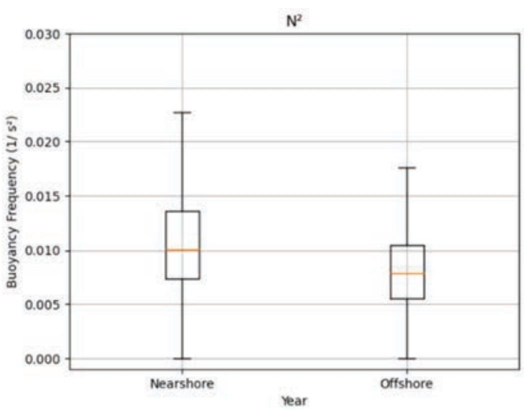

Figure 4: Boxplot of buoyancy frequency (N^2) values for all profiles nearshore (< 50 m isobath) and offshore (> 50 m isobath) across all years. The outliers of each dataset are not shown in these figures.

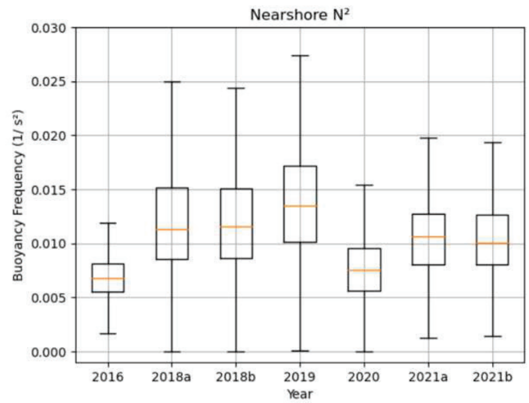

Figure 5: Boxplot of all nearshore profiles (< 50 m isobath) for years 2016 to 2021. Separate glider missions active in the same year were distinguished with an (a) or (b).

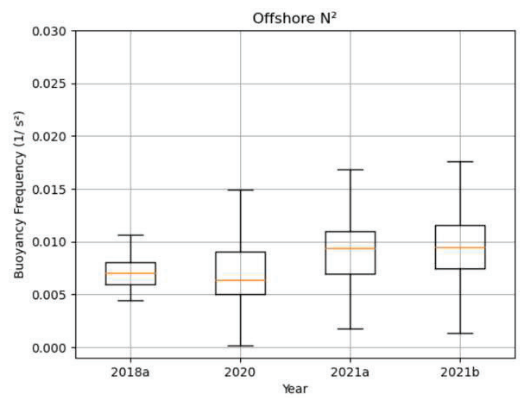

Figure 6: Boxplot of all offshore profiles (> 50 m isobath) for years 2018, 2020, and 2021. There were no profiles over 50m in depth for glider missions RU28 (2016), RU30 (2018b), and RU28 (2019).

IV. Discussion

Using raw glider data available from the public Rutgers ERDDAP data domain, we processed and quantified the mixing parameter buoyancy frequency for multiple years along the Rutgers University Endurance Line. The results indicated the average buoyancy frequency N^2 across the shelf for all years is approximately 0.010 s^{-2}, where nearshore profiles have a similar average N^2 of 0.011 s^{-2} and offshore buoyancy is slightly lower at 0.008 s^{-2}. Plots of buoyancy frequency with depth revealed similar results to past studies along the E-Line that saw a stronger stratification within 80 km nearshore and a more diffused pycnocline offshore [16]. The area of strongest change in N^2 with depth was between 10-20 m for nearshore profiles while offshore profiles had a less distinct change in N^2 (Figure 7b).

Few studies of maximum buoyancy frequency exist within the MAB, however many studies use the vertical temperature gradient to evaluate stratification strength. To compare our results to past studies on Cold Pool stratification, we calculated the maximum change in temperature with depth ($\frac{dT}{dz}$) for each

[1] ¹Due to the presence of outliers in the data the 'minimum' and 'maximum' values illustrated on the boxplots are calculated as Q1-1.5*IQR and Q3+1.5*IQR.

unique profile. We found the temperature gradient to be stronger in the nearshore region than the offshore region. Nearshore profiles had a higher maximum average of 3.16 °C/m and offshore profiles had an average of 2.25 °C/m. Median $\frac{dT}{dz}$ values for the two regions were closer in value than the average values with a nearshore $\frac{dT}{dz}$ median value of 2.92 °C/m and offshore value of 2.12 °C/m. Existing literature on Cold Pool stratification revealed varying maximum thermal gradients from 0.5 - 0.8 °C/m in nearshore profiles to >1.0 °C/m in both nearshore and offshore sites [4, 17].

Our results indicate that nearshore profiles have a higher maximum buoyancy frequency and larger temperature change with depth, which agrees with previous studies that found a stronger thermal gradient in nearshore sites despite a shorter duration of Cold Pool presence [17]. It is possible that river runoff from the Hudson River may contribute to a salinity dominated stratification nearshore during the summer months, whereas offshore is dominated by temperature induced stratification from the Cold Pool and shelf break [9]. The offshore region is also subjected to internal tidal forcings that may result in weaker stratification [18]. A strong density gradient in nearshore sites may be partially attributed to shallow depths where the difference in warm, fresh surface waters and cold, salty bottom waters create a strong top-to-bottom density difference in a relatively short water column (Fig 7a).

Our results may be influenced by the lack of offshore data in our selected time and spatial window. The unequal sample size of nearshore versus offshore profiles may have underestimated the mean buoyancy frequency of offshore regions due to lack of data available in the offshore region from the active glider missions in the area from 2016-2021. Out of the 7 glider missions chosen for this study, 4 of them had profiles deeper than 50 m, whereas all 7 missions had nearshore profiles (< 50 m isobath). This difference in sample size between nearshore and offshore profiles may have biased the calculation of N^2 and $\frac{dT}{dz}$ in the offshore region. Adjusting the nearshore and offshore data pools with additional offshore glider missions in the near future may result in less biased average buoyancy frequency. These findings as well as the notable overlap between the leased offshore wind farms and the Cold Pool indicate there is a need for further research on offshore wind development effects on the Cold Pool.

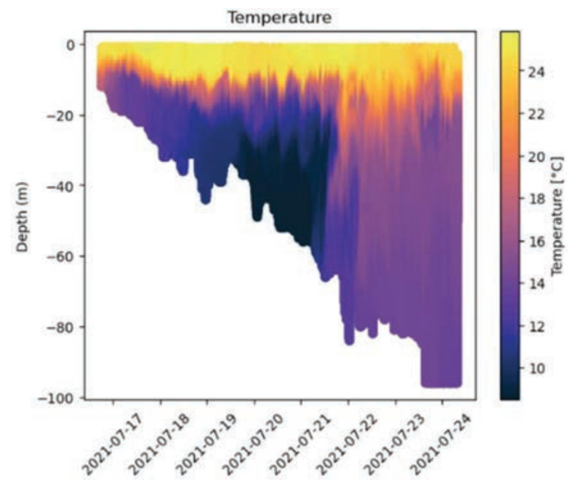

Figure 7a: Cross section of temperature with depth from a segment of RU30 July 2021 mission. Change in color represents the change in temperature with depth with lighter colors corresponding to a greater value. Note the dark (<10 °C) area in the middle of the figure that illustrates the presence of the Cold Pool.

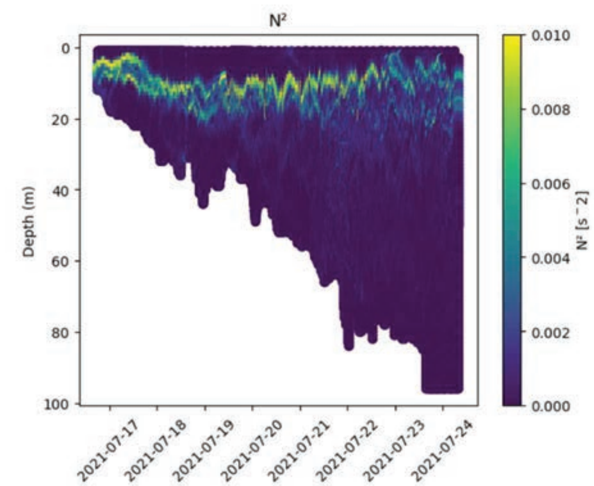

Figure 7b: Cross section of buoyancy frequency with depth from a segment of RU30 July 2021 mission. Change in color represents the change in buoyancy frequency with depth with lighter colors corresponding to a greater value. Note the strong stratification in the nearshore (< 50 m) region whereas in the offshore (> 50 m) regions buoyancy frequency values are spread more evenly with depth.

Analyzing existing stratification conditions in the planned offshore wind energy areas will aid in future research aimed at quantifying the amount of turbulence induced by wind turbines in the Mid-Atlantic region. Understanding the physical effects of monopile structures on stratified seas requires a thorough understanding of the existing state of the water column including the internal wave frequency and its stability. Using *in situ* water column data gives a realistic estimate of buoyancy frequencies in nearshore and offshore regions of the NJ coast, which can be used in models to study possible turbine-induced mixing on the Cold Pool. The methodology used here may assist in preliminary studies that predict the effects of turbine structures in stratified flow. A study conducted in the German Bight observing the stratified flow around wind turbines saw an additional 7-10% of mixing from flow around a monopile structure [19]. The time scale of this enhanced mixing was on a comparable time scale to the rate of stratification formation, indicating this supplementary mixing may have significant effects on a weakly stratified water column. However, a more recent study in the German Bight saw a reduction in wind speed and shear force at the ocean surface, leading to a decrease in momentum transfer between atmosphere and ocean surface that resulted in less turbulent mixing tens of kilometers within offshore wind farms and thus enhanced stratification strength [7]. The multiple influences of atmospheric and oceanic conditions make it difficult to predict the impact of turbines on stratification.

Additionally, regional differences between the North Sea and the MAB limit the correspondence between European studies and the present study. The MAB has both weaker currents (3-15 cm/s versus nearly 1.0 m/s in the German Bight) and a deeper water column than the North Sea [20,8]. The stratification used to analyze turbulent mixing in European OWFs is much weaker than the peak stratification of the Cold Pool during the summer months [8]. Therefore the additional mixing created by flow past turbines will be of greater significance in regions with weak stratification than those with strong stratification such as the Cold Pool. Furthermore, the lack of buoyancy data along the NY/NJ Bight make it difficult to compare the present results to existing studies in which the primary method of determining stratification strength is based on surface to bottom gradient differences [21]. The methods provided in this paper may promote further research on stability of the water column in the MAB especially in regards to monopile installation.

V. CONCLUSIONS

The Mid-Atlantic Cold Pool is an essential feature of the eastern U.S. seaboard that provides habitats and spawning grounds for various economically important benthic species. The strong thermal stratification of the Cold Pool enables cool bottom temperatures to persist throughout the summer months and support local and commercial fisheries. With the development of offshore wind farms overlapping the Cold Pool, little is known about the possible implications of turbine-induced mixing on the stratification of the Cold Pool. By using observational glider data, we quantify the buoyancy frequency of nearshore and offshore regions of Southern NJ to analyze the water column stability of these regions.

Here we provide a new approach to aggregating large volumes of raw glider data and methods of processing the data. The trimmed AUV datasets allow for a precise analysis of the sea state around the E-Line including temperature gradients, density gradients, and buoyancy frequencies of nearshore and offshore profiles. Our results infer coastal waters are more stable than offshore in the Southern NJ area, possibly due to a stronger density gradient and less tidal mixing than offshore. We acknowledge the limitations of our study, including the lack of offshore data that may lower the actual value of offshore buoyancy frequencies. Future research in deeper water (>50m) is needed to improve this estimate of offshore stability. This work will aid in on-going projects and coastal management based on research and monitoring of the MAB in regards to offshore wind construction including the NJ Research and Monitoring Initiative (RMI) as well as current and planned NJDEP projects.

ACKNOWLEDGMENT

We would like to thank Rutgers Department of Marine and Coastal Sciences, the Coastal Ocean Observing and Leadership team, and the Masters of Operational Oceanography students for their endless support.

DATA AVAILABILITY

The data used for this analysis was collected from the Rutgers University ERDDAP Glider Table Dap page (https://gliders.ioos.us/erddap/search/advanced.html?page=1&itemsPerPage=1000&protocol=tabledap) and the Python notebooks described in the Methodology section are available on GitHub (https://github.com/emilybusch1/Separating_nearshore_offshore_glider_profiles).

***Abstract*— There is a global need for skilled workers across multiple sectors within the marine industry (research, renewable energy, fisheries, ports/shipping, infrastructure, national security, tourism, etc.). In order to prepare this workforce, we must collectively take action to establish attractive, innovative, agile and equitable educational opportunities. These opportunities should capitalize on skill sets for a range of workers and encourage engagement pathways for life-long learning through obtaining stackable microcredentials and professional certificates to promote personal growth, keep pace with technological changes, and capitalize upon opportunities within the sector.**

Keywords—ocean technician, workforce development, education, microcredentials, marine technology

I. Introduction

There is a global need for skilled marine industry workers for available positions in various sectors, including research, renewable energy, fisheries, shipping, infrastructure, national security, and tourism [1]. Remarkably, many of these positions do not require advanced degrees in engineering or science but instead necessary skills and proficiencies that align with technical requirements common to the industries they serve.

To foster these vital skills within a condensed timeframe, there is an imperative for innovative and adaptable educational programs. These programs must break away from the conventional, compartmentalized education model and, instead, offer multiple expedited routes to degree and certification attainment. This shift towards a competency-focused credentialing framework will open up opportunities for a more diverse talent pool to meet the expanding workforce requirements.

To address this need, in collaboration with community members, the Marine Technology Society (MTS) is actively establishing the infrastructure necessary to issue a diverse range of stackable microcredentials. These microcredentials will create accessible and flexible pathways to learning and vocational training. The microcredentials address core competencies required for employment in the ocean/marine/blue economy. These flexible learning pathways will be of value to a spectrum of learners including those: entering the workforce; looking to applying skill sets acquired during military service; seeking acknowledgement of skills acquired "on the job"; and in need of employment retraining. The cross training/upskilling provided through the microcredentials framework is intended to form workers capable of generating innovation and new applications and/or refinements of existing technology, and development of new technologies.

II. Development of MTS Microcredentials

A.1. What are microcredentials?

The concept of microcredentials is not new. Microcredentials began their ascent over 20 years ago in computer science as a method for capturing skills and discrete knowledge for recognition by colleagues and employers. The concept took hold in the field with organizations such as Google, Cisco and Microsoft leading the way by recognizing and offering the "stackable" learning opportunities [2]. The concept has grown in several other industries and are currently quickly gaining popularity.

Microcredentials are short, competency-based recognition that are smaller in scale and scope and represent specific knowledge and/or skills acquired and demonstrated. Microcredentials can be "stacked" in various ways – like interlocking blocks, or pathways – to build toward specific certification and/or employment goals.

A.2. Why microcredentials?

Microcredentials are quickly gaining popularity because they represent a personalized approach to education. Learners, within reason, can create their own pathway based on interests and career goals and address gaps in skills. Once a learner demonstrates their competency, a digital badge is issued. Badges are a transferrable symbol used to verify the attainment of specific competencies and can be added to resumes, LinkedIn profiles or other social media platforms as instant recognition of their personal skill set. Therefore, a learner can instantly demonstrate their skills instead of waiting several years for a degree to be issued.

Flexibility is key to the modern college student. Currently, the majority of undergraduate students in the U.S. are employed full-time while attaining their degree, are 25 years or older, and attain their degree while attending college part-time. Less than 20 percent of undergraduates live on a campus [3].

A.3. Why MTS microcredentials?

MTS identified the convergence of the pending and future industry employment needs and the need for flexible learning pathways to engage and broaden the talent pool. These flexible learning pathways will be of value to a spectrum of learners including those: entering the workforce (undergraduate and graduate students); looking to applying skill sets acquired during

National Science Foundation (NSF-OCE 2308556) .

OCEANS 2024 - Halifax | 979-8-3315-4008-1/24/$31.00 ©2024 IEEE | DOI: 10.1109/OCEANS55160.2024.10753811

979-8-3315-4008-1/24/$31.00 ©2024 IEEE

military service; seeking acknowledgement of skills acquired "on the job"; and in need of employment retraining.

MTS also recognized a wide-spread issue of individual schools struggling to have their microcredentials acknowledged by potential employers. With a wide array of definitions, robustness of skill recognition and ability levels represented with individual school issued microcredentials, employers can be at a loss to understand what learning and skills a microcredential represents.

To address this need, MTS applied for and received a grant from the National Science Foundation (NSF-OCE 2308556) to begin the effort of creating microcredentials representing skills needed for the blue economy workforce. In collaboration with community members (academia, industry, military and government), MTS is actively establishing the infrastructure necessary to issue a consensus-based framework of competencies for a diverse range of stackable microcredentials. The framework will be openly available on the MTS website for use by educators and employers. The hope is for employers to use the articulated competencies in job descriptions and educators will partner with MTS to issue microcredentials representing the various competencies.

B. Development Process

The Microcredentials Core Team met over the first three months of the project to discuss the draft framework to house the competencies for the MTS microcredentials. The team settled on the following general structure (Table 1):

Table 1. Trainee/Student Level
Foundational
Learning focus Validated Experience: • 30 – 40 hours (camp cycle) • Fundamentals of the technology • Beginning concepts • Uses/application • Basic knowledge demonstrated
Intermediate
Learning and competency demonstration/practicum Validated Experience: • Months/crosswalk • Technology applications • Intermediate concepts • More complex uses • Intermediate level knowledge demonstrated • PD at work and application
Advanced
Competency mastery through demonstration Validated Experience: • Practical experience leading to success in the course • Capstone Camps ○ Platforms ○ Sensors ○ Data

The National Science Foundation grant is for the development process needed to establish Foundational level microcredentials for the Trainee/Student Level for three marine technologies - Sonar, Glider and ROV – and Intermediate level microcredentials for Sonar and Gliders.

The Microcredentials Development team (technical and education experts) met periodically over the span of four months to generate the draft competencies for the Sonar, Glider and ROV Foundational microcredentials. Once the drafting process was complete, the Microcredentials Core Team recruited people to serve on the Microcredentials Review teams (sonar, glider and ROV). Each team was comprised of representatives from academia, industry, military and government. This action was purposeful to benchmark the competencies required to obtain the Fundamental and Intermediate credentials through the lens of each sector. The intention is to create microcredentials valued in all sectors, and create a malleable talent pool to address employer needs.

The Fundamental competencies for sonar, ROVs and gliders were vetted by the committees during the Spring of 2024.

The development cycle worked well during the first iteration and is planned for use again during the development of the Intermediate microcredentials beginning late Autumn 2024. However, the development cycle will be continually evaluated to look for improvement or streamlining as additional microcredentials are added to the MTS portfolio.

III. Implementation

The developed Foundational competencies were used as the content outline for two MTS Summer Workshops. The first workshop was conducted by partner school Rutgers University, June 10 -14, 2024. Ten learners (Figure 1) attended the workshop and each attendee earned two Foundational microcredentials, Glider Hardware and Glider Software (Piloting). Please see Waite, et al, 2024 OCEANS paper for more details on the workshop.

Figure 1. Workshop participants disassembling a glider.

The second workshop was conducted by partner school Northwestern Michigan College, June 17 – 21, 2024. Thirteen learners attended the workshop and each attendee earned two Foundational microcredentials, Sonar and ROV. Please see Van Sumeren, et al, 2024 OCEANS paper for more details on the workshop.

Figure 2. Workshop participants preparing an ROV for deployment.

Data gathered through program evaluation of the workshops is being analyzed and will inform the guidelines for developing future microcredentials. In addition, a select few workshop participants will be asked for an interview with the Project Evaluator to understand from the student point of view any major gaps in the learning experiences. The evaluation data will be shared with the partners to improve delivery of the material and better understand how to collectively improve the programs and processes.

Both schools, Rutgers University and Northwestern Michigan College, intend to continue the partnership with MTS and issue microcredentials to their registered students throughout the academic year.

IV. PARTNERSHIPS AND EXPANSION

As MTS microcredentials are developed and ready for implementation, MTS will seek partnerships with several institutions to implement the Foundational, Intermediate and Advanced skills training locally. Learners can earn microcredentials at the institutions during discrete workshops, like the MTS summer workshops, or as part of regular college courses. The MTS Microcredentials Core Team will work with the institutions to identify components of existing curricula which address the competencies outlined in the MTS competencies framework. In that scenario, a learner could earn academic credit through their respective colleges, while earning the relevant MTS microcredential badges. If the colleges also offer their own microcredentials, the learner would also earn the "sister" microcredential from the college. The course credit would count toward the eventual degree, however, instantly the student could share their earned microcredentials on their resumes, social media channels, or to employers.

Again, the goal is to create a consensus-based set of competencies led by MTS. Utilizing the openly available framework and partnership model, the "guesswork" will be removed for potential employers. If an applicant provides a transcript and/or resume that contains MTS issued microcredentials, the employer will be able to understand exactly which skills the learner has mastered.

To ensure all partner institutions are providing the agreed upon competencies to their learners, a Partners Review Committee will work with the partners to review curricula and/or instructional materials. Each vetted partner will commit to delivering the core materials to the agreed upon competencies and standards. The application and partner schools will be reviewed periodically to ensure quality control.

V. CONCLUSIONS

The MTS microcredential framework will create accessible and flexible pathways to learning and vocational training and recognize skills and abilities over traditional degrees. The cross training/upskilling provided through the microcredentials framework is intended to form workers capable of generating innovation and new applications and/or refinements of existing technology, and development of new technologies.

The stackable MTS microcredentials, endorsed by accredited partners (government, industry, NGOs, academic) institutions, will directly address the workforce preparation requirements while enhancing education institutions' ability to shift some of their programs towards skills-based credentialing. This approach will better equip learners for the workforce in a shorter time frame. The microcredentials system accommodates various individuals, including those in the early stages of their careers seeking entry into the industry, those looking to enhance their existing knowledge and skillset, individuals aiming to transition into new industries, and those interested in formal recognition for their existing skills.

Recognition of the value of MTS microcredentials across sectors is intended to accelerate job placement and contribute to the development of a globally competitive STEM, and specifically an ocean technician workforce prepared to support the exploration, research and development that lies ahead.

ACKNOWLEDGMENT

The authors would like to thank the many members of the Microcredentials Review teams (sonar, glider and ROV) for their assistance, valuable insight and expectations regarding competencies.

Abstract

Food resources in the ocean are often found in low densities, and need to be concentrated for efficient consumption. This is done in part by oceanographic features transporting and locally concentrating plankton, creating a highly patchy resource. Lagrangian approaches applied to ocean dynamics can identify these transport features, linking Lagrangian transport and spatial ecology. However, little is known about how Lagrangian approaches perform in ageostrophic coastal flows. This study evaluates two Lagrangian Coherent Structure metrics against the distribution of phytoplankton; Finite Time Lyapunov Exponents (FTLE) and Relative Particle Density (RPD). FTLE and RPD are applied to High Frequency Radar (HFR) observed surface currents within a biological hotspot, Palmer Deep Canyon Antarctica. FTLE and RPD identify different transport patterns, with RPD mapping single particle trajectories and FTLE tracking relative motion of paired particles. Simultaneous measurements of circulation and phytoplankton were gathered through the integration of vessel and autonomous glider surveys within the HFR footprint. Results show FTLE better defined phytoplankton patches compared to RPD, with the strongest associations occurring in stratified conditions, suggesting that phytoplankton congregate along FTLE ridges in coastal flows. This quantified relationship between circulation and phytoplankton patches emphasizes the role of transport in the maintenance of coastal food webs.

Keywords: lagrangian transport; coastal oceanography; spatial ecology; food web focusing; lagrangian coherent structures

Introduction

Ocean food resources are patchy, concentrated in some areas and sparse in others. This uneven distribution creates ecosystems with fragmented spatial and temporal distribution of both primary producers and their consumers (Benoit-Bird 2023). Food resources (e.g. plankton) must be concentrated either physically or biologically in order to support larger upper trophic species, maintaining a sustainable food supply (Lasker 1978). The processes that govern the attraction of upper trophic species to areas of concentrated food resources is called food web focusing (Genin 2004). As if visiting marine "grocery stores," mobile grazers and foragers rely on concentrated food sources that have been grown elsewhere and transported and concentrated in higher density patches. Besides transport, biological processes can also drive patchiness including population growth, swarming behavior, or predation. Recent studies have demonstrated the importance of physical advection to both concentrate plankton in the creation of these patches (Hofmann and Murphy 2004, Kohut et al. 2018 Oliver et al. 2019) and to maintain connectivity between neighbouring systems sharing resources (Michael et al. 2006). The role of surface currents in the concentration and transportation of plankton has been widely studied in pelagic, open ocean, mostly geostrophic systems on mesoscale and days-long time-scales (Lehahn et al. 2007, Hernández-Carrasco et al. 2011, 2018, Huhn et al. 2012, Li et al. 2015, Lévy et al. 2018, Liu et al. 2018). However, the role of advective transport in more complex, nonlinear, ageostrophic coastal flows is more difficult to characterize. Flow in productive nearshore ecosystems is complicated by tides, buoyancy, highly variable winds, and complex bathymetry, which all contribute to the advection and concentration of plankton patches. This study investigates how coastal ocean currents create localized marine "grocery stores" by transporting and concentrating phytoplankton into discrete patches.

A variety of Lagrangian Coherent Structure (LCS) metrics are used for their ability to quantify advective transport in fluid flows. Attracting LCS are distinct areas within a flow field that have a strong influence on the attraction of neighboring particle trajectories (Farazmand and Haller 2012, 2013, Haller and Beron-Vera 2012, 2013, Haller 2015) using either a single or a paired particle tracking method. When applied to oceanic systems, attracting LCS metrics have the potential to quantify mechanisms of plankton concentration (Huhn et al. 2012), aid in the rescue of overboard passengers (Serra et al. 2020), and relate ocean features to a variety of biological activity including the migratory patterns of birds (Tew Kai et al. 2009), foraging behavior of apex predators (Cotté et al. 2011, Della Penna et al. 2015, Abrahms et al. 2018) and the distribution and efficiency of fishing vessels (Prants et al. 2014, Watson et al. 2018). This study aims to improve field-wide usage of these metrics by comparing a single particle trajectory metric (Relative Particle Density, RPD) to a more complex paired particle LCS metric (Finite Time Lyapunov Exponent, FTLE). The RPD metric maps regions where particles accumulate, whereas FTLE characterizes how neighbouring particles move relative to each other, diagnosing underlying patterns of trajectories. These two metrics quantify and map unique particle behaviors given the same input ocean circulation. RPD and FTLE were evaluated against alignment with simultaneous observations of phytoplankton patch distribution. Because RPD map accumulation and FTLE identify boundaries between distinct modes of flow, phytoplankton patch centers and edges were distinguished with the hypothesis that RPD will better align with patch centers and FTLE with patch edges. Given these differences in LCS metrics, the following study evaluates the relevance of each to defining phytoplankton patches observed in a complex coastal biological hotspot.

In this manuscript, our approach is to reveal patterns in phytoplankton abundance and advective transport at smaller spatial (O 1 km) and temporal (O 1 h) scales than have been previously examined in ageostrophic coastal flow (Shadden et al. 2009, St-Onge-Drouin et al. 2014). The proper application of LCS metrics allows us to better understand the role of advection in the concentration and transport of plankton patches. The following sections will detail the methodology and results of our comparison between RPD, FTLE, and phytoplankton distribution with a discussion on the implications of using two-dimensional LCS in coastal regions, the differences between single (RPD) and paired (FTLE) particle tracking suggesting when each metric is appropriate, the creation of the interior of phytoplankton patches vs. the border, and how differing levels of stratification affect these relationships.

Materials and methods

Data

The data used in this study are collected from Palmer Deep Canyon, Antarctica in January through March of 2020 as part of a National Science Foundation funded project, SWARM. These data provide coincident dynamic distribution of both plankton patches and underlying physical features over the entire local penguin foraging season. These observations were provided through an integrated polar observatory that included three High Frequency Radars (HFRs), a Slocum glider, and twice-weekly ACROBAT towed surveys between January and March 2020 (Fig. 1). The ACROBAT is small (0.5 m)-winged instrument that profiles the surface ocean (0–50 m), highly resolving light and physical properties. HFRs produce hourly surface current maps at 1 km resolution covering about 1500 km^2, the glider profiled to 1000 m completing one dive (two profiles) every 4 h at the head of Palmer Deep Canyon, and 16 ACROBAT towed surveys (60 km) were completed observing 40 distinct phytoplankton patches (Fig. 1).

Palmer Deep Canyon

Palmer Deep Canyon's relatively short and tightly coupled food web (Saba et al. 2014) makes it a unique ecological laboratory to quantify the impact of concentrating features on phytoplankton. Phytoplankton are a major food sources for Antarctic Krill (*Euphausia superba*), a keystone species for many top predators in the region, including penguins. Penguin colonies surrounding Palmer Deep Canyon have persisted for millennia, according to geologic records (Fraser and Trivelpiece 1996, Emslie et al. 1998, Schofield et al. 2013) despite significant variations in climate conditions. Such endurance of Palmer Deep Canyon's penguin colonies suggests the presence of a strong concentrating mechanism at the base of the food web, able to supply reliable phytoplankton to krill during interannual climate oscillations.

Recent studies in Palmer Deep Canyon have shown the surface residence time scale (~2 days) is much shorter than the phytoplankton doubling timescale (~7–70 days) (Kohut et al. 2018). These findings suggest that increased phytoplankton availability in Palmer Deep Canyon compared to neighboring regions is likely due to transport from other regions rather than stimulated local growth from upwelled, nutrient-rich Upper Circumpolar Deep Water as was previously thought (Kavanaugh et al. 2015). Additionally, recent glider observations have been unable to detect nutrient delivery via upwelling during the growing season (Hudson et al. 2019). Even if nutrient availability was higher in Palmer Deep Canyon compared to neighboring regions, phytoplankton in this system have been shown to be light limited rather than nutrient limited (Carvalho et al. 2019). It is within this transport-driven coastal ecosystem that this study investigates the role of Lagrangian features to define the distribution of phytoplankton patches.

HFR

HFRs use doppler-shifted radio waves backscattered off the ocean surface to observe surface velocity. Signals are transmitted and received by an HFR antenna, and Bragg peaks in the measured Doppler spectra are used to calculate radial components of the surface velocity (Barrick et al. 1977). Measured radial components of the surface ocean velocity are directed toward the HFR antenna with a range resolution of 500 m horizontally and 5° in azimuth. Radial components from the three HFR stations are added together to construct magnitude and direction of surface current velocities using an optimal interpolation algorithm (Kohut et al. 2006) providing hourly maps of surface currents at 1 km spatial resolution (Fig. 2a).

The three-site network included two remote locations on the Wauwermans and Joubin islands operated at a center frequency of 25 MHz and a third site at Palmer Station operated at 13 MHz (Fig. 1). The two remote sites located beyond existing power grids used Remote Power Modules constructed on site. More details on the installation of this 3-site network are provided in Statscewich and Weingartner (2011) and Kohut (2014).

The three HFR sites collected hourly radial maps of ocean surface current component vectors over our study area, covering about 1500 km^2 more than 80% of the time (Fig. 2a). The hourly, two-dimensional surface current maps derived from the radial component vector maps provided by each of the three HFR sites were used to derive our two LCS metrics (Fig. 2b and c). Before the LCS calculations were done, gaps within

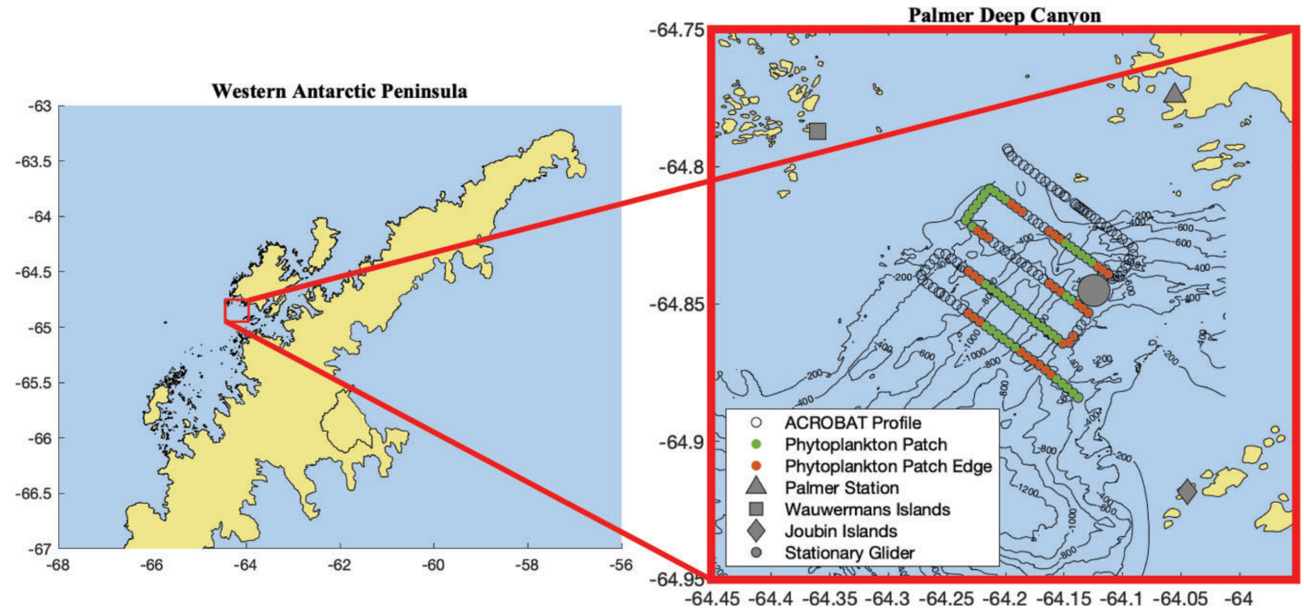

Figure 1 Study area indicating locations of three HFRs (Palmer Station, Wauwermans Islands, and Joubin Islands,) ACROBAT towed survey, and stationary glider around Palmer Deep Canyon, Antarctica. The canyon bathymetry is contoured with 200 m isobars. the 80% coverage area of the HFR maps were filled using a rigorous HFR-specific method (Fredj et al. 2016). This follows methodologies in Veatch et al. (2022).

ACROBAT towed surveys

Twice weekly ACROBAT surveys were conducted along transects over Palmer Deep Canyon (Fig. 1) between January and March 2020. The ACROBAT instrument was towed behind a small, (10.2 m) rigid hull boat at ~6 kts (about 3 m s^{-1}) as the instrument undulated continuously between a depth of 1 and 50 m. The ACROBAT was equipped with a fast-sampling (16 Hz) Seabird 43 FastCAT CTD (conductivity, temperature, and pressure), and a Wetlabs Ecopuck optical sensor (chlorophyll-*a* and CDOM fluorescence and optical backscatter at 700 nm). Profiles had a 300-m resolution over the 60-km transect for ~160 vertical profiles per survey. A total of 16 surveys were conducted. ACROBAT data was processed, quality controlled, and profiled using a MATLAB toolbox (Reister 2023) and the methods as described in Martini et al. (2016).

For each profile, the mixed layer depth (MLD) was calculated as the maximum buoyancy frequency in the upper 50 m following methods in Carvalho et al. (2017). For profiles with no clear mixed layer in the upper 50 m, the deepest ACROBAT measurement was designated as the MLD. Phytoplankton abundance was measured as the particle backscatter (m^{-1} sr^{-1}) above the MLD of each profile, integrated using a trapezoidal integration. Particle backscatter was used instead of chlorophyll-*a* fluorescence to negate for effects of nonphotochemical quenching and photo acclimation. Particle backscatter has been shown to correlate linearly with chlorophyll-*a* fluorescence in Palmer Deep Canyon (Carvalho et al. 2016), making particle backscatter a good indicator of chlorophyll biomass. To address the resolution mismatch between the ~300 m separated profiles and the 1-km HFR grid resolution, a sliding filter with a 1-km window was applied to the MLD and particle backscattering data. ACROBAT transects took 4–6 h to complete. It was determined that the ACROBAT did not resample phytoplankton patches that were advected back over the survey from previously sampled waters (Supplementary material S1).

The distribution of phytoplankton patches for each survey were derived from the ACROBAT profiles. To do this, each profile was designated as "phytoplankton patch," "phytoplankton patch edge," or neither. An ACROBAT profile with integrated mixed layer particle backscatter 5% higher than that survey day's median was designated as "phytoplankton patch" following the threshold method from Thomalla et al. (2015). A daily threshold was used for the definition of phytoplankton patches to capture concentrating mechanisms even on days that had lower phytoplankton abundance, which shows a strong seasonal signal. Survey thresholds of particle backscatter ranged from 0.0177 to 0.1184 m^{-1} sr^{-1}. The ACROBAT profiles on either side of the phytoplankton patch, the first and last profile of the phytoplankton patch, and the second and second to last profile of the phytoplankton patch were designated as "phytoplankton patch edges" (Fig. 1), following methodologies in Veatch et al. (2022). Deciphering between patch interior and edge will be used to test for differences in the horizontal advection mechanisms that created the center of accumulation and where the patch ended. Phytoplankton patches that were less than a kilometer and a half long were not used in analysis given that the 1-km resolution of the HFR input data likely did not resolve advective transport that created a phytoplankton patch that small.

Stratification was calculated from the ACROBAT CTD data as the density difference between the surface and 50 m for each ACROBAT profile. "Stratified surveys" were defined as the 8 survey days with the highest average density difference and "mixed surveys" were defined as the surveys with the lowest average density difference (Figure S1).

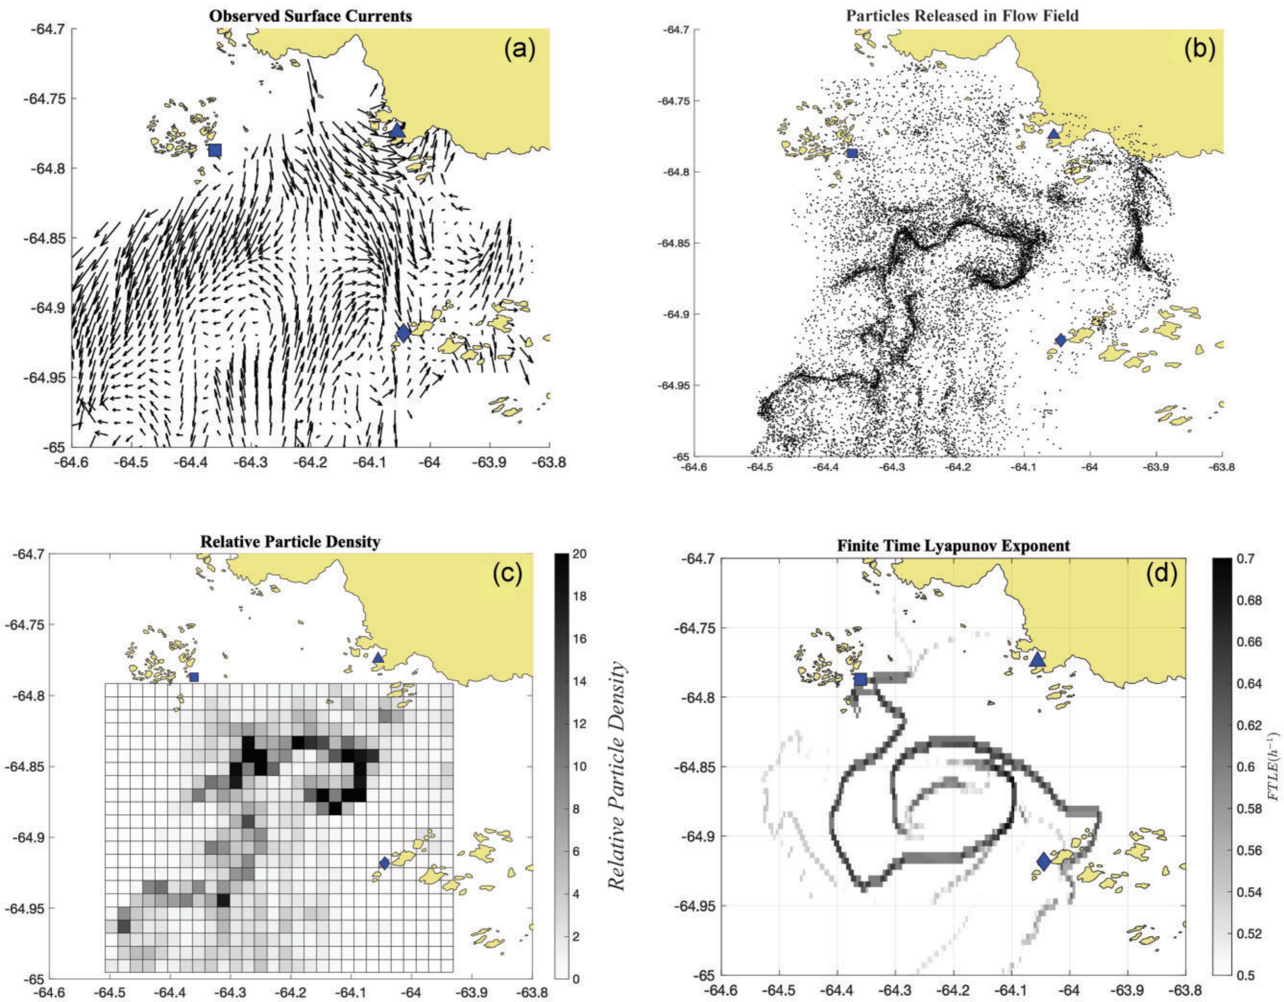

Figure 2 The HFR observed surface current velocity field (a), advected particles released following methods detailed in section, "RPD" (b), RPD, only positive values are shown (c), and FTLE (d) from 9th January 11:00 GMT over the study region. The three HFR stations are indicated with polygons. (© 2022 IEEE. Reprinted, with permission, from Veatch et al. (2022, preprint: not peer reviewed).

Autonomous glider

A Slocum glider was deployed in Palmer Deep Canyon from January to March 2020. Gliders are buoyancy driven autonomous vehicles that dive and climb through the water column in a "sawtooth" pattern. The glider used in this study was piloted to hold station at the head of Palmer Deep Canyon, profiling the same region throughout the season from the surface to 1000 m, just above the seafloor (Fig. 1). The glider sampled at a 0.25-m vertical resolution. Aboard the glider was a sensor suite that measured physical structure of the water column (CTD, Seabird), phytoplankton fluorescence and particle backscatter (Eco Triplet, Wet Labs), and krill biomass (Acoustic Zooplankton Fish Profiler, ASL Environmental Sciences).

Data from the stationary glider was profiled and MLD was calculated as the maximum buoyancy frequency following methods in (Carvalho et al. 2017), the same methodology used to determine MLD from the ACROBAT data. Similar to the ACROBAT, glider profiles were designated as "phytoplankton patches" if the particle backscatter integrated over the mixed layer was 5% higher than the daily median, adapted from Thomalla et al. (2015). These data were used in the calculation of the time-scale of phytoplankton patches detailed in section, "Determining integration time".

LCSs

Several LCS techniques have been applied to ocean systems in the past decade for their ability to quantify areas in ocean currents (or any velocity field) that exert an impact on nearby drifting particles (Haller 2015). Such areas are known as coherent structures. Coherent structures can identify local extrema of repulsion, attraction, and shearing of flow (Haller 2015). Attracting coherent structures will quantify the attraction of passive drifters in a flow field, or plankton in ocean currents (Shadden et al. 2005, Haller 2015).

In this study, LCS metrics from two distinct classes will be used to quantify physical advective features within the HFR observed surface current field: RPD, which have been used in Palmer Depp Canyon in previous studies (Oliver et al. 2019, Veatch et al. 2022) and FTLE, which have been used in a variety of open ocean ecological studies (Haller 2001, Huhn et al. 2012, St-Onge-Drouin et al. 2014, Fahlbusch et al. 2022, Veatch et al. 2022). This paper will suggest appropriate uses for both metrics dependent on available ecological observations, ensuring that the ecological community applies appropriate LCS techniques with an understanding of how these tools differ.

RPD

RPD reports the position of drifters at a single timestamp by normalizing the density of drifters within a gridded bin system in the study field. RPD calculations begin with releasing virtual particles over a regular grid and tracking them through a velocity field. RPD is then quantified by summing the number of drifters in each grid box, and normalizing by the median number of drifters in all grid boxes (Fig. 2c). New particles were released in a regular grid across the 80% coverage of the HFR footprint every 3 h. Particles were not counted until they had been advected in the velocity field for 6 h and were no longer counted when they were advected out of the HFR domain, or after they became three days old. The 6-h integration time is explained in section "Determining integration time". Given the average residence time of 2 days (Kohut et al. 2018), the 3-day threshold was chosen to coordinate with the time phytoplankton will spend in the surface layer of the study domain. This methodology follows that used by Oliver et al. (2019) and Veatch et al. (2022). Two dimensional HFR data is used to calculate RPD, relying on the assumption that the integrated surface divergence is zero, and no particles are lost from or added to the surface due to vertical velocities. Therefore, RPD will map the instantaneous concentration of surface associated particles across the entire domain given the evolving surface current fields provided by the HFR.

To negate artifacts in results caused by the edges of the HFR domain where particles entering or leaving the domain may be unaccounted for, the domain of RPD results used was smaller 3 km smaller than the domain of the inputted velocity field (Fig. 3). This is about how far the average particle travels over the integration time (6 h).

FTLE

FTLE use the horizontal separation distance between two particles relative to a fixed point over a defined time interval to quantify the strength of coherent structure (either repelling or attracting) at each point on a gridded velocity field. To calculate repelling FTLEs, a forward trajectory is used, and to calculate attracting FTLEs, a backward trajectory is used. In this study, attracting FTLEs were calculated. FTLE's ability to integrate over trajectories sets this technique apart from instantaneous separation rate (Okubo 1970, Weiss 1991) by introducing particle position "memory." Coherent structures are defined by the FTLE metric as ridges in the flow field where neighboring particles are converged toward, and then diverged along a ridge. The strengths of these ridges are quantified by the integrated attraction/separation rate between two particles (Fig. 2d).

FTLE calculations begin with a velocity field over some selected time. Finite differencing is then used over a defined auxiliary grid to numerically compute the derivative of the flow map. Next, the Cauchy–Green strain tensor field is computed from the derivative of the flow map as well as its eigenvalue field and eigenvector field. Then, the "stretching" of the field is computed as in (1), where $S(x_0)$ is the maximum stretching at point x_0, λ_i is the eigenvector field, and C is the Cauchy–Green strain tensor.

$$S\left(x_0\right) = \left[max_{i=1:N}\lambda_i\left(\mathrm{C}\left(x_0\right)\right)\right]^{1/2}. \tag{1}$$

FTLE is then computed with (2) over a finite time T (Dosio et al. 2005, Haller 2015, Haller et al. 2018).

$$FTLE\left(x_0, t_0, T\right) = \frac{1}{T}\ln(\mathrm{S}(x_0)). \tag{2}$$

These calculations result in a time dependent FTLE field for every timestamp of inputted velocity data. In the case of this study, a map of FTLE was produced every hour for the two-and-a-half-month study period.

This relative motion between two neighboring particles and the inclusion of a rate of change component are the key ways in which the FTLE metric differs from the RPD metric. Like RPD, FTLE will vary over space and time when applied to a discrete set of velocity data. FTLE calculations (1 and 2) result in a material surface that then can be projected at a set resolution back onto the study region. FTLE results were projected at the resolution of the HFR (1 km) so as to not stretch the observations further than the input data should be able to resolve.

FTLE calculations were performed using a MATLAB software toolbox (Halleret al. 2015) that was modified for use on HFR data (Fig. 2d). To negate artifacts in results caused by the edges of the HFR domain where it may seem that particles suddenly stop or are lost, the domain of FTLE results used was smaller than the domain of the inputted velocity field. As with the RPD results, the domain was shrunk by 3 km (Fig. 3).

Determining integration time

In calculating FTLE results, varying integration time will identify transport features of different scales. As if fine tuning a microscope, features of a certain scale will come into focus as the integration time is adjusted. This study is interested in the scale of horizontal advective features that create ephemeral phytoplankton patches, therefore observations of phytoplankton patches and surface currents were used to determine the integration time of LCS calculations. To calculate the biological time-scale, the stationary glider was used (Fig. 1). Glider profiles were determined as observing a phytoplankton patch or not. Consecutive profiles of phytoplankton patches were considered to be from the same phytoplankton patch. The average time of consecutive phytoplankton patch profiles was determined to be the average time a phytoplankton patch remains in the same geographic location, 6.2 h, and therefore is the time-scale of the phytoplankton patches. To calculate the physical time-scale, the HFR observed surface currents were used. The autocorrelation of the HFR observed surface current velocities was calculated at each grid point in the HFR

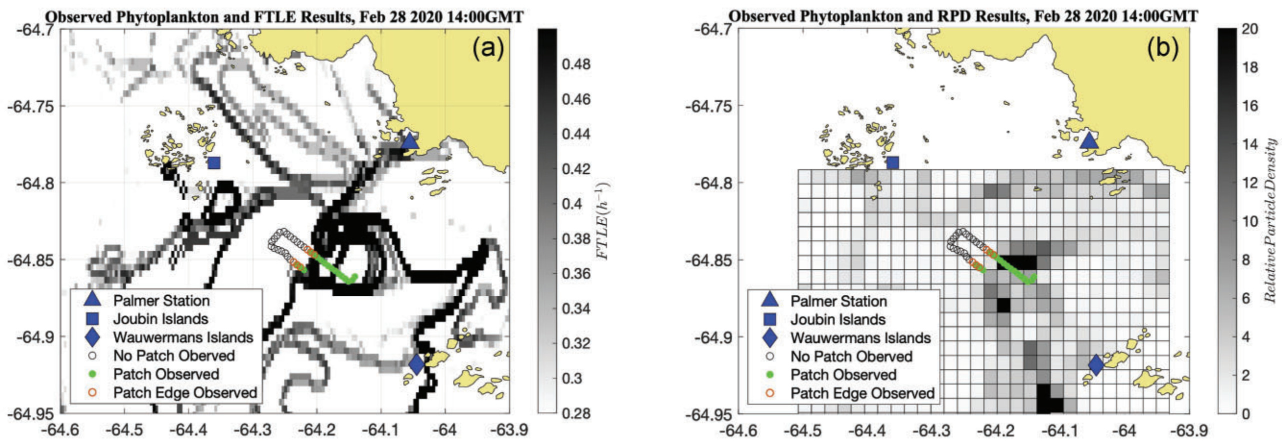

Figure 4 Example of LCS results plotted with 1 h of phytoplankton observations from the ACROBAT towed survey on 28th February at 14:00 GMT, (a) FTLE and (b) RPD.

field and normalized to variance. Autocorrelation was then averaged over each grid point of the same lag time. The time when the HFR observed surface current velocities decorrelated was defined as when the normalized autocorrelation function passed the e-fold scale: 5.5 h. This calculation was repeated with starting times during various stages of the tidal cycle and similar results were found each time. These results are shown in Fig. 3 of Veatch et al. (2022) and follow methods described therein.

The physical and biological timescales of Palmer Deep Canyon reflect the strength of tidal influence in the system. Recent studies have shown the effect of tides on surface ocean particle trajectories (St-Onge-Drouin et al. 2014, Gomez-Navarro et al. 2022) and the response of upper trophic creatures (Adélie penguins) to shifts in tidal regimes in Palmer Deep Canyon (Oliver et al. 2013). Therefore, the tidal cycle influence on particle dispersion, surface currents, and ecology in this system is consistent with these studies.

Based on this analysis, the integration time used for FTLE calculations was 6 h, which approximates the decorrelation time scales of phytoplankton patches and surface current velocities. In the calculation of RPD, particles were not counted in density calculations until 6 hours after their release. Unlike RPD, FTLE's integrate over the particle's trajectory in time, meaning the maps of FTLE results produced at a timestamp incorporate trajectory data from the previous 6 h.

Matching LCS results to phytoplankton patches

To compare the collocation of coherent structures and phytoplankton patches, results were matched in both space and time (Fig. 4). LCS results are space and time dependent, and produce mapped results every hour. The observation time of each phytoplankton patch was rounded to the nearest hour and compared to that hour's corresponding LCS field. Next, each ACROBAT profile was assigned an FTLE and RPD value from the nearest grid point to the ACROBAT profile's GPS location. The ACROBAT profile was always within 500 m of the nearest FTLE and RPD point, which are on 1 km grids. The FTLE and RPD values of all ACROBAT profiles within the same defined phytoplankton patch were averaged into a patch average value. The same was done for each defined patch edge. This resulted in each defined phytoplankton patch having one average patch center FTLE and RPD value and two average patch edge FTLE and RPD values. Phytoplankton patch definitions from the stationary glider were only used to calculate decorrelation scales and were not matched to LCS results to simplify the interpretation of results.

Creating a null model

To evaluate the performance of the LCS overlap with the observed plankton patches, a null model was created to represent a random distribution of patches. Within the bounds of the LCS results (Fig. 3), the ACROBAT transect was randomly rotated and translated along longitude, and randomly translated along latitude. A total of 100 random transects were created from each of the 16 survey days, culminating in 1600 randomly generated transects. The LCS values of each observed phytoplankton patch could then be compared to the LCS values of the 100 randomly generated versions of that patch. If LCS values of the observed patches were significantly greater than the LCS values of the 100 randomly generated versions of those patches, passing a one-sided Wilcoxon rank-sum test, then it was concluded that the observed patches were collocated with a strong LCS. To visualize the difference between observed and randomly generated patch LCS values, the difference was taken between each observed patch LCS value and the average of the corresponding 100 randomly generated patches. This was done for patch centers and patch edges.

Results

Throughout the 16 ACROBAT surveys, 40 distinct phytoplankton patches and 80 phytoplankton patch edges profiles were observed. These data were used to test the collocation of phytoplankton patches in space and time with our two LCS metrics (FTLE and RPD; Fig. 4).

RPD collocated with phytoplankton patches

RPD values had little difference between phytoplankton patches observed by the ACROBAT and randomly generated phytoplankton patches (Fig. 5a). The distributions of observed and randomly generated phytoplankton patch centers failed a one-sided Wilcoxon rank-sum test ($P = .8458$) indicating that the RPD values of the null model (randomly generated patch centers) are not significantly less than the RPD values of the observed phytoplankton patch centers. The distributions of

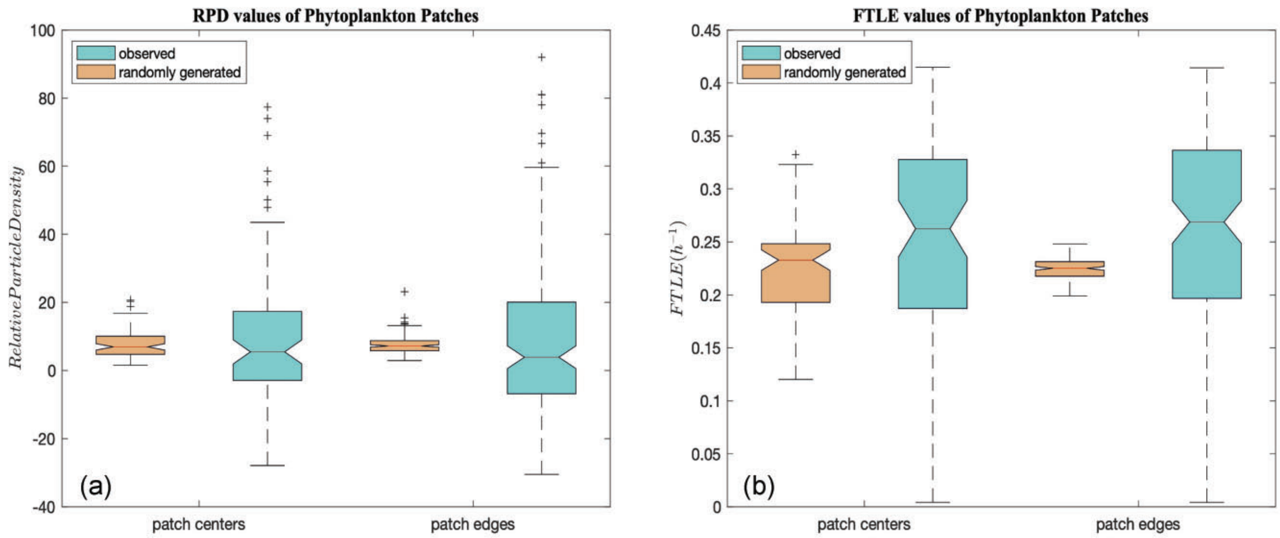

Figure 5 Box and whisker plots of RPD values (a) and FTLE values (b) of phytoplankton patch centers and phytoplankton patch edges of observed (teal) and randomly generated (orange) phytoplankton patches. Boxes represent the interquartile range, whiskers represent the data range, outliers are plotted as +, the median of the data is shown with a horizontal line, and notches represent the confidence interval for the median.

observed and randomly generated phytoplankton patch edges also failed a one-sided Wilcoxon rank-sum test ($P = .9941$) indicating that the RPD values of the null model (randomly generated patch edges) are not significantly less than the RPD values of the observed phytoplankton patch edges.

The distribution of RPD is shifted slightly above zero. Although RPD is a relative amount, this was expected because the edges of the RPD were not used (section "FTLE", Fig. 3), negating the likely low RPD values right at the edge of the HFR domain.

FTLE collocated with phytoplankton patches

The FTLE values of observed phytoplankton patches were higher than the randomly generated null model (Fig. 5b). The distributions of observed and randomly generated phytoplankton patch centers passed a one-sided Wilcoxon rank-sum test ($P = .0034$) indicating that the FTLE values of the null model (randomly generated patch centers) are significantly lower than the FTLE values of the observed phytoplankton patch centers. The distributions of observed and randomly generated phytoplankton patch edges also passed a one-sided Wilcoxon rank-sum test ($P = 4.6017 \times 10^{-6}$) indicating that the FTLE values of the null model (randomly generated patch edges) are significantly lower than the FTLE values of the observed phytoplankton patch edges. In Fig. 6, the distribution of results is mostly positive, indicating that for most patch centers and patch edges the randomly generated "background" FTLE values were less than the observed patch FTLE values. This signal was slightly stronger in patch edges than patch centers for all surveys, although this difference was not significant (one-sided Wilcoxon rank-sum test, $P = .2661$). This pattern holds when the phytoplankton center and edge data are combined and compared to the combined null model values, with the observed data having greater FTLE values with statistical significance (one-sided Wilcoxon rank-sum test, $P = 1.1892 \times 10^{-7}$).

Differences between observed and randomly generated FTLE patch center and patch edge values were separated into "stratified surveys" and "mixed surveys." The difference between observed and randomly generated patch center FTLE values for stratified surveys and mixed surveys are significantly different (one-sided Wilcoxon rank-sum test, $P = .0230$) with higher FTLE values on stratified days. The same pattern holds for patch edges, with the difference between observed and randomly generated patch edges on stratified days having significantly higher FTLE value differences than those on mixed days (one-sided Wilcoxon rank-sum test, $P = .0013$) (Fig. 6).

Case studies of FTLE on stratified and mixed days

To better understand these results, four case study survey days were examined. They were designated as stratified well performing, mixed well performing, mixed poor performing, and stratified poor performing (Fig. 7). Stratified, well performing survey days such as 3rd March had long, thin FTLE structures that persisted for multiple hours (Fig. 7a). The ACROBAT observed phytoplankton patches on these narrow, persistent structures and observed no phytoplankton patches when the survey left these structures. 3rd March also had an average maximum particle backscatter depth of 2.72 m, meaning that most phytoplankton patches were close to the surface within the region where the HFR sampling is most accurate. This is in contrast with the mixed, well-performing survey days such as 28th January which had round, short FTLE structures (Fig. 7b) and an average maximum particle backscatter depth of 17.07 m. On survey days when large amounts of phytoplankton were observed, such as 28th January, there was enough phytoplankton to fill the wider round structures more typical of mixed days and the phytoplankton patches were observed within the FTLE structures. This is shown in Fig. 8(b) where the 28th January survey has many occurrences of high particle backscatter, similar to the 3rd March survey. It was concluded that an abundance of large phytoplankton patches is an important prerequisite to a mixed survey having well-performing FTLE.

Mixed, poor-performing survey days such as 21st February had very few FTLE structures within the survey region (Fig. 7d). Compared to the other three case study days, 21st

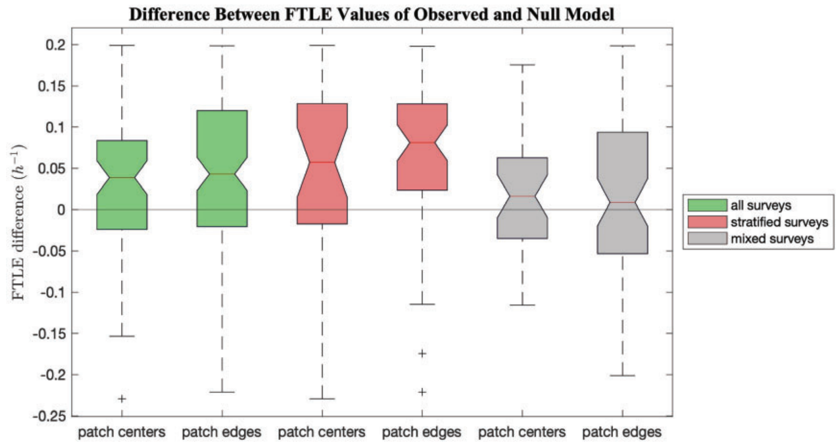

Figure 6 Box and whisker plots of the difference between FTLE values of observed phytoplankton patch centers and edges and randomly generated patch centers and edges of all surveys (left two box and whiskers), stratified surveys (middle two box and whiskers), and mixed surveys (right two box and whiskers). The horizontal line at zero difference separates the well-performing FTLE and patch matches above the line, and poor performing FTLE and patch matches below the line. Boxes represent the interquartile range, whiskers represent the data range, outliers are plotted as +, the median of the data is shown with a horizontal line, and notches represent the confidence interval for the median.

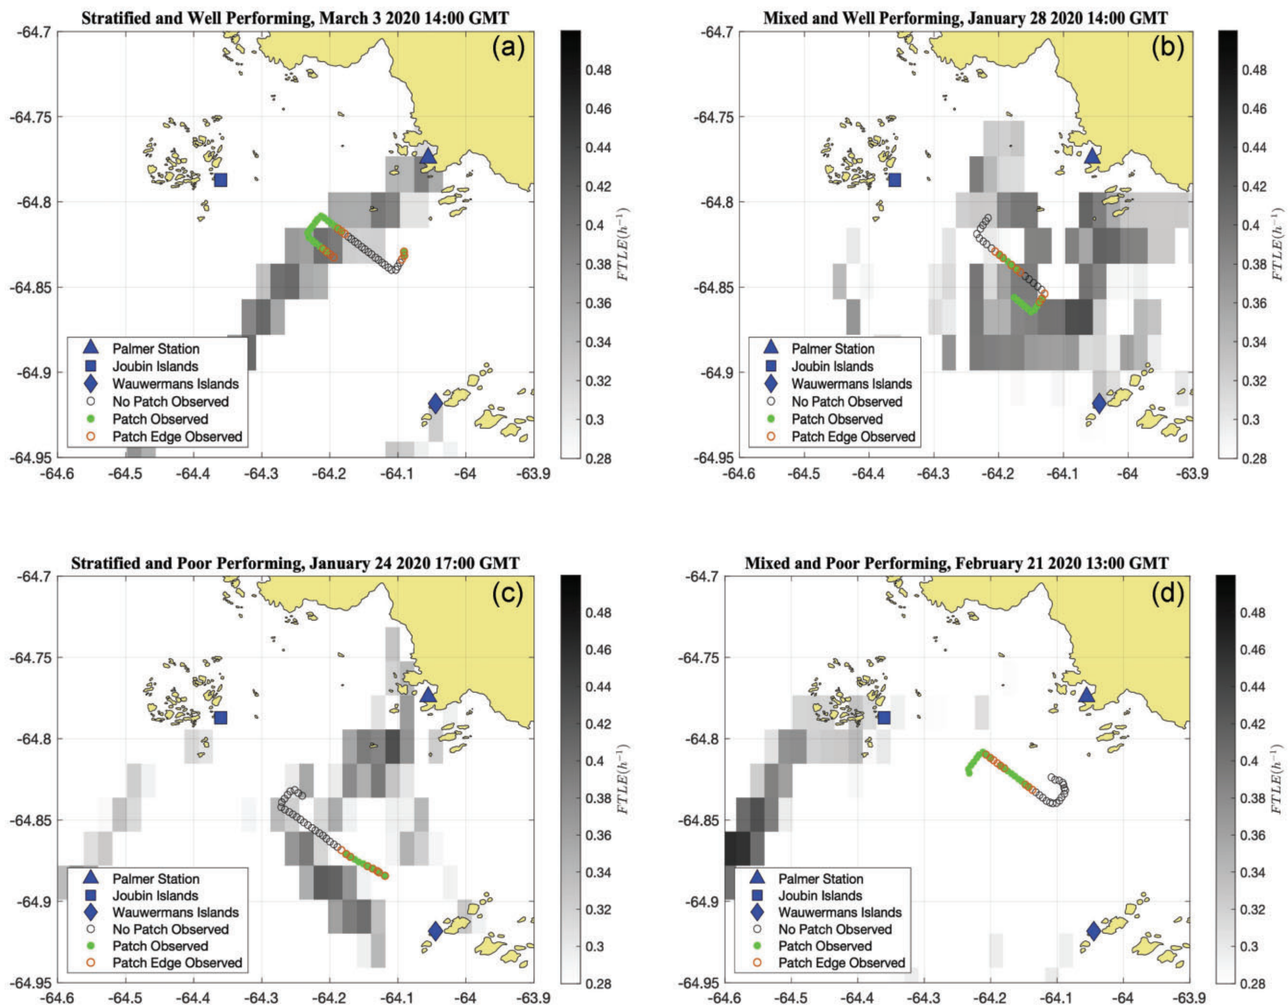

Figure 7 Four case study days of ACROBAT observed patch centers (filled circles) and patch edges scattered over FTLE results. Stratified day with high correlation between high FTLE values and phytoplankton patches (a), mixed day with high correlation between high FTLE values and phytoplankton patches (b), stratified day with low correlation between high FTLE values and phytoplankton patches (c), and mixed day with low correlation between high FTLE and high values and phytoplankton patches (d).

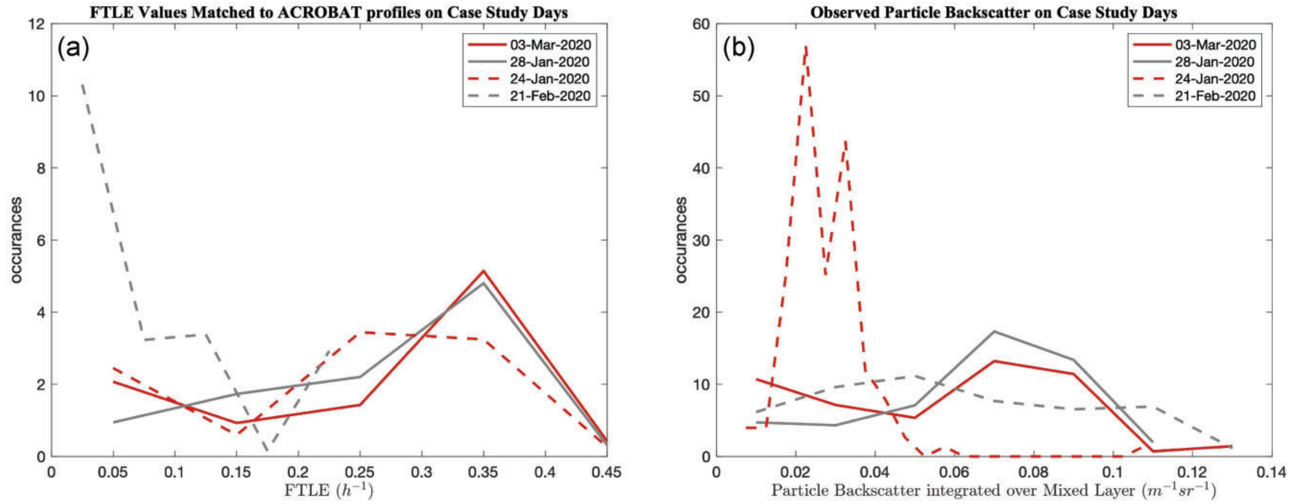

Figure 8 Histogram of (a) FTLE values matched in space and time with each ACROBAT profile observed during the four case study survey days in Fig. 6 and (b) particle backscatter observed by the ACROBAT integrated for each profile to the MLD of the four case study survey days shown in Fig. 7.

February had many observations of low FTLE values (Fig. 8a). It is important to remember that due to the nature of our definition of "phytoplankton patch" normalized to the survey day, there will always be phytoplankton patches defined in a given survey, even if there are no strong FTLE features. It was concluded that the lack of defined FTLE features was the reason this survey day had few phytoplankton patches collocated with FTLE defined attracting features.

Stratified, poor performing survey days such as 24th January were expected to perform well due to well-defined surface layers and shallow phytoplankton patches (Fig. 7c). In the case of the 24th January survey, it is suspected that low abundances of phytoplankton were the cause of the FTLE results' poor performance. In a histogram of integrated mixed layer particle backscatter (the proxy used to define "phytoplankton patches") observed during the ACROBAT surveys of our four case study days, 24th January has a high occurrence of low mixed layer particle backscatter measurements (Fig. 8b). Figure 8(b) suggests that the phytoplankton during the 24th January survey were diffuse across the study region, with many observations of low particle backscatter. Low phytoplankton levels could be because Palmer Deep Canyon had lower abundances of phytoplankton that day, or because our ACROBAT survey transect missed the FTLE features that were concentrating large amounts of phytoplankton. Again, due to the nature of our definition of phytoplankton patch, there were "patches" defined even though phytoplankton observations were overall of low concentration. Many observations of low phytoplankton suggests that the phytoplankton are not well concentrated, but diffuse throughout the study region. On days when there are no attracting features or when the ACROBAT survey does not encounter any attracting features, this is expected. In contrast, the well-performing days have many occurrences of high phytoplankton, suggesting that there is enough phytoplankton biomass to be concentrated into distinct patches.

The poorer performance of FTLE on some survey days could be due to inhomogeneous currents in the surface layer, a lack of large phytoplankton patches on mixed days, a lack of strong attracting physical features, or likely some combination of these three. These four case studies demonstrate that FTLE ridges tend to be narrower and more filament-like on stratified surveys and wider on well-mixed surveys, and that surveys with low amounts of phytoplankton or FTLE do not show phytoplankton patches to align as often with higher FTLE values than surveys that have high amounts.

Discussion

Concentration of sparse food sources into discrete patches is an important mechanism for the maintenance of coastal biological hotspots such as that in Palmer Deep Canyon. Using Palmer Deep Canyon as a natural laboratory, this investigation has determined the importance of physical advection in the distribution of plankton patches at the very base of the food web. LCS metrics, when applied carefully, can be used as tools to elucidate the role of advective transport in complex coastal regions. In this study, FTLE expounds the relationship between HFR observed surface currents and phytoplankton patch location. The difference between single particle tracking methods like RPD and paired particle tracking like FTLE provides a roadmap for when each metric is appropriate to apply to coastal ecosystems.

Two-dimensional assumptions in LCSs

The use of LCS allows for the identification of ocean features that cannot be seen from velocity fields alone. LCS applied to ocean currents have the capacity to quantify underlying patterns in fluid trajectories that potentially concentrate marine resources in the ocean. However, there are limitations to these LCS, which must be thoroughly understood to properly apply metrics and interpret results. LCS must have the same dimensionality as their input. In this study, two-dimensional velocity data from three HFRs were used to calculate LCS, constraining resulting LCS to two dimensions at the ocean surface. Additionally, HFRs observe surface flow while phytoplankton patches can exist at variable depths. Below we explore the implications of two-dimensional LCS in coastal regions and the depth of HFR measurements, demonstrating that these limitations do not impede this study's ability to quantify phytoplankton concentrating features.

Pelagic, open ocean regions that are dictated largely by geostrophic, two-dimensional flow have been the subject of past studies using LCS to identify patterns of phytoplankton transport (Lehahn et al. 2007, Hernández-Carrasco et al. 2011, Huhn et al. 2012, Li et al. 2015, Lévy et al. 2018, Liu et al. 2018). In contrast, coastal regions are complicated by vertical velocities creating a three-dimensional flow field. Vertical velocities in our study region, Palmer Deep Canyon, are small compared to horizontal surface flow, especially given the short residence time of the region. With an average residence time of 2 days (Kohut et al. 2018) and an average vertical velocity magnitude of 2.84×10^{-5} ms^{-1} between January and March (calculated from divergence in HFR), a free drifting particle in Palmer Deep Canyon experiences on average 4.9 m of vertical displacement during its ~2 day residency in the system. This average vertical displacement of 4.9 m is within the average surface MLD of ~20 m. Consequently, it is reasonable to accept the two-dimensional LCS assumptions. Previous work has shown LCS in the open ocean associated with relatively strong vertical velocities at fronts (Mathur et al. 2019, Siegelman et al. 2020). In Palmer Deep Canyon, maximum vertical velocities are around 0.405×10^{-3} ms^{-1}, which is an order of magnitude smaller than maximum vertical velocities found at open ocean LCS by Siegelman et al. (2020) of 1.15×10^{-3} ms^{-1} at fronts. Whereas LCS in the open ocean can last for days, LCS in Palmer Deep Canyon have a lifespan on 5 h on average, which is when the autocorrelation function of FTLE results pass the e-folding scale, on average throughout the study domain and season. Vertical velocities associated with LCS in Palmer Deep Canyon are likely smaller due to the short lifespan of these features.

There could be small vertical velocities not detected by the 1 km resolution of the HFR data, likely more present on survey days designated as "mixed." These vertical velocities although small in spatial scale may be large in magnitude, and are more likely within strong gradients associated with density fronts. Such vertical velocities could have an impact on phytoplankton (Mahadevan 2016). Our dataset cannot resolve these vertical velocities, exposing a limitation of the data rather than of the two-dimensional assumption of the LCS metrics.

HFR measurements observed only the horizontal surface layer of the flow (Stewart and Joy 1974, Paduan and Graber 1997). For the HFR frequencies deployed in Palmer Deep the surface measurement is within the upper 2 m of the water column. When the mixed layer is completely homogeneous, these measurements can be extrapolated to represent the whole mixed layer. Use of HFR to calculate LCS has had some success in previous studies (Shadden et al. 2009, Hernández-Carrasco et al. 2018, Fahlbusch et al. 2022, Veatch et al. 2022) extrapolating HFR data to represent the whole mixed layer. In this study, phytoplankton patches were defined by ACROBAT observed profiles integrated to the observed MLD. The sensitivity of the integration depth to patch definition was evaluated and described in greater detail in Supplementary material S3. This analysis repeated patch definition with a constant integration depth of 5 m, which is closer to the effective depth of the HFR measurements (Stewart and Joy 1974) than most MLDs (average MLD is 20.8 m). However, the same patterns were found with both integration depths (Figures S2 and S3), showing that the depth of integration (constant 5 m or variable mixed layer) did not affect our conclusions.

Further, the physical and biological timescales of Palmer Deep Canyon are ~6 h, within 1 h of each other, which is within the time resolution that we expect the HFR and glider data (Fig. 1) to observe. Matching physical and biological time-scales indicates that both the surface currents and the phytoplankton patches are changing at the same rate, suggesting that the main driver of change in phytoplankton patch location is advection resolved by the HFR observed surface currents. This provides further confidence that LCS can quantify a major mechanism of phytoplankton patch formation in Palmer Deep Canyon.

Phytoplankton patch collocation with FTLE and RPD

LCS values of observed patches in comparison to the null model (the randomly generated patches) suggest that higher values of FTLE results collocate with phytoplankton patches more often than higher values of RPD results (Fig. 5). In assessing this result, it is important to note that the two LCS metrics differ in several ways including single particle (RPD) vs. pair of particles tracking (FTLE), FTLE's ability to incorporate rate of change, and FTLE's flexible integration times.

The fact that FTLE often collocate with phytoplankton patches in Palmer Deep Canyon suggests that phytoplankton are acting as free drifters in the surface layer. So then, why do the particle trajectories of the RPD metric, which is designed to track the accumulation of surface drifters, do such a poor job of collocating with phytoplankton patches? Let us begin with considering cases when simple particle trajectories (RPD) are useful for tracking free drifters. Seeding particles where drifters are observed and running a trajectory backwards in time will track the source of those drifters, or when the source is known, such as in an oil spill, particles released at the observed source will track where those drifters accumulate. However, in this study we seek to identify areas in the HFR observed surface current field that have stronger attracting mechanisms than elsewhere in the field, without any added information about the source or location of drifters (phytoplankton) in the LCS calculations. In this case, LCS calculated from relative positions of pairs of particles characterize these areas of attraction independent of particle initial position, and dependent on the integrated backwards trajectories of those particles. This concludes that simple particle trajectories (RPD) are useful when the source or destination and relative abundance of plankton is known, so particle releases can be catered to location and density. FLTE are useful when the source or destination is unknown and the entire flow field is searched for attracting features. While single particle trajectory methods such as RPD use simpler calculations, these results suggest that ecologists should take the time to use more complex, paired particle tracking such as FTLE when investigating the role of physical advection in the spatial ecology of phytoplankton.

Where RPD only accounts for the location of the drifters at one timestep, FTLE accounts for the velocity of the drifters relative to other drifters, introducing a rate of change consideration into the quantification of attraction (Haller 2015). The rate of change (velocity) used in FTLE calculations incorporates additional information that the location-based calculations in RPD do not. Additionally, FTLE integrate over particle trajectories giving each calculation a "memory" of the inputted integration time (6 h in this case, section "Determining integration time") (Haller 2015). Application of FTLE allows for the scale of the features that are transporting and concentrating plankton in Palmer Deep Canyon to be elucidated (St-Onge-Drouin et al. 2014). The ability to determine this integration time allowed us to calculate FTLEs that identified the scale of feature that we knew to be important in the system from our analysis. Both rate of change and integration considerations could contribute to their better performance, diagnosing the underlying flow responsible for transport rather than following the flow field as the RPD analysis does. Such flexibility in FTLE calculations could make FTLE a powerful tool in coastal systems when working with submesoscale features on subtidal scales and highly variable nonlinear flow. Therefore, the improved performance of FTLE over RPD in aligning with observed phytoplankton patches suggests that processes that overlap with patches are best identified by the attraction of paired particles, not the absolute concentration of a field of released particles.

It should be noted that this study does not account for biological mechanisms of phytoplankton concentration, such as grazing pressure or growth. Because the growth period of phytoplankton is greater than the residence time in Palmer Deep Canyon, growth rate was not considered (Kohut et al. 2018). This study also assumes that phytoplankton are not limiting in Palmer Deep Canyon, meaning grazing pressure would not have a large effect on results.

FTLE performance on patch centers and patch edges during stratified and mixed conditions

For each survey, we mapped both phytoplankton patch centers and edges to investigate if each LCS metric better aligned with specific regions of the patches. It was originally hypothesized that RPD would better align with patch centers while FTLE would better align with patch edges because the FTLE paired particle metric better characterizes boundaries between distinct modes of flow (Haller 2015) while RPD characterize a concentration of drifters (Oliver et al. 2019). The distinction between patch centers and patch edges investigates whether different transport mechanisms determine where the center of attraction (the patch center) vs. the extent or cut-off point of the phytoplankton patch. FTLE performed slightly better on patch edges than patch centers. This could be because the areas where particles diverge along a ridge, categorized by FTLE as strong coherent structures, separate water with different phytoplankton levels. However, in this study the distribution of edge and center FTLE values were not significantly different. If there is a difference between edge and center it is likely that we would need to have a higher sample size to detect it.

FTLE collocated with phytoplankton patches more often on stratified surveys than mixed surveys (Fig. 6). Stratification in the upper water column will change the complexity of the surface flows over our study site. When the upper water column is strongly stratified, the surface layer will flow more independently of the subsurface, with little exchange between the two layers, setting up two-dimensional flow in the surface layer. Mixed conditions are more indicative of the surface and subsurface layers exchanging physical properties through vertical mixing. It was originally hypothesized that LCS would not perform well on a well-mixed water column because vertical velocities would invalidate the two-dimensional assumption of LCS. However, it was found that the vertical velocities in Palmer Deep Canyon were negligible at the studied scales. Additionally, there was little difference between the vertical velocities over the ACROBAT survey on survey days that were determined as mixed and those that were determined as stratified, 3.47×10^{-5} m s^{-1} for mixed days and 3.60×10^{-5} m s^{-1} for stratified days. This suggests that the better alignment of FTLE and phytoplankton patches on stratified surveys was due to (1) homogeneous and inhomogeneous mixed layers or (2) a biological response in the way phytoplankton patches are formed on mixed surveys.

A mixed water column with a deep MLD may be indicative slight differences in ocean velocities between the surface and bottom of the mixed layer. Although these mixed layers pass the definition of a mixed layer (Carvalho et al. 2017), the surface waters where the HFR is observing the flow may be different than a few meters below the surface, still in the mixed layer, where the phytoplankton are experiencing the flow. This would mean that on mixed days the HFR is less representative of the currents that are concentrating the phytoplankton patches.

The four most mixed (smallest difference in density between the surface and 50 m) surveys had an average depth of maximum particle backscatter (the proxy used to define phytoplankton patches) of 11.80 m with a standard deviation of 15.05 m, well below the few meters the HFR can safely observe. The four most stratified surveys had an average depth of maximum particle backscatter of 2.97 m with a standard deviation of 1.98 m. This implies that on mixed days, where the mixed layer may be less uniform, the phytoplankton patches are deeper in the mixed layer and are likely experiencing ocean currents that are not well resolved by the HFR data. Therefore, the poorer match between FTLE and phytoplankton patches on mixed days is likely due to a limitation in observed data rather than a limitation in the dimensionality of the FTLE. However, even on well-mixed survey days, FTLE still often collocated with phytoplankton patches (Fig. 6), just not as often as they did on stratified surveys.

Conclusion

Our analysis indicates that HFR derived FTLE can be used to identify concentrating mechanisms in biological hotspots with complex submesoscale flows, validating their use in coastal systems (Fig. 5). Comparing the single particle tracking metric (RPD) with the paired particle tracking metric (FTLE) provided a mechanistic understanding of how surface currents in Palmer Deep Canyon are transporting and locally concentrating phytoplankton. The paired particle tracking metric (FTLE) more often identified areas of the flow field where phytoplankton were being concentrated into patches. FTLE's ability to incorporate rate of change, flexible integration times, and consideration of relative distance rather than final position allowed this metric to better capture the transport of phytoplankton.

FTLE does a slightly better job at identifying phytoplankton patch edges than centers, characterizing separatrices in ocean currents that separate different ocean flow patterns as well as high phytoplankton from low phytoplankton areas (Fig. 6). However, the difference between patch edges and patch centers was not significant, meaning that phytoplankton patch edges and patch centers both collocate with FTLE-identified coherent structures, and therefore are likely maintained by the same advective mechanisms. It was also concluded that the FTLE metric performs best when the water column is stratified, which is indicative of vertical velocities and heterogeneity in the mixed layer being at a minimum, and phytoplankton patches closer to the surface within the sampling domain of the HFR. This is when the two-dimensional assumption of the FTLE calculations is the most accurate and the phytoplankton patches are closer to the surface enabling the HFR data to best measure the flow that the colocated phytoplankton are experiencing (Fig. 6). FTLE collocate with phytoplankton patches more often when the system has a substantial amount of strong coherent structures (Fig. 8a) and phytoplankton (Fig. 8b), meaning there are physical features present to concentrate the phytoplankton and there are large enough phytoplankton patches to fill the coherent structures.

The novelty of this study's application of LCS lies in the scale at which these metrics are applied, looking for structures that organize plankton dispersion on the order of hours within a few kilometers. This is the scale of the ocean at which the krill and the forage fish are interacting with ocean flows as they swarm, creating the prey availability central place foraging penguins rely on in Palmer Deep Canyon (Oliver et al. 2019). Results solidify the role of physical advection in the concentration of phytoplankton patches in Palmer Deep Canyon on these short time-scales, suggesting this area is sustained by delivery of phytoplankton through advection rather than local growth.

Further investigation of FTLE applied to coastal biological hotspots could inform ecosystem models by predicting bioactivity from ocean currents. Findings will also broaden the use of HFR data to locate areas of food web focusing, furthering our understanding of how coastal biological hotspots are maintained.

Acknowledgements

Many thanks to the Antarctic Support Contractor and their teams aboard the ARSV Laurence M. Gould, at Palmer Station, and headquarters in Denver, CO without whom a study of this scale would not be possible. Thank you to the students, postdoctoral scholars, and field assistants for their valued involvement in the SWARM project, in particular Ashley Hann, Dr Katherine Gallagher, Dr Jerome Pinti, Dr Thilo Klenz, Ethan Handel, and Jordi Maisch. We thank the Palmer Long-Term Ecological Research team and the Commission for the Conservation of Antarctic Marine Living Resources, for their advice and collaboration.

Supplementary material

The following Supplementary material is available at *ICES JMS* online. Supplementary material provides an explanation of methodology used to determine the low reencounter rate of phytoplankton patches on the ACROBAT towed survey mentioned in section "ACROBAT towed surveys". Details on the methodology for determining "stratified" and "unstratified" survey days (Figure S1) are also included. Last is the inclusion of a repeated analysis with a different definition of phytoplankton patch, integrating to a constant 5 m instead of the mixed layer depth (Figures S2 and S3), i.e. mentioned in Section "Two-dimensional assumptions in LCSs".

Funding

This project is funded through the National Science Foundation, award number: 1745009.

Data availability

Data and code used in this study are publicly available on NSF funded project SWARM's BCO-DMO site and GitHub. High Frequency Radar observed surface currents are available in the gap-filled version used in this study on BCO-DMO (https://www.bco-dmo.org/dataset/917884). Code used to gap-fill these data are available on GitHub (https://github.com/JackieVeatch/SWARM_CODAR). Lagrangian Coherent Structure Results for both FTLE and RPD metrics are available on BCO-DMO (https://www.bco-dmo.org/dataset/917914, https://www.bco-dmo.org/dataset/917926) and the code used to produce these results can be found on GitHub (https://github.com/JackieVeatch/SWARM_LCS). The code was modified from open-source MATLAB library (Haller et al. 2015) for use on HFR data. ACROBAT data used to map phytoplankton can be found on BCO-DMO (https://www.bco-dmo.org/dataset/916046) and the code used to identify phytoplankton patches can be found on GitHub (https://github.com/JackieVeatch/SWARM_ACROBAT). Initial processing of the data was done with an open-source MATLAB library (Reister 2023). Glider data used to calculate the biological time-scale can be found on Erddap (https://slocum-data.marine.rutgers.edu/erddap/tabledap/ru32-20200111T1444-profile-sci-delayed.html) and the code used to calculate the biological and physical time-scales can be found on GitHub (https://github.com/JackieVeatch/SWARM_scales). All other code for analysis can be found on GitHub (https://github.com/JackieVeatch/SWARM_analysis). Any questions can be directed to Jacquelyn Veatch (jveatch@marine.rutgers.edu).

Food for Thought articles are essays in which the author provides their perspective on a research area, topic, or issue. They are intended to provide contributors with a forum through which to air their own views and experiences, with few of the constraints that govern standard research articles. This Food for Thought article is one in a series solicited from leading figures in the fisheries and aquatic sciences community. The objective is to offer lessons and insights from their careers in an accessible and pedagogical form from which the community, and particularly early career scientists, will benefit. The International Council for the Exploration of the Sea (ICES) and Oxford University Press are pleased to be able to waive the article processing charge for these Food for Thought articles.

Abstract

Over the last 30 years, ocean sciences have been undergoing a technological revolution. Changes include the transition of autonomous platforms from being interesting engineering projects to being critical tools for scientists studying a range of processes at sea. My career has benefitted immensely from these technical innovations, allowing me to be at sea (virtually) 365 days a year and operate ocean networks globally. While these technical innovations have opened many research doors, many aspects of oceanography are unchanged. In my experience, working/talking/scheming with scientists is most effective face-to-face. Despite the growing capabilities of robotic platforms, we will still need to go to sea on ships to conduct critical experiments. As the responsibilities of scientists expand with mandated outreach efforts, I strongly urge young scientists to leverage the expertise of Broader Impact professionals, who are increasingly available to our community, in order to maximize the effectiveness and efficiency of our outreach efforts. Given the increasing observations of change occurring in the ocean, our work is ever-more important while still being fun. I am blessed to have had a career as an oceanographer exploring this planet.

Keywords: ocean observations; marine networks

Reflecting on my science journey is a fun exercise (a BIG surprise given my youthful persona) and has provided me an opportunity to appreciate that I am blessed with having the greatest job in the world. People ask me about what my job is like, and my usual response is that I don't have a job; I have a hobby. What an awesome life! Over the years, my excitement and passion have grown reflecting both an expanding fascination of this amazing, interconnected world and the growing urgency to understand our planet's trajectory given mounting evidence of human impacts on the Earth system. My journey has occurred during a period of fundamental change in how scientists explore the ocean, transition to open data science, and recognition of the importance of translating science knowledge to diverse stakeholders. These changes are altering the definition of what an oceanographer is. I believe that these changes will enable the next generation, armed with novel tools, to meet grand societal challenges. *I must admit to being envious of the new generation of researchers who will be so important in helping society during a critical time. As the sun rises on this new era I am grateful to have been working in the early dawn of the future of oceanography*.

How did I end up as an oceanographer?

I would love to think that my career is a story of committed logical strategic thinking, BUT there has also been much luck that provided me unexpected opportunities, people, and perspectives. Those opportunities started early. I grew up swimming, fishing, diving, and surfing in the Pacific, which dominated any spare time I had. I hope this personal connection to the ocean remains true until I leave this planet. Additionally, my biological father (Max Gumpel) was a driven scientist (Davies and Gumpel 1960) with a full lab in the back of the house and weekends would start with him announcing some projects for us to do. One of my favorites was the weekend we built and installed a Richter scale in the basement. He disappeared when I was young (stories best shared over a beer). My stepfather (Paul Schofield) raised me and even though he was not a scientist, he provided me many career skills. Paul is an amazing storyteller, and early on, he gave me the passion of communicating across diverse communities. My early years hanging out with gifted people in southern California, some going on to become professional surfers, it was clear that my "stork" style of surfing was not going to provide a career path. My love for the ocean expanded to all aspects of the sea (science, history, and art). This led me to my local school (University of California at Santa Barbara), where I was so lucky to join a leading research university with gifted and passionate teachers. At that time, I quickly found myself working with two professors who changed my life. Barbara Prézelin introduced me to the beautiful process of photosynthesis and the physiological ecology of phytoplankton. Raymond (Ray)

Smith introduced me to the strategies and tools for studying processes in a dynamic ocean. Ray's first lecture to me as an undergraduate focused on the importance of understanding spatial and temporal scales in the ocean and that effective sampling would require integrated multiplatform networks. Unknown to me at the time, this concept would become a major focus of my career. Upon graduation, I took a laboratory technician position with ½ of the time focused on mass culturing of algae for a pharmaceutical company in Barbara's laboratory and the other ½ deploying to Antarctica as a krill technician. These experiences convinced me to apply to graduate school working on phytoplankton with Barbara.

Graduate school, remaining with Barbara and Ray, was a joy full of great teachers–friends, and much time at sea studying aquatic bio-optical properties, the impact of the Antarctic ozone hole on plankton, and phytoplankton physiology. When in graduate school I was lucky to be embedded in a culture of open intellectual flexibility that was not averse to students diving into entirely new endeavors. My graduate experience went quickly but much life happened. My first child was born during my Ph.D. After the birth of my daughter, I began to experience physical issues that eventually was diagnosed as Stage 4B Hodgkin's lymphoma. The oncologists put me on a very aggressive chemotherapy and radiation regime but with the support of my wider academic community and family I was able to beat the disease with 8 months of weekly treatments. Seven months after being cleared I deployed to Antarctica to study the impact of the ozone hole on phytoplankton. My cancer experience impacted me as I had gained an appreciation in my early 20's that life is fleeting and for *me* the best remedy was to charge at full speed while able.

During graduate school, I was very lucky to have time interacting with John Kirk. He, while working in the United Kingdom, was one of the first to isolate plant plastids (Kirk 1970, 1971), but then relocated to Australia to start a new career and helped create the field of hydrological optics (Morel 1977, Smith 1978, Kirk 1994, Zaneveld 1995, Morel 2008). His advice to graduate students was to conduct a major shift in research focus about every 5–10 years to keep yourself a hungry novice. I see this reflected in my career with an initial focus on phytoplankton photosynthesis, to the cellular physiology of stress, to autonomous ocean observing networks, to evolution of phytoplankton taxa, to climate-driven changes in ocean systems, and now moving to integrated terrestrial–marine food security strategies. Some of these changes grew organically out of the work being conducted, but often it was the incorporation of new methodologies/technologies that got me invited into large interdisciplinary expeditions. These opportunities early in my career were enabled through the strong advocacy of my graduate student advisors.

As I had been at UC Santa Barbara as an undergraduate and graduate student, my thought when finishing my Ph.D. was that it was time to do something different to expand my horizons and try to differentiate myself from my biological oceanography peers to better compete for a permanent job. Through a friend, I met David Millie at an ASLO Ocean Sciences meeting and our discussion resulted in a postdoctoral position in the Department of Agriculture in New Orleans, as a food flavor quality biologist. The project was to develop methods to discriminate specific taxa of algae using optical approaches and, if possible, provide insight into the physiological state of the algae. This work was motivated by the commercial aquaculture industry, specifically catfish, where a major economic bottleneck for the industry was the production of off-flavor metabolites by cyanobacteria in the farm ponds that made the product unpalatable. I figured the title food flavor quality biologist would catch people's attention, but my Ph.D. advisors were not stoked thinking that I was going to fall out of the oceanography community.

Our first effort focused on identifying specific algal taxa using bio-optical techniques. For those efforts, David and I collaborated frequently with Gary and Barbara Kirkpatrick from Mote Marine Laboratory, where for decades we developed signal processing approaches to discriminate different algal taxa based on their cellular absorption properties (Millie et al. 1997, Kirkpatrick et al. 2000). These efforts resulted in a decades-long partnership with the Kirkpatrick's, focusing not only on the discrimination of harmful algal bloom species but also on the development of new tools to make measurements over sustained periods of time (Kirkpatrick et al. 2003, Schofield et al. 2008). David was an active mentor and within a week of joining his group, he required that I apply to a job at Rutgers University (he said he had a hunch it would be good for me, but I thought I had already pissed him off and he was trying to get rid of me), and I was fortunate to get the job during my first year as a post-doctoral researcher. That said, I applied for many positions in that year (I used to keep a binder of rejection letters for graduate students to see and know that we all go through uncertain periods), but compared to many, I had a relatively short wait. I credit my graduate and postdoctoral advisers, who were always pushing me to be completing manuscripts and finishing projects.

The diverse experiences and collaborations prepared me to thrive when I joined Rutgers in 1995, where I was hired by Frederick Grassle, who was tasked with building a new oceanography program in New Jersey. It was during my job interview that I met Scott Glenn and we started a conversation on ocean dynamics, biophysical coupling, ocean observation, and modeling. That conversation has continued for 30 years. It has been an unparalleled gift to work with a great friend. We come from disparate science backgrounds. He was a physical oceanographer with a background in waves and sediment resuspension processes and I was a biological oceanographer interested in physiological ecology of phytoplankton. Our respective mentoring committees discouraged this partnership often saying it would distract us from our fundamental research, which was important to us achieving tenure. I find this humorous now looking at the numerous current grant calls for transdisciplinary research across disciplines while back then having a physical and biological oceanographer merging groups was considered risky. Both Scott and I are happy that we ignored the well-meaning advice provided at the time.

As a team, we developed the Coastal Ocean Observation Lab (COOL), which grew quickly, hosting many diverse interdisciplinary programs spanning from forecasting coastal upwelling and its biogeochemical consequences to the fate of river plumes and their potential transport of urban contaminants across continental shelves and associated impacts on water quality. Our other focus was on developing tools (instruments and models) to resolve the time and space scales required to address the questions at hand. We hosted the Office Naval Research Hyperspectral Coastal Ocean Dynamics Experiment (HyCODE) off New Jersey, where over 4 years every summer, over 200 researchers, up to 11 ships, and 3 aircraft joined us. Many of the groups that participated in the experiments were not funded by the actual HyCODE project but came through their funding to conduct focused experiments in a well-sampled 3D ocean with a range of forecasting products guiding adaptive sampling of their processes of interest. Some groups arrived unannounced. We had Navy SEALS show up, which was awesome, and my favorite memory was when a science group (who shall go nameless) showed up by accident a year early. Around the 24:7 sampling, a large community of scientists connected as we had rented almost a block of summer rental houses and it became the equivalent of a giant nerd block party with dinner debates ranging from turbulence closure schemes, optical inversion techniques, and who was the best cook in the group. This was much fun, but I was still going through the tenure process, which was stressful. I wish I had more training in management skills/tools and cooking for large groups (I signed up to be our head cook for the group, and quickly found a need to diversify meals outside of my comfort zone).

The success of HyCODE convinced many organizations of the value of these novel data streams. For example, the state of New Jersey has anchored its coastal water quality sampling with COOL gliders for over a decade; hundreds of fishermen throughout the mid-Atlantic use the open-access satellite data on a daily basis; and US Coast Guard Search and Rescue tools now include high-frequency surface current radar data. This was a challenge for us, as COOL was/is funded one project at a time with no sustained funding to maintain the operational data streams that are critically important to numerous external communities. We therefore suggested-forced-coerced the University to transition us into a University Center, which provided a means to garner support to maintain a large portfolio of projects and better utilize resources of the larger University. As we had built the COOL "brand" globally, we also wanted to maintain our existing name recognition and came up with the name Center of Ocean Observing Leadership so that we could keep our acronym. Developing a funding base to maintain a large group is difficult. My advice is to keep an open mind of potential funders and diversifying (federal agencies, foundations, and local stakeholders) the funding pot, which is an effective strategy to survive the shifting priorities of any specific agency. This strategy takes time to develop and working with a cohort collaborators is required to navigate diverse funding streams and to stay sane when funding is tight.

With the autobiographical story out of the way, I want to focus on how much oceanography has been changing. For this, it is important to review where the world was then, and how much it has fundamentally changed to provide context of what I believe are exciting opportunities moving forward.

Where were we in the 1980's and early 1990's?

As I was entering graduate school, it was well known that the ocean was spatially/temporally complex and that the available tools were not up to the task to address many of the critical questions. This was especially true for the coastal ocean characterized by compact turbulent layers and boundaries (land, ocean, and atmosphere). Grand challenges at the time included balancing the planet's carbon budget anchored by understanding the fluxes of carbon and nutrients in the ocean (see Oceanography 2001), uncovering picoplankton communities in the open ocean (Waterbury et al. 1979, Chisholm et al. 1988), and understanding carbon export to the deep sea (Boyd and Trull 2007, Iverson 2023, Siegel et al. 2023). Meanwhile, fundamental ocean features such as marine viruses, one of the most abundant and rapidly evolving forms of life on Earth, were not discovered until the early 1990's (Bergh et al. 1989, Proctor and Fuhrman 1990, Hara et al. 1996). Walter Munk and Carl Wunsch (1982) highlighted that many of the knowledge gaps reflected limitations in our ability to observe the ocean over the relevant time and space scales.

The gaps in ocean-observing capabilities were significant. The ability to transmit and share information remotely was limited. "Live" communication was limited to expensive satellite phones and custom mail messaging services of miniscule bandwidth in the late 1980's and often text messages from land to ships were satellite transmitted and then printed on paper. The "world wide web" was still in its infancy and collaborations relied on "slow" mail. As but one example, I found out where I was going to graduate school via a global community of HAM radio operators while working as a krill technician in Antarctica in 1988. At sea, we relied on fax machines over which we could receive low-resolution maps of satellite imagery. Satellite oceanography had fundamentally transformed oceanography and provided scientists with amazing imagery of warm and cold core rings, major currents, enhanced phytoplankton biomass trailing ocean storms, and ocean weather (Halpern 2000). *In situ* data was collected by ship-based systems for limited windows of space/time or with moorings providing Eulerian time series. Moorings, despite their great value, could never provide a realistic dynamic view of the ocean spatially but drove home the importance of episodic events in structuring marine systems (Dickey et al. 1998, Toole et al. 2000), which was poorly resolved by traditional ship sampling. Autonomous underwater vehicles were still in early development and the few field deployments of robotic platforms were conducted by teams of engineers to learn about feasibility of the technology, not by scientists using the technology to address fundamental questions (Straton 1969, Manley 2003, Wynn et al. 2014). The promise of autonomous sampling was still a dream. A great example of this was the science fiction vision provided by Henry Stommel, who described graduate students at Woods Hole Oceanographic Institute (WHOI) remotely navigating an underwater robot on an ocean circumnavigation (Stommel 1989). Since then, AUVs as well as sea floor cables (Schofield et al. 2002, Favali and Beranzoli 2006), drifters (Lumpkin et al. 2017), profiling floats (Riser et al. 2016, Claustre et al. 2020), animal-borne sensors (Costa et al. 2012, Watanabe and Papastamatiou 2023), and air-borne drones (Johnston 2019) have all matured to become science tools. Ocean modeling, data assimilation, and prediction have rapidly evolved with growing skill, inclusion of increasingly complex chemical–biological processes, and improving temporal and spatial resolution capable of resolving the mesoscale (Peloquin 1992, Smith 1993). These evolving technical capabilities are altering how scientists maintain a sustained presence at sea, which is allowing us to quantify in space and time the importance of episodic events (storms, river plumes, and subsurface jets). As bio-optical and chemical sensors were developed, it revealed the spatial complexity in the subsurface ocean not visible to satellites.

Beyond technical limitations, the dissemination of marine science was different then. It was the era of proprietary data, where all information was formally embargoed by grant specifications for up to 3–5 years. In addition, the timeline to open up the data was rarely enforced. The early years of transitioning to open-access data were an adventure. As part of the COOL group, we started by posting raw real-time satellite data to the web, which resulted in our group being sued by commercial entities that were selling imagery to the general public. These conflicts resulted in clarification of the Federal Open Sky policy, where everyone had the right to share raw tax-payer-sponsored satellite imagery publicly but value-enhanced imagery could be a protected product that could be sold. We as a group decided that we would share data as rapidly as available to facilitate adaptive sampling during large experimental efforts. In the late 90s, our efforts included large community experiments focused on developing ocean forecasting approaches for coastal regions in the mid-Atlantic Bight to coordinate science sampling of the biogeochemical dynamics (Glenn et al. 2004). While managing these field campaigns was a significant time sink, it provided datasets that could serve the wider community simultaneously but did present some frustrations. Despite still being in the tenure stream, some researchers published data that I had worked hard to collect without offering me authorship. My anger was constructively tempered by talking to my colleagues who gently pointed out that I had many more ideas than I had time to publish so don't waste energy and focus on getting my stories out. This did not "right the wrong" but it shifted my frustration into constructive energy. I also saw that the "bad players" were often marginalized over time reflecting their recurring bad behavior. These experiences were rare and more often than not the community were excited to collaborate and work as a team.

The transition to open data has not diminished the importance of peer-reviewed manuscripts but now provides another metric for demonstrating science impact. The fact that the datasets are now published and often required by science journals is a great sign of cultural progress (Pendelton et al. 2019, Fredston and Stewart Londes 2024)! There is still much more progress to be made on this front by increasing open access data (along with the critical metadata) without burdening the scientists that often are not adequately resourced to do so. Many different data systems exist; however, they are often scattered among different disconnected repositories, and so, while publicly available, many data sets are still difficult to find. *Despite the need for more progress, this new era of open data and collaborations, facilitated by the internet, is broadening our oceanographic community. Oceanography is no longer dominated by those lucky few who had access to ship time. Anyone with internet access and desire can now ask fundamental science questions. In my opinion, this will ultimately help democratize oceanography across large and small research-teaching-outreach institutions.*

Finally, it was predicted that science productivity (the rate of getting science manuscripts published) would accelerate if data were delivered in real-time back to the researchers on shore. If data were streaming directly to computers worldwide then the historical lag between data collection and synthesis would be minimized. This idea has been tested by comparing the publication rates from large programs that collected data using either traditional oceanographic approaches vs. those experiments that used real-time data streaming (Schofield and Glenn 2004). The lag between data collection and eventual publication were similar often taking 3 years between data collection and publication. Quality science capable of surviving peer review still requires time for critical thinking and synthesis. Thus, while new technologies do provide us an unprecedented amount of data, science is more than a data report, and our work will still require significant creative and rigorous work to turn data into new science knowledge.

Where are we heading?

The technologies now available to the oceanographic community will enable us to address a wide range of science questions needing information on mesoscale processes with temporal/spatial resolutions that cannot be resolved using traditional approaches (Godø et al. 2014). Future graduate students will conduct studies using autonomous networks of remote sensing and mobile platforms. The platforms will be diverse consisting of airborne, surface, and subsurface vehicles. These systems will provide spatial data over time in which traditional sampling from ships to moorings will be embedded. The networks will allow both ship- and shore-bound scientists to adaptively sample the chemical, physical, and biological properties in a sustained manner over time. Sampling will be aided with model forecasts. This 4-dimensional view will be open access and much of the data will be available and visualized in near real-time (as example see https://www.hubocean.earth/platform). Scientists will know when and where to conduct shipboard experimental manipulations and the observational data will provide context to interpret/extrapolate the experimental results. The open data will allow large communities of scientists to work together despite being distributed across the globe. As the networks grow, they will increasingly rely on machine-to-machine-to-model networks capable of automated optimization of the network in the field to study specific processes of interest (Schofield et al. 2010, Ramp et al. 2009). Like many numerical models, these networks will be nested within each other to provide varying degrees of spatial and temporal resolution. For example, the global ARGO-Global Ocean Biogeochemistry Floats-model arrays will provide basin-scale integrated datasets in which continental-shelf networks will sample more compact space and time scales required to understand these systems. Scientists from around the world will work together using real-time data collected in the ocean and the barriers that prevent groups from working together will continue to be minimized. The exponential growth of machine learning and artificial intelligence will be a new revolution helping synthesize and use diverse, complex, and large data streams. I believe these approaches will complement but not replace analytical modeling built upon fundamental first principles.

Beyond the development of infrastructure enabling science to maintain a sustained presence in the ocean, we are in the midst of an ocean sensor/measurement revolution. A vast array of new tools now allow us to measure the ocean physics, chemistry, and biology with unprecedented detail. This is especially true for the biological sciences, where, e.g. the "omic" revolution provides the first potential synthetic view of overall systems biology that will allow biologists to characterize community diversity, gene expression profiling, transcriptional regulation, protein and lipid identification/modification, metabolism, elemental profiles, morphological, and physical traits. Combinations of these measurements will provide insights into a range of physiological/ecological processes, including particle sinking–flocculation processes, grazing, and animal movements (diel behavior, migrations, and population transport and connectivity). New fluorometers offer the potential to measure photosynthetic activity through measurements of electron transport. These approaches will be important to providing insights into fundamental rate processes (Packard 2018). These new capabilities will benefit from the data/forecasts provided by the ocean observing networks, which will inform when and where data will need to be collected. Discrete ocean sampling will transition from fixed grid sampling to adaptive sampling grids that incorporate the evolving structure of the ocean. As a community, we will need to learn how best to use these new multi-platform approaches. The success of these networks will depend on optimizing measurements to resolve specific processes that will require specific temporal/spatial sampling. Given this, the systems will need to be flexible in their use and open to evolving as the questions change based on our increasing knowledge of the ocean. I am an optimist and believe the combination of sustained high-resolution sampling combined with experimental efforts will provide novel insights into a range of critical transdisciplinary questions facing society.

With these new capabilities, the questions I am increasingly thinking about are broad and, despite my best efforts, will be a focus of our science community well after I retire. A major interest for me is mean state transitions in ocean ecosystems and the adaptive capacity of ecosystems to respond to change. This is critical given a changing climate and a rapidly increasing industrialization/urbanization of the ocean. Additionally, I am thinking about how these changes will influence the overall carrying capacity of the ocean for providing food and energy. This is a question of increasing importance as ocean and inland waters provide >20% of the protein supply for a growing human population. My interest in these questions has grown over the last few decades as I have personally observed the ocean exhibiting significant change. One of my major study sites, for over 30 years, is the West Antarctic Peninsula, which is one of most rapidly warming regions on the planet and I have witnessed declining sea ice and the corresponding changes rippling throughout the food web from the plankton to the penguins. Watching these changes has been eye opening-scary-concerning and has spurred me to think about the potential trajectory of marine food webs in the near future (years to decades). Beyond potential climate-driven changes, the activity of humans on the ocean has been increasing. For example, in my backyard in the mid-Atlantic Bight construction has started on building the world's largest offshore wind network with >3000 turbines to be deployed over the next decade. This development is arguably the deployment of the world's largest artificial reef. How will this construction alter the food web? How will these man-made changes interact with climate-driven changes? All these potential changes increase the importance of marine science to help society navigate potentially dramatic shifts in the ocean.

Over my career, there has been a growing appreciation that there is a critical need to bring science and its processes directly to stakeholders-society. In the past, this was not a scientist's responsibility as it was often assumed our "brilliant" insights would be spontaneously and enthusiastically devoured by the public. This assumption is not grounded in reality. This responsibility has become a formal responsibility for the scientist with many funding agencies now requiring a dedicated focus on outreach. For example, the National Science Foundation in the USA began considering broader impacts in proposal reviews in the 1960s. However, it only became a separate and distinct criterion in 1997. What outreach should be conducted is generally not prescribed and it can span from communicating the process of basic research and the scientific method to the general public, training teachers, or educating local-state-federal regulators. Each of these audiences requires a distinctly different set of communication strategies. Many institutions have dedicated professionals who can help in deciding and connecting with potential stakeholders. Finding these broader impact (BI) professionals to collaborate with is a key to maximizing the effectiveness of the time dedicated to the effort.

I have been uniquely lucky in my career to have collaborated with BI professionals during my entire time at Rutgers. Janice McDonnell has been a partner for broader impacts spanning from student–teacher–scientist training and public engagement efforts. Working with her has been critical for me to learn a totally distinct skill set from my science training and evolve my Broader Impact identity (Risien and Stoeksdieck 2018). Developing a Broader Impact identity is focused on blending science interests to the potential impacts of a specific community of interests. This identity is likely to change over the course of one's career as perspectives/interests evolve. My initial efforts were focused on conducting elementary through high school teacher training and over time expanded to general public outreach associated with feature-length documentary movies (*Atlantic Crossing: A Robot's Daring Mission* and *Antarctic Edge: 70° South*) and national radio (*You're the Expert*, https://podcast.app/youre-the-expert-p8942). What I have learned is that the time commitment and the resources required vary dramatically with the audience. What does not vary is that none of these efforts would have been possible without Janice helping me to navigate the effort and help hone my message. These efforts have generated some of the most rewarding moments of my career. She has been critical to keep me growing as a public outreach communicator, including pushing me out of my comfort zone. My most recent event was a public story reading of a piece I had written in a New York City bar with professional short story tellers. That event was truly humbling. Compared to those experienced and talented speakers, I felt like a novice. I know where my efforts to practice will be focused over the next few years. *Working with BI professionals is critical to maximizing our outreach to stakeholders-society, which is amazing as this growing class of professionals did not exist when I began my career*.

What has not changed?

The importance of curiosity driven science

Ever since Vannevar Bush's groundbreaking report (Science, the Endless Frontier, https://www.nsf.gov/od/lpa/nsf50/vbush1945.htm) advocated for fresh thinking to unleash the intellectual capacity of civil society, basic research has been fundamental to the modern science enterprise. The value of this vision was not only that curiosity-driven science was fundamental to making novel discoveries but also that these advancements would meet the needs of society. To do this well (I am still learning), it is critical to focus on taking the time to develop good science questions. I have found that good questions, whether fundamental research or applied science, can find funding with dogged persistence. Unclear and unfocused questions will often not find a funding home. I warn all new graduate students that the hardest, but most rewarding, part of a thesis is formulating good questions. This is hard work. Make sure that you *take the time* to develop these questions, and continuously bounce them off all your science colleagues. For me, my clarity usually comes at sunrise, when it is quiet, or when I am weeding on the organic farm that my wife and I have. What works is different for each person, so find your creative space and use it! Where to get the good questions funded is another challenge but cast a wide net between local-state-federal-international agencies, foundations, and philanthropies.

Don't forget that science is fun!

Despite the stress of competing for grants and the many commitments associated with a science job, after 35 years, I still find science creative-frustrating-exhilarating-fun-consuming and full of twists and turns associated with each new insight. Too often, with life chaos, it is easy to lose track of the gift of having a career focused on exploration. My curiosity has grown as I am continually learning through field expeditions, laboratory experiments, and the continuous stream of discoveries published in the primary literature. Reading/listening about the science being conducted at this time leaves me stunned by the exciting and audacious work of our community. Given the many demands on our time, what is my advice to keep science fun?

- Increasingly in a virtual world, there are fewer contiguous time windows to focus and just think about the science. Therefore, it is important early on to take control of your calendar and formally block time to think-discuss-do science. In the modern world, everything has deadlines (grants, classes, meetings, and committees) except for the actual science, which does not have a formal deadline, which leads it to be the task too often postponed until tomorrow. Great advice I continually receive from my father-in-law, a successful scientist (Syukuro Manabe), is don't mistake busy work for science thinking. Deep thinking requires time. *Make science deadlines/goals and block the time do it. Treat this time religiously, turn off email and phones, but if needed turn on the music that helps you escape into the work. Close the door or hide in the library but revel in your explorations*.
- Choose a meeting-webinar-lecture series outside your expertise at least once a year. Block out the time to truly attend. When I mean truly attend, keep your computer shut, phone off, with at most a notebook to take notes. As stated in a James Bond movie, "Sometimes the old ways are the best." Stay nimble to learn the questions and languages of different disciplines. Science has transitioned from interdisciplinary to transdisciplinary discussions. This is relatively new. Today I see scientists successfully working with others in engineering, medicine, oceanography, art, public policy, and supply chain economics. What a wonderful evolution and my only response is "amen." This evolution is recent and I believe that the new generation of scientists will need to be trained differently in order to better to conduct transdisciplinary science. What that training is I am still working on. While a broad supporter of these efforts, I often struggle on how to design/conduct this transdisciplinary research, probably a symptom of a small brain. I am still learning the language and communities in completely separate disciplines. *My best advice, given I still learning how to do this, is to go collaborate with creative people who push you into uncomfortable areas you might have never considered*.

Science is important and worth the effort

As our climate changes, humanity is facing many critical issues. Mine and future generations will need to figure out how humanity should respond to changes in the Earth system, how human activity might become sustainable, and how we might develop a science community that reflects humanity's rich diversity. These are not theoretical challenges, but are urgent and require plans, a strategy, and action. Science and technology will be central to meeting these challenges and in an increasingly polarized global political environment decisions will need to be based on science and not ideology. I do not accept the premise that science has become an ideology and believe these verbal attacks are a deliberate strategy to delay and obfuscate what we have learned and delay or prevent societal actions that should flow from fact-based knowledge. Our science is critical to this planet, and in my mind, this is a noble and grand task i.e. worth the energy I invest.

The people in our community are the life gold mine

Above, I identified a handful of people who were critical to my journey. For every person I mention (Barbara, Ray, John, David, Gary, Barbara, Fred, Scott, Janice, Deborah, and Syukuro), there are another dozen who I could/should have highlighted. The take-home message is that our community is blessed with amazing, funny, passionate, and wonderful people. What a blessing that I have an extended "nerd" family. This is a community that provides life-long friends. A great example in my career is my decades-long collaboration with Deborah Steinberg. I met her as an undergraduate freshman in basic biology and we now co-manage large programs together. What a gift to work with your best friends.

While there are occasional bad apples, I have been lucky to not have encountered many. I learned when working on ships that it is critical to make sure everyone feels secure, safe, and valued. I believe it is critically important for science leaders to publicly and formally communicate expectations and be clear that certain behaviors will not tolerated. While issues remain, I have seen improvement. When I was an undergraduate going to sea, my advisor was often the first woman chief scientist in the ship's history, and I witnessed many instances of a toxic male culture. One example was that Barbara often had to insist that the public rooms should not broadcast pornographic movies. This is unfathomable now, but back then, her insistence was met with outrage from the often all-male crew. While we are evolving for the better, much more work is required to ensure at sea and on land, our culture is open, accepting, and supportive.

One piece of advice is to make sure that you work to develop collaborations as much as possible face-to-face. While this web-world allows for global and distributed collaboration, the value of human–human interactions cannot be overemphasized. This was recently highlighted in an article in Nature (Adams 2023) that expounded upon how remote collaboration allows for an expanded pool of knowledge. The cost is that distributed teams often don't integrate fully and thus are less vested in the conceptual debates that can lead to "disruptive" breakthroughs. Given that our community is full of great people, take advantage of this and maximize your time to work with them face-to-face. It leads to great science.

I have had the pleasure of working with Doug Webb for several decades and he has provided me and my students sage advice maybe we should all follow. "*Work hard, have fun and change the world.*"

Spatial and Seasonal Controls on Eddy Subduction in the Southern Ocean

Michael L. Chen[1] and Oscar Schofield[1]

[1]Department of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, USA

Key Points:

- Eddy subduction in the Southern Ocean is observed as subsurface anomalies in spice and oxygen measured by autonomous profiling floats
- Spatial distribution is controlled by weak stratification and strong lateral buoyancy gradients, diagnosed using satellite altimetry
- Bio-optical proxies suggest that eddy subduction is most active in spring/early summer, driven by weak vertical stratification

Accepted 4 SEP 2024

Abstract Carbon export driven by submesoscale, eddy-associated vertical velocities ("eddy subduction"), and particularly its seasonality, remains understudied, leaving a gap in our understanding of ocean carbon sequestration. Here, we assess mechanisms controlling eddy subduction's spatial and seasonal patterns using 15 years of observations from BGC-Argo floats in the Southern Ocean. We identify signatures of eddy subduction as subsurface anomalies in temperature-salinity and oxygen. The anomalies are spatially concentrated near weakly stratified areas and regions with strong lateral buoyancy gradients diagnosed from satellite altimetry, particularly in the Antarctic Circumpolar Current's standing meanders. We use bio-optical ratios, specifically the chlorophyll *a* to particulate backscatter ratio (Chl/b_{bp}) to find that eddy subduction is most active in the spring and early summer, with freshly exported material associated with seasonally weak vertical stratification and increasing surface biomass. Climate change is increasing ocean stratification globally, which may weaken eddy subduction's carbon export potential.

Plain Language Summary Oceans play an important role in global climate by soaking up and sequestering atmospheric carbon dioxide. Photosynthetic activity at the surface turns carbon dioxide into organic carbon, and if this carbon leaves the surface to the deep ocean, it can be locked away from the atmosphere. One way this occurs is through the physical circulation associated with swirling eddies, which can rapidly transport organic carbon-rich surface waters and "inject" them into deep waters. However, we still don't fully understand the seasonal timing of this process, or what drives its spatial distribution. We investigated this in the Southern Ocean, which is very important to global climate, using data collected by drifting robots. We find that this process is the most active in regions where eddies drive strong surface stirring, and during the spring, when weak stratification allows injections to penetrate deep into the ocean. Because this process is poorly represented in climate models, these findings will improve our understanding of how the ocean absorbs carbon.

1. Introduction

Oceans play a critical role in regulating global climate by sequestering carbon from the atmosphere (Gruber et al., 2009). A key driver of this is the biological pump, a suite of processes that exports carbon from the ocean's surface to the interior, and is estimated to keep 1,300 Pg C sequestered from the atmosphere (Nowicki et al., 2022). The best understood mechanism is the biological gravitational pump, or the sinking of large particles out of the euphotic zone, which is estimated to comprise about 70% of global carbon export (Boyd et al., 2019; Nowicki et al., 2022). However, other mechanisms are increasingly being recognized (Boyd et al., 2019). These include transport by vertically migrating mesopelagic organisms (Bianchi et al., 2013), and physical processes such as carbon detrainment from shoaling mixed layers (the "mixed-layer pump"; Dall'Olmo et al., 2016; Lacour et al., 2019), large-scale water mass subduction (the "subduction pump"; Levy et al., 2013), and submesoscale vertical velocities associated with frontal boundaries and eddies (the "eddy subduction pump", or "ESP"; Omand et al., 2015; Resplandy et al., 2019). If these submesoscale vertical motions coincide with the presence of organic carbon in the surface ocean, carbon export can occur. During phytoplankton blooms, models and observations show that filaments of organic carbon-rich surface waters can be injected to depth along eddy peripheries (Davies et al., 2019; Omand et al., 2015).

Eddy subduction (henceforth, also "subduction") remains particularly understudied due to the challenges of observing submesoscale processes. In recent decades, submesoscale physics has emerged as a key driver of vertical exchange. Advances in numerical modeling have revealed a dynamic eddy field at horizontal scales of O (1–10) m, associated with ageostrophic vertical velocities reaching up to 100 m day^{-1}. These evolve on timescales of O (1) days with a vertical extension of O (100) m, and strongly contribute to vertical tracer variability (Balwada et al., 2018; Capet et al., 2008; Klein & Lapeyre, 2009; Lapeyre & Klein, 2006; Lévy et al., 2012; Mahadevan & Tandon, 2006; Rosso et al., 2014). Mechanisms energizing these vertical submesoscale flows include surface frontogenesis (Held et al., 1995; Lapeyre & Klein, 2006; Rosso et al., 2015) and baroclinic instabilities within the mixed layer ("mixed layer instabilities"), which extract potential energy stored in lateral buoyancy gradients and deep mixed layers (Boccaletti et al., 2007; Callies et al., 2015, 2016; Erickson & Thompson, 2018).

Once subducted, parcels of water retain tracer signatures of their surface origins, including elevated oxygen and surface-like temperature-salinity (Davies et al., 2019; Omand et al., 2015). Recently, Llort et al. (2018) used these signatures to develop an algorithm that detects eddy subduction in BGC-Argo float profiles. This algorithm identified subsurface anomalies in two variables known to reflect recent subduction from the surface: apparent oxygen utilization (AOU) and spice, a temperature-salinity variable least-correlated with density, which helps identify water mass movement along isopycnals. These anomalies were often associated with elevated particulate organic carbon (POC), and were spatially located in energetic regions of the Southern Ocean (SO). Since then, this approach has enabled the identification of eddy subduction in regions such as the SO (Lacour et al., 2023), the North Atlantic (A. R. Johnson & Omand, 2021) and the Kuroshio Extension (Chen et al., 2021), and has generated estimates of eddy subduction's contribution to carbon export. However, these vary widely, ranging from up to 50% of exported POC during spring blooms, to as little as <5% (Davies et al., 2019; Llort et al., 2018; Omand et al., 2015; Resplandy et al., 2019; Stukel & Ducklow, 2017).

A critical knowledge gap is our poor understanding of eddy subduction's seasonality, which determines what kind of particles are exported and their sequestration potential, and is a major uncertainty in global carbon export calculations (Nowicki et al., 2022). Previous observational studies have mixed findings, detecting the most subduction events either during the summer (A. R. Johnson & Omand, 2021; Llort et al., 2018), spring (Chen et al., 2021), or throughout the year (Lacour et al., 2023). A challenge in assessing seasonality in float-based studies is determining the "age" of subduction events. A detected subsurface feature may have been subducted months ago, as AOU and spice anomalies may persist at depth for months (A. R. Johnson & Omand, 2021). To this end, ratios of bio-optical proxies are a promising tool to help "age" subducted material (Lacour et al., 2019), but have yet to be applied to basin-scale studies of eddy subduction.

Here, we use BGC-Argo floats in the SO to provide basin-scale analysis of eddy subduction's spatial distribution and seasonality, and tie them to physical mechanisms. For the first time, we integrate bio-optical ratios in a basin-scale eddy subduction study to more robustly address seasonality, and find a seasonal peak in the austral spring, associated with weak vertical stratification and increasing surface biomass. Integrating satellite altimetry, we find that strong lateral buoyancy gradients and weak stratification shape eddy subduction's spatial distribution. This work demonstrates the utility of bio-optical ratios in observational carbon export studies. Our mechanistic findings are also an important step toward resolving when and where submesoscale carbon export occurs, an urgent need in understanding the ocean's role in carbon cycling and climate change.

2. Data and Methods

2.1. Float Data

BGC-Argo float data are from the Southern Ocean Carbon and Climate Observations and Modeling (SOCCOM) program. Floats conduct 2,000 m vertical profiles every 10 days, and drift at a parking depth of 1,000 m. Vertical sampling frequency varies between two float types: Navis floats sample every 2 m in the upper 1,000 m. APEX floats sample less frequently, with resolution decreasing with depth. Sampling schemes are described in Johnson et al. (2017), as well as processing of bio-optical parameters, including particulate backscatter at 700 nm (b_{bp}), which is used to derive POC, and chlorophyll *a* fluorescence, which is used to derive chlorophyll *a* concentrations (Chl). Quality control procedures for all other variables are described in Maurer et al. (2021). Only data flagged as "good" were used.

Variables such as conservative temperature (CT) and absolute salinity (S_A) were derived using the Thermodynamic Equation of Seawater 2010 (TEOS-10; McDougall & Barker, 2011). Spice was calculated as a function of CT and S_A, following McDougall & Krzysik, 2015. AOU was calculated as (AOU = O_2^{sat}–O_2^{obs}), where O_2^{sat} is the oxygen saturation concentration calculated using the coefficients of Garcia and Gordon (1992, 1993), and

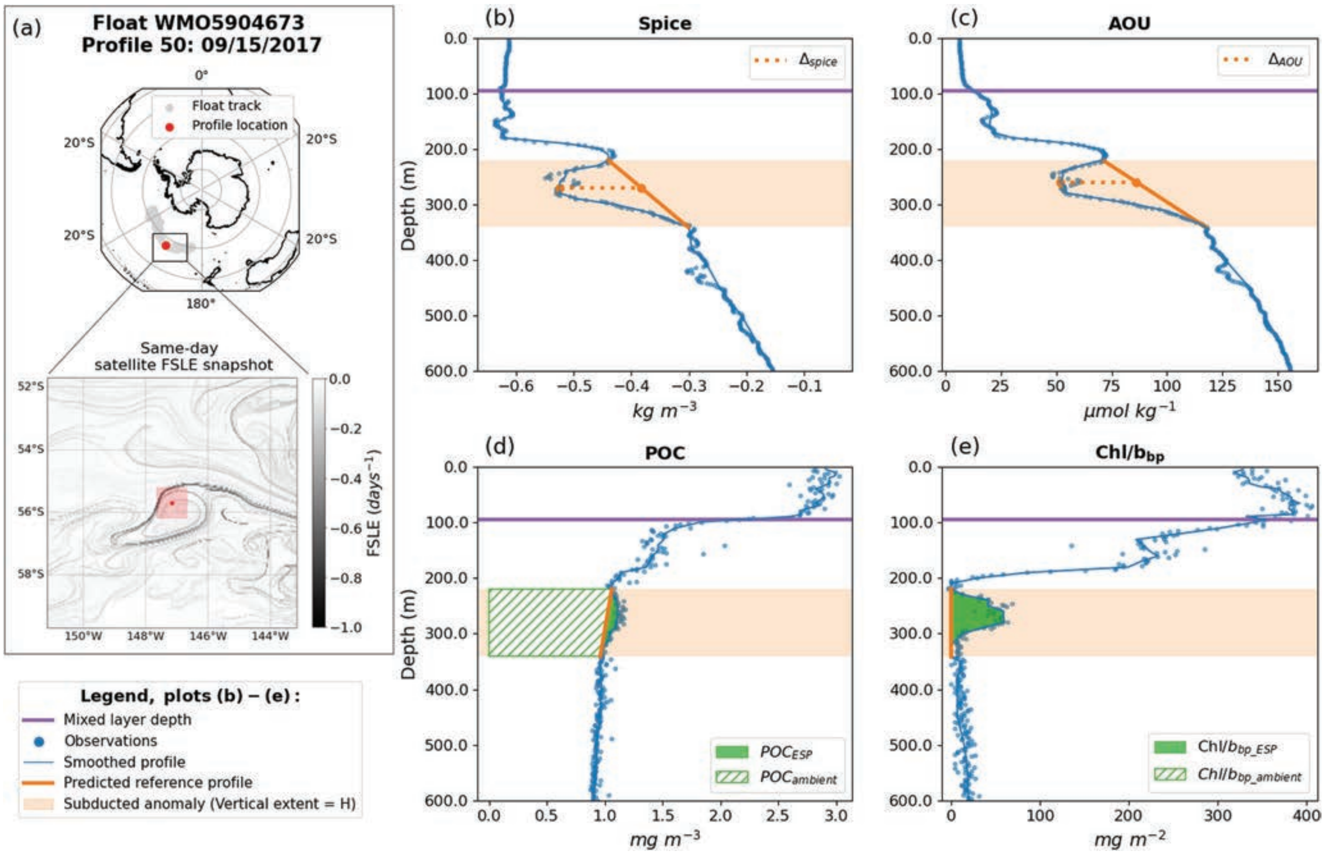

Figure 1. Example of an eddy subduction anomaly detected in a float profile. (a) Map depicting float track and profile location (red circle). Inset shows the same-day surface FSLE field. Red circle = profile location. Shaded red box = the 1° × 1° area used to retrieve the strongest FSLE in the profile's vicinity. The float's vertical profiles are shown in (b)-(d), with the MLD indicated by a purple line. Blue lines depict smoothed profiles. The shaded orange band indicates H, the vertical extent of the subduction anomaly. (b) Spice profile. Dotted orange line shows Δ_{spice} at depth h_{spice}, or the difference between the observed value and the calculated reference value (orange circles). The reference profile is shown by the orange line. (c) AOU profile, with reference profile and Δ_{AOU}, similar to the spice profile. (d) POC profile. Shaded green region: $POC_{ESP,}$ the integrated quantity of subduction-driven POC. Hatched region: $POC_{ambient}$, the subtracted, integrated quantity of ambient POC. (e) Chl/b_{bp} ratio profile. Shaded green area: Chl/b_{bp_ESP}, similar to POC. Hatched region: $Chl/b_{bp\_ambient}$, not visible because values are roughly 0.

O_2^{obs} is the observed dissolved oxygen concentration. Mixed layer depth was defined using a density difference threshold of 0.03 kg m^{-3} from the surface, and buoyancy frequency squared (N^2) was calculated using TEOS-10.

2.2. Eddy Subduction Anomaly Detection

We identified eddy subduction anomalies in float profiles using an algorithm adapted from Chen et al. (2021) and Llort et al. (2018). An example is shown in Figure 1, detected on the periphery of a mesoscale eddy (Figure 1a). We considered profiles between 30°S and 65°S, and discarded profiles with surface salinity >35 psu, following Llort et al. (2018). We also only considered profiles where the median spice value in the mixed layer was lower than that at 600 m, as increasing spice with depth in the upper 1,000 m is characteristic of SO waters (Tailleux, 2021). Navis floats were down-sampled by selecting data at APEX sampling depths, allowing for comparable vertical resolution. Profiles were vertically smoothed with a 3-bin rolling median. The total dataset contained 9,354 profiles with temperature, salinity, and oxygen collected from February 2008 through August 2023, with 8,545 measuring Chl and b_{bp}.

For each smoothed profile, we identified co-occurring peaks in spice and AOU between the MLD and 600 m depth (relative minima found within 30 m of each other, at depths h_{spice} and h_{AOU}; Figures 1b and 1c). We then defined reference profiles to simulate "background", ambient values in the absence of subduction (orange lines, Figures 1b and 1c). An initial guess for the reference profile is defined as the straight line between the maximum values above and below each peak (within 100 m in either direction), following Chen et al., 2021. The top and bottom boundaries of this initial guess are then iteratively adjusted to ensure the boundaries are coherent (see Figure S1 in Supporting Information S1). We then calculated the difference between the observed value and the calculated reference value at h_{spice} and h_{AOU}, yielding Δ_{spice} and Δ_{AOU}, respectively (Figures 1b and 1c). Peaks were classified as eddy subduction pump anomalies ("ESP anomalies") if $\Delta_{spice} < -0.05$ kg/m^3 and $\Delta_{AOU} < -8$ μmol/kg, following Llort et al. (2018). The anomaly depth was defined at h_{AOU}, and the vertical extent of the anomaly (H) was defined as the extent of the reference profile for AOU. We discarded anomalies found within 100 m of the MLD in order to avoid misidentifying detrainment from shoaling mixed layers (Lacour et al., 2019).

We then sought to quantify biogeochemical values (e.g., POC, Chl/b_{bp}, AOU) associated with anomalies, and isolate the portion driven by subduction, versus by ambient processes such as gravitational sinking. Taking POC as an example, we first calculated the total value by integrating the observed profiles over the vertical span of the anomaly (H):

$$\mathrm{POC}_{\mathrm{ESP}_{\mathrm{total}}} = \int_{\mathrm{H_{bottom}}}^{\mathrm{H_{top}}} \mathrm{POC}_{\mathrm{observed}} \tag{1}$$

We estimated the ambient value by integrating through the reference profile (hatched regions in Figures 1d and 1e):

$$\mathrm{POC}_{\mathrm{ESP}_{\mathrm{ambient}}} = \int_{\mathrm{H_{bottom}}}^{\mathrm{H_{top}}} \mathrm{POC}_{\mathrm{reference}} \tag{2}$$

From the ambient and total values, we calculated the subduction-driven value (green shaded regions in Figures 1d and 1e):

$$\mathrm{POC}_{\mathrm{ESP}} = \mathrm{POC}_{\mathrm{ESP}_{\mathrm{total}}} - \mathrm{POC}_{\mathrm{ESP}_{\mathrm{ambient}}} \tag{3}$$

Finally, we normalized these by H to yield the depth-averaged, subduction-driven value in the original units:

$$\mathrm{POC}_{\mathrm{ESP}_{\mathrm{avg}}} = \frac{\mathrm{POC}_{\mathrm{ESP}}}{\mathrm{H}} \tag{4}$$

2.3. Satellite Data

Finite-size Lyapunov Exponents (FSLEs) were downloaded from AVISO+. FSLEs describe stretching and compression by quantifying the exponential rate of separation (λ) of neighboring particles advected in a flow field: $\lambda(d_0, d_f) = \frac{1}{t} log\left(\frac{d_f}{d_0}\right)$, where d_0 and d_f are the initial and final distances between the particles, respectively, and t is the time it takes for the particles to reach d_f (d'Ovidio et al., 2004). The AVISO + product uses daily, altimetry-derived geostrophic velocity fields to advect particles backward-in-time, so FSLEs are negative, with stronger negative values indicating stronger stretching; these FSLE ridges indicate transport barriers and are preferentially located between eddy cores (Siegelman, Klein, Thompson, et al., 2020).

3. Results and Discussion

3.1. Spatial Distribution of Eddy Subduction

The BGC-Argo dataset provides basin-wide spatial coverage of the SO over 15 years. We find eddy subduction anomalies in 4.4% of profiles, defined as coherent, negative mesopelagic anomalies in spice and AOU (Figures 1b and 1c), frequently associated with positive anomalies in bio-optical parameters (67% with positive b_{bp}, 56% with positive Chl a) (Figures 1d and 1e). These anomalies are spatially concentrated around the Polar Front and Antarctic Circumpolar Current (ACC), consistent with Llort et al. (2018) (Figure 2a). Also consistent with Llort et al. (2018) and Dove et al. (2022), their circumpolar distribution is uneven, with most detected in the ACC's standing meander regions: the Eastern Pacific Rise, the Kerguelen, Crozet, and Campbell Plateaus, and the Drake Passage. These regions are known for enhanced eddy kinetic energy (EKE) and vertical exchange (Dove

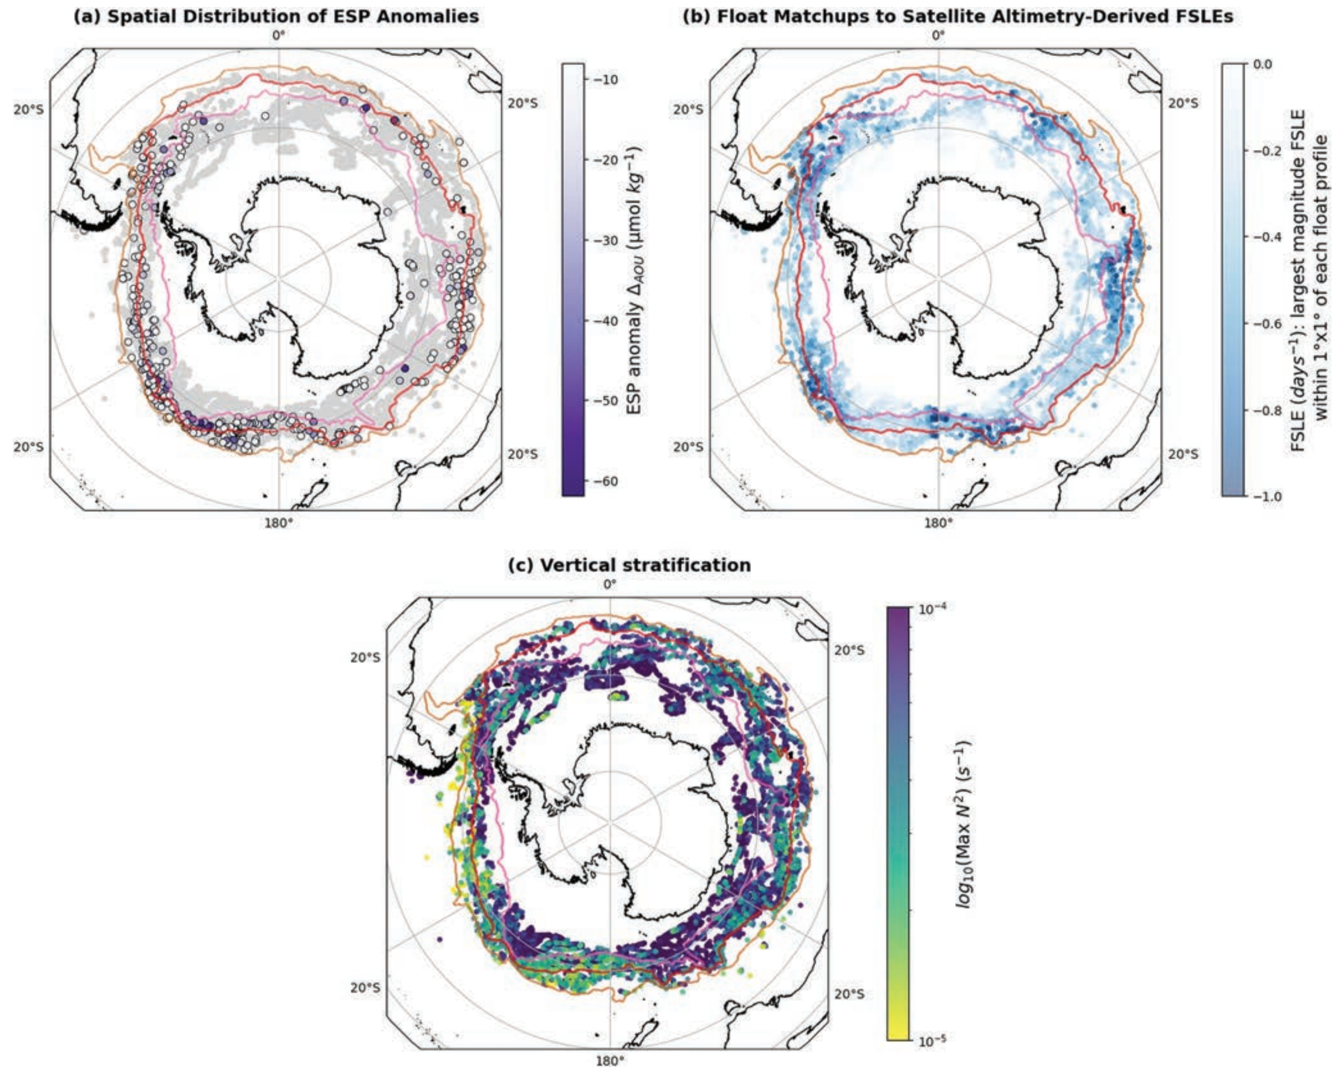

Figure 2. Maps of the float dataset. Colored lines indicate front locations as defined by mean dynamic topography from satellite altimetry (Park & Durand, 2019): orange = Subantarctic Front (SAF); red = Polar Front (PF); pink = Southern ACC Front (SACCF). (a) Locations of eddy subduction anomalies across the SO. Gray circles indicate all profiles considered in the analysis. Purple-scale colored circles indicate detected ESP anomalies, colored by the magnitude of Δ_{AOU}. (b) Spatial distribution of FSLEs. Each point is a satellite matchup to a float profile, showing the strongest FSLE within 1° × 1° of each profile. (c) Spatial distribution of vertical stratification (maximum N^2) in each float profile, and displayed on a log-scale. The colorscale maximum is limited to 10^{-4} (roughly the median of the maximum N^2 distribution; see Figure 4d) to emphasize variation in the lower half of the distribution.

et al., 2022), as the ACC interacts with underwater topography and generates mesoscale eddies that strain surface density fields and energize submesoscale motions (Rosso et al., 2015).

To better assess spatial distribution, we use altimetry-derived FSLEs. FSLEs are elevated within the ACC's standing meanders (Dove et al., 2022), and strong FSLEs are co-located with strong, deep-reaching submesoscale lateral buoyancy gradients and intense vertical velocities (Siegelman, et al., 2020a, 2020b). To assess whether a given float profile was in the vicinity of submesoscale fronts, we matched each profile with its same-day satellite FSLE field and identified the strongest FSLE within the surrounding 1° × 1° area (e.g., within the red square in Figure 1a). These matchups are displayed in Figure 2b and show the ACC's standing meanders as submesoscale hotspots, largely congruent with the distribution of eddy subduction anomalies.

However, groups of anomalies are detected in comparatively quiescent regions in between the standing meanders, such as 60°W–120°W and 150°W–180°W (Figures 2a and 2b). Although stratification shows a less dramatic spatial pattern, many profiles in these regions have comparatively weak stratification (yellow colors in Figure 2c), which may influence eddy subduction's spatial distribution by allowing deeper vertical penetration of

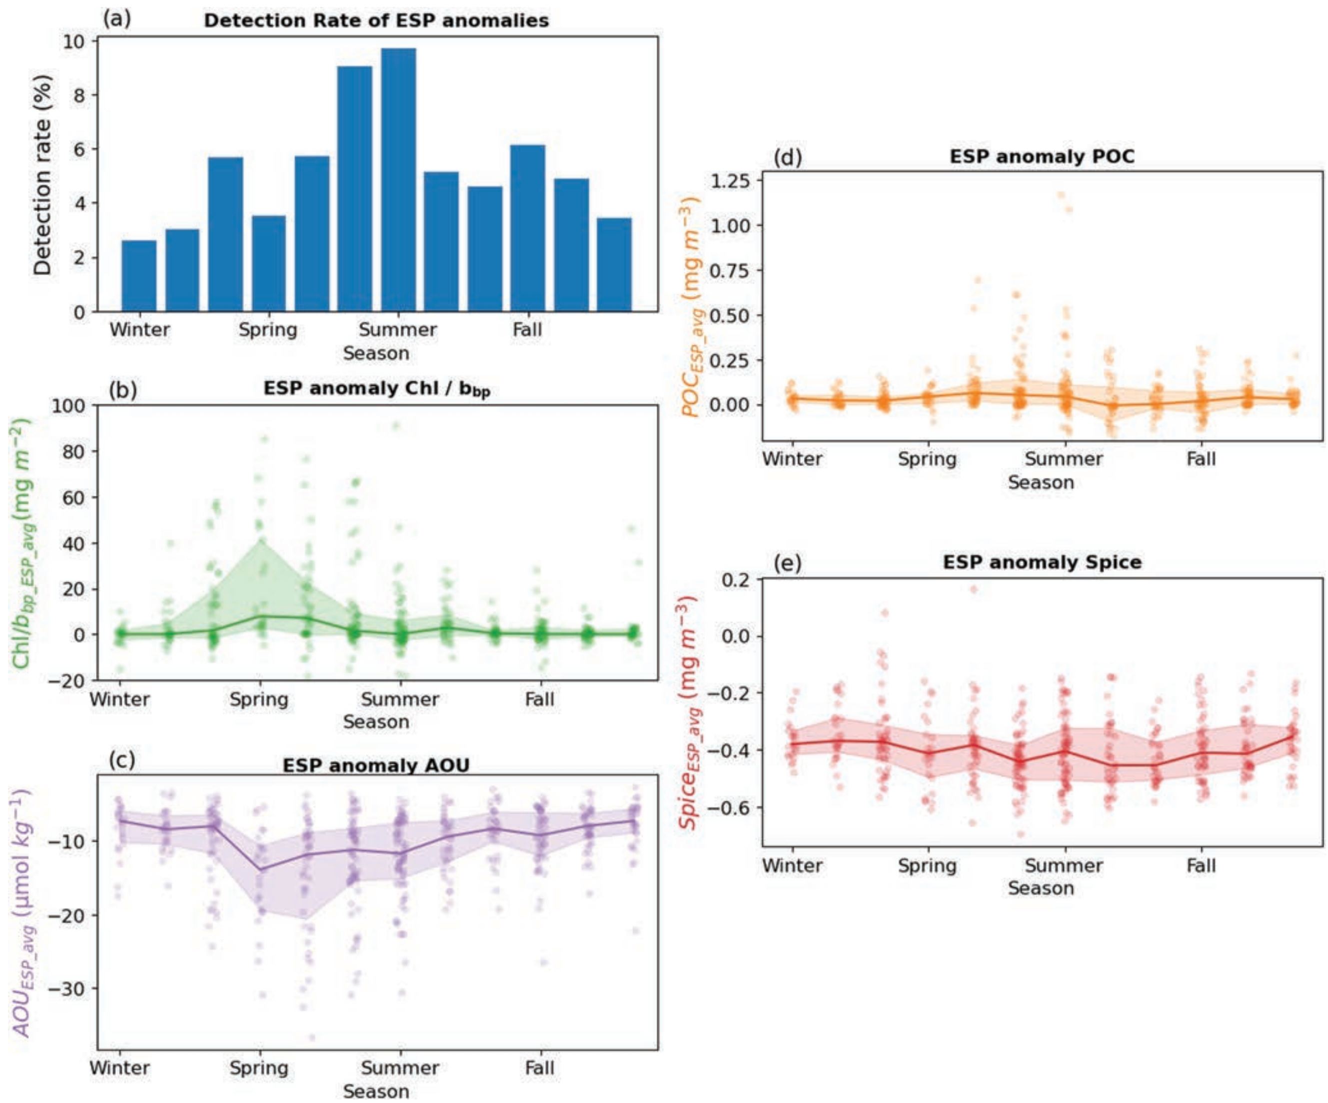

Figure 3. Seasonal patterns across observed ESP anomalies. *X*-axis ticks correspond to [June, Sept, Dec, Mar]. (a) Detection rate of ESP anomalies per month, normalized by the total number of profiles per month. Plots (b)-(e) show seasonality of depth-averaged, subduction-driven properties within ESP anomalies. Line plots depict medians, with shaded regions indicating interquartile ranges. Overlain strip plots show individual data points. (b) $POC_{\_ESP\_avg}$, (c) $Chl/b_{bp\_ESP\_avg}$, (d) $AOU_{\_ESP\_avg}$, (e) $spice_{\_ESP\_avg}$. Axis limits in (b) and (d) display 98% of data points.

submesoscale flows (Callies et al., 2016; Erickson & Thompson, 2018). These mechanistic relationships will be further explored in Section 3.3.

3.2. Seasonality of Eddy Subduction

We detect subduction anomalies more frequently during summer months (Figure 3a). However, our method only identifies subsurface anomalies after subduction occurs, and these anomalies may persist for months at depth afterward (A. R. Johnson & Omand, 2021).

To better assess the timing and "age" of subduction, we integrate bio-optical ratios, particularly Chl/b_{bp} — the ratio of chlorophyll *a* to particulate backscatter. At the surface, this ratio reflects phytoplankton photophysiology, community composition, and particle assemblage (Barbieux et al., 2018; Cetinić et al., 2015; Rembauville et al., 2017). However, beneath the mixed layer, it can be a proxy for the freshness of exported material; after particulate material leaves the mixed layer, Chl/b_{bp} decays by a power law as phytoplankton pigments degrade (Lacour et al., 2019). Calculating a precise age for a given Chl/b_{bp} observation at depth is difficult; however, we argue it is a rough but robust proxy for particle age in the mesopelagic SO. First, values in the surface mixed layer and in the mesopelagic are distinct: over an order of magnitude lower in the mesopelagic (Figure S2 in Supporting Information S1); thus, high mesopelagic values likely indicate recent surface origins. Second, ambient Chl/b_{bp} at depth shows strong seasonality, with a summertime peak that is tightly coupled to seasonal POC maxima at the surface and at depth (Figure S3 in Supporting Information S1), reflecting a pulse of fresh sinking organic matter after surface phytoplankton blooms. By contrast, Chl/b_{bp} at the surface shows weak seasonality (Figure S3 in Supporting Information S1), controlled to first-order in the SO by community composition (Barbieux et al., 2018); thus, seasonality in surface Chl/b_{bp} is unlikely to strongly influence values at depth. Together, these suggest that high Chl/b_{bp} values at depth are largely controlled by how recently material left the surface.

Within subduction anomalies, Chl/$b_{bp\_\mathrm{ESP\_avg}}$ is frequently elevated relative to ambient mesopelagic waters, indicating freshly subducted phytoplankton biomass (Figure 1e). It has a distinct seasonal cycle, with the highest values (the most freshly subducted material), occurring during the spring and early summer (Figure 3b). AOU (as AOU$_{\mathrm{_ESP_avg}}$) shows a similar seasonality, with the most negative values occurring during the spring (Figure 3c), indicating less respiration, or "aging", has occurred. Springtime events are also slightly closer to the mixed layer, consistent with more recent isolation (Figure S4 in Supporting Information S1). By comparison, the seasonal cycle of eddy-subducted POC (POC$_{\mathrm{_ESP_avg}}$) is weak, although the highest POC$_{\mathrm{_ESP_avg}}$ event outliers are detected in the summer (Figure 3d). This suggests that although eddy subduction may be most active in the spring, these events may not necessarily export large amounts of POC. Interestingly, spice$_{\mathrm{_ESP_avg}}$, a purely physical variable, does not show a seasonal cycle (Figure 3e), suggesting that the relative roles of physics versus respiration in dissipating features after subduction need to be untangled through high-resolution sampling.

Most importantly, the seasonal cycles we show are distinct from those of other processes in the mesopelagic and from surface Chl/b_{bp}, lending confidence that they reveal patterns unique to eddy subduction. For example, ambient mesopelagic POC and Chl/b_{bp} are tightly coupled to the summertime peak in surface POC (Figure S3 in Supporting Information S1), and is likely mediated by the gravitational sinking of large particles from surface blooms (Figure S5 in Supporting Information S1). Eddy subduction's springtime peak thus represents a distinct seasonality, and could facilitate export of different pools of carbon present in the spring (i.e., dissolved or inorganic carbon, which we do not discuss here). Future work should investigate this seasonality's implications for carbon sequestration.

3.3. Physical and Biological Mechanisms Controlling Spatial and Seasonal Patterns

Next, we link the previously discussed spatial and seasonal patterns to biological and physical processes required for eddy subduction of POC: POC availability at the ocean's surface, strong lateral buoyancy gradients, deep mixed layers, and weak vertical stratification (Callies et al., 2016; Erickson & Thompson, 2018; Fox-Kemper et al., 2008). We define vertical stratification as the maximum N^2 over the entire profile, as well-defined mixed layers often do not exist in energetic regions (Erickson & Thompson, 2018). However, our results are unaffected if we instead use N^2 at the base of the mixed layer (Figure S6 in Supporting Information S1).

Examining seasonal cycles in these variables, spring/early summer emerges as a period conducive to eddy subduction, with an overlap of deep mixed layers, weak vertical stratification, and increasing surface POC (Figure 4a). This aligns with the seasonality discussed in Section 3.2. Interestingly, altimetry-derived FSLEs do not show a seasonal cycle here (Figure 4b), suggesting that lateral buoyancy gradients in this region may not drive eddy subduction's seasonality.

Statistical distributions of float profiles provide further insights. Profiles with subduction anomalies are shifted towards higher surface POC (Figure 4c), demonstrating that carbon must be available to be exported. Similarly, profiles with subduction anomalies are shifted towards weakly stratified water columns (Figure 4d). Profiles with anomalies in the top quartile of Chl/$b_{bp\_\mathrm{ESP\_avg}}$ values, likely most recently subducted, are even more weakly stratified. Direct comparison of maximum N^2 to Chl/$b_{bp\_\mathrm{ESP\_avg}}$ suggests that weak stratification is a prerequisite for detecting recent eddy subduction (Figure S7 in Supporting Information S1). Interestingly, despite its strong seasonality, mixed layer depth shows little effect–distributions are similar between profiles with and without subduction anomalies (Figure 4e). Conversely, although FSLEs do not show seasonality, profiles with subduction anomalies are strongly shifted towards stronger nearby FSLEs (Figure 4f).

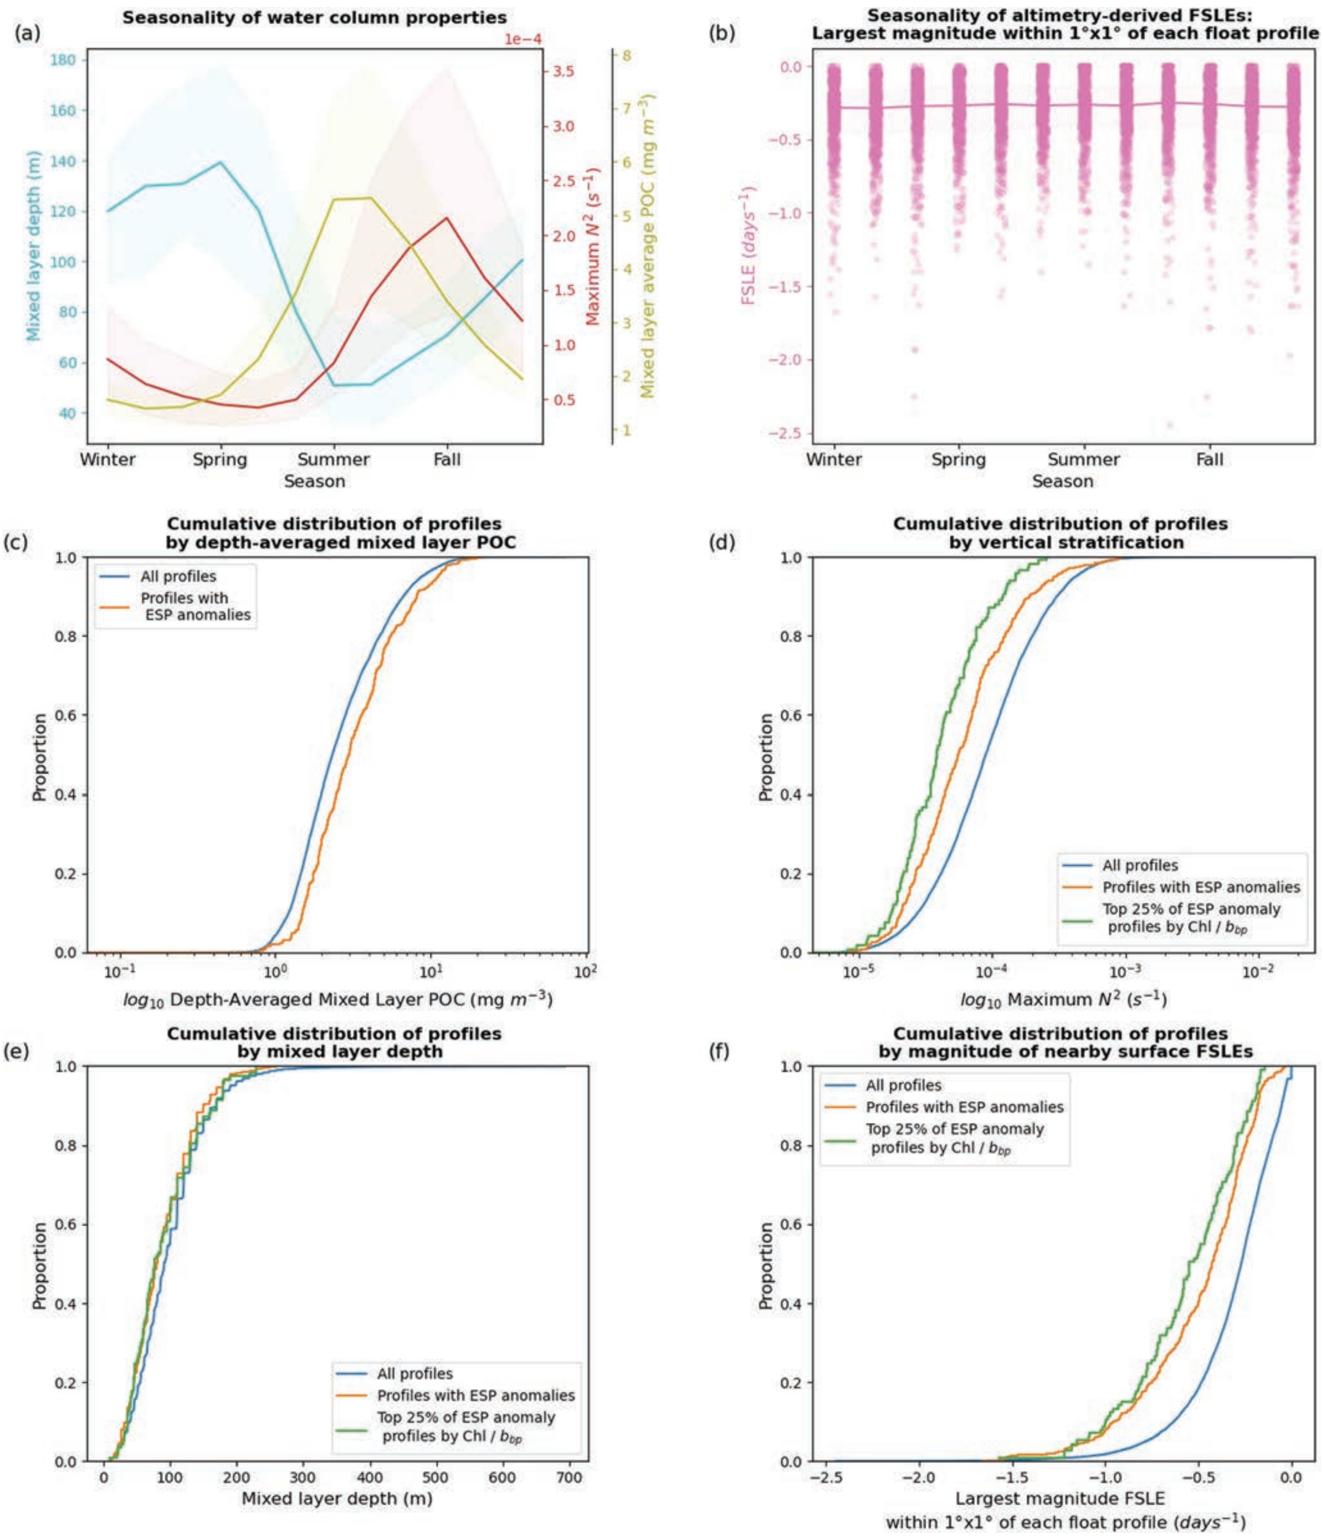

Figure 4. Mechanisms driving eddy subduction. (a) Seasonality of water column properties for all float profiles, showing MLD (blue), maximum N^2 (red), and depth-averaged POC within the surface mixed layer (olive). The line plot depicts medians, with shaded regions indicating interquartile ranges. (b) Seasonality of altimetry-derived FSLE magnitudes. The strip plot shows satellite matchups to each float profile, showing the strongest FSLE within $1° \times 1°$. Line plot as in (a). (c)-(f) Cumulative distribution plots of profiles by various mechanistic variables. Each curve represents the cumulative proportion of observations falling below the corresponding *x*-axis value. Colors indicate all profiles (blue), only profiles with ESP anomalies (orange), and only profiles with ESP anomalies with the highest 25% Chl/$b_{bp\_ESP\_avg}$ values (green) (c) Depth-averaged mixed layer POC (log_{10}) (d) Maximum N^2 (log_{10}). (e) Mixed layer depth. (f) Magnitude of the strongest altimetry-derived FSLE within a $1° \times 1°$ area.

These analyses indicate that in the SO, strong lateral buoyancy gradients and weak vertical stratification exert significant physical controls on eddy subduction. The spatial analyses in Section 3.1 suggest that these drive eddy subduction's concentration in standing meanders and weakly stratified areas. Meanwhile, the seasonal analyses in Sections 3.2 and 3.3 suggest that vertical stratification and seasonal availability of surface POC are dominant drivers of seasonality. Mixed layer depth appears to exert little influence. Consistent with Stommel's Demon theory, weak springtime stratification may act as a seasonal trapdoor in areas prone to submesoscale motions, determining whether they can export material beneath the mixed layer (Stommel, 1979).

4. Conclusions

Our work has broad implications for our understanding of carbon export and submesoscale dynamics, and emphasizes open questions for the community. First, we identify a seasonal cycle in eddy subduction, which has remained unresolved in global carbon export calculations (Nowicki et al., 2022). Future work should assess global variability beyond the SO, and assess the implications of seasonality on what pools of carbon are exported and their sequestration potential. Second, we highlight the utility of bio-optical ratios in studies of carbon export. However, high-resolution sampling is necessary to quantify the evolution and aging of tracers after subduction. Third, we emphasize the power of contextualizing subsurface float observations with Lagrangian surface diagnostics, such as satellite FSLEs. Finally, we identify strong lateral buoyancy gradients, weak vertical stratification, and POC availability as spatiotemporal controls on vertical exchange in the SO. Future investigation should untangle specific physical mechanisms (i.e., frontogenesis vs. instabilities; Archer et al., 2020; Callies et al., 2015; Erickson & Thompson, 2018; Klein & Lapeyre, 2009; Rosso et al., 2015) and use these parameters to model when and where submesoscale carbon export occurs. Finally, climate change is increasing stratification strength across global oceans (Sallée et al., 2021), potentially decreasing eddy subduction's export potential, and underscoring the importance of understanding this process's role in ocean carbon sequestration.

Data Availability Statement

Float data were downloaded from the UCSD SOCCOM and GO-BGC data archive. Our analyses use the delayed-mode, quality controlled, low-resolution snapshot from 2023 to 08-28 (Riser et al., 2023). Altimetry-derived FSLEs were produced by Ssalto/Duacs in collaboration with LOcean and CTOH and distributed by AVISO+, with support from CNES (https://www.aviso.altimetry.fr/en/data/products/value-added-products/fsle-finite-size-lyapunov-exponents.html). Analyses were conducted in Python 3.8.17 using Xarray version 2022.11.0, available under the Apache license at https://docs.xarray.dev/ (The Xarray Development Team, 2022); GSW version 3.6.17, available under the GSW License at https://www.TEOS-10.org (McDougall & Barker, 2011); and Pandas version 1.5.3, available under the BSD 3-Clause "New" or "Revised" License at https://pandas.pydata.org (The Pandas Development, 2023). Figures were plotted using Matplotlib version 3.7.1, available under the Matplotlib license at https://matplotlib.org (The Matplotlib Development Team, 2023); Seaborn version 0.12, available under the BSD 3-Clause "New" or "Revised" License at https://seaborn.pydata.org (The Seaborn Development Team, 2022); and Cartopy version 0.21.1, available under the BSD-3 Clause License at https://scitools.org.uk/cartopy/ (The Cartopy Development Team, 2022). The software associated with this manuscript for data processing and analysis is licensed under MIT and published on GitHub https://github.com/mchen96/southern_ocean_eddy_subduction/, and can be run in a zero-install environment on the cloud at https://mybinder.org/v2/gh/mchen96/southern_ocean_eddy_subduction/main (M. Chen, 2024).

Acknowledgments

***Abstract*—Predictions of AcousticS with Smart Experimental Networks of GlidERS (PASSENGERS) is a research project on pairing data-assimilative ocean models with adaptive-sampling buoyancy gliders for improved acoustic predictions in strong frontal and eddy-rich environments. The PASSENGERS field campaign consisted of two research cruises near the Atlantis II Seamount in November, 2022 and May/June, 2023. More than 4,500 glider CTD profiles were taken by 7 gliders simultaneously operating in teams and more than 110 days duration of glider hydrophone data were recorded in the vicinity of acoustic source moorings. Tests on using thrusted profiling and hover thrust modes for glider operations in November yielded a maximum through the water glider speed of 0.74 m/s and implementation of these modes in May/June allowed operation of the gliders in the swift Gulf Stream currents over the seamounts. Errors in Naval Coastal Ocean Model facilitated predictions of glider paths ranged from 21-58 km per day in the Gulf Stream, but with daily course corrections the Guidance for Heterogeneous Observation SysTem (GHOST) was able to guide a glider 150 km to pass very close by an acoustic source mooring with similar performance to a human-piloted glider under the same conditions. A PASSENGERS deployed acoustic source generated mid frequency (3-10 kHz) full band LFM up and down sweeps and multi-tone frequency-shift keyed sequences that were recorded by the glider hydrophones. Subsurface acoustic ducts were routinely observed by the gliders operating south of the Gulf Stream and these may have aided reception of the acoustic source transmissions at greater distances.**

***Index Terms*—operational oceanography, ocean observing platforms, forecasting, gliders, acoustics**

I. Introduction

Ocean acoustic propagation is subject to frequency-dependent sensitivity to ocean variability over a wide range of scales: from meter-scale gradients in the vertical to range-dependent horizontal gradients over distances of kilometers to tens of kilometers. Subsurface ocean structure constraints from satellite altimetry are subject to very high uncertainty, and submesoscale features cannot be resolved with their nine days or greater repeat cycles. The world's network of ARGO floats can resolve one-meter vertical scales but have sparse spatial coverage relative to submesoscale ocean structures and profile too infrequently to resolve their quickly evolving dynamics. In regions of strong currents such as the Gulf Stream, mobile ocean sensing platforms are quickly advected $>$ 100 km in less than a day's time. All of the above issues impact ocean forecasting because of the need to assimilate dynamically-representative temperature and salinity profile data on a daily basis. The challenges are compounded for predicting acoustics because acoustic pathways are sensitive to the small-scale temperature and salinity gradients that are particularly difficult to resolve in models.

As part of the Office of Naval Research (ONR) Task Force Ocean (TFO) initiative, the Predictions of AcousticS with Smart Experimental Networks of GlidERS (PASSENGERS) project is conducting research on these challenges in and around the region where the Gulf Stream crosses the Atlantis II Seamount (Fig. 1). A focus of our research is on how teams of buoyancy gliders [1] may be used in novel ways to improve ocean acoustic forecasting. The buoyancy gliders in PASSENGERS serve two purposes in this effort: 1) their temperature and salinity data are used in the ocean forecast model to improve its accuracy, and 2) each glider carries a passive acoustic monitoring system (PAM) that records transmissions coming from deployed acoustic sources for validation of acoustic forecasting. Optimizing glider paths for their sensing capabilities has been studied before, for example in [2], [3], and others, but in PASSENGERS the optimal sampling locations for ocean data assimilation and the optimal paths to collect acoustic data for validation and analysis do

not always align. Furthermore, while use of a variational assimilation technique as in [4] is likely to lead to a better solution than objective analysis for a data sparse environment, it also makes the sensor optimization problem more complex. Finally, areas with strong and recurrent small-scale oceanic features tend to also have strong and variable currents, which limit glider path choices and optimization schemes. This is particularly true for the PASSENGERS experiments.

II. Experimental Setting and Measurements

A. PASSENGERS Measurements

The PASSENGERS field research campaign consisted of two research cruises near the Atlantis II Seamount, one pilot cruise in November 2022 and a longer effort in May/June 2023 as part of the New England Seamount Acoustics (NESMA) 2023 field campaign. Atlantis II is a seamount within the far offshore extent of the New England Seamount Chain and close to the normal pathway of the Gulf Stream. The presence of the seamounts and the Gulf Stream fronts make accurate acoustic predictions particularly challenging, which further motivates our research on the effects of small-scale ocean features on acoustic propagation and prediction. Fig. 1 shows the measurements that were taken during the two field campaigns.

During the November 2022 cruise, the glider deployments and ship sampling focused on assessing the capability of gliders to hold station against the strong Gulf Stream currents, while also collecting a baseline ambient acoustic and glider self-noise dataset. The results of the pilot experiment were used for design of the 2023 glider sampling plan and active acoustic transmit schedule. During the November experiment, six gliders were operated in two teams over Atlantis II Seamount, the nearby Caldera seamount structure, and across the Gulf Stream. The gliders were assigned waypoints along two transects originating at Atlantis II Seamount. One transect was aligned southeastward towards the Caldera (NRL640 with 200 m profiles, Electa with 350 m profiles, RU32 with 1000 m profiles, and RU36 with 1000 m profiles), and the other was northwestward towards the open ocean (NRL640 with 200 m profiles, NRL641 with 1000 m profiles, and Murphy with 1000 m profiles).

All gliders were equipped with CTDs, resulting in 1,400 glider CTD profiles. PASSENGERS also collected 16 deep (2000 m) ship CTDs and 58 Underway CTDs to about 900 m depth along the experiment transects in November. All of the gliders were outfitted with calibrated HTI96-min hydrophones and Loggerhead LS1 recorders and they captured ambient and self-noise from gliders in the mid-frequency (3-24 kHz) range throughout the 12-day test.

During May 2023, due to initial technical problems with the PASSENGERS acoustic source (MIT Lincoln Lab, MITLL Fig. 1), PASSENGERS gliders were deployed within hearing range of either the Woods Hole Oceanographic Institution Transceiver (WHOI TR) or the Scripps Institution of Oceanography North (SIO N) moored acoustic sources. WHOI TR had a mooring with low frequency (LF 500-600 Hz) and mid frequency (MF, 2750-4250 Hz) sources at 700 m depth transmitting 2.5-second length, 10-second pulse repetition interval (PRI), linear frequency modulated (LFM) up sweeps for 5 minutes at the top of every hour. SIO N had a source at 1100 m depth transmitting 3 sets of LFM up/down sweeps from 230 Hz to 320 Hz at the top of every hour. Each up or down sweep was 1-minute long, adding up to a total transmission time of 6 minutes.

Two gliders (NRL641 with 1000 m profiles and Electa with 350 m profiles) were deployed near WHOI TR to track the highest predicted sound speed gradients that increased with depth at 300 m. Because temperature stratification at 300 m is usually strong enough to insure that sound speed decreases with depth at that level, an increasing-with-depth sound speed at 300 m is indicative of the presence of a local sound speed minimum above 300 m, forming a subsurface acoustic duct. By tracking these increasing-with-depth subsurface sound speed gradients, we aimed to characterize the subsurface ducts by having gliders profile through them and map their horizontal extents. Sound speed profiles from glider Electa shown in Fig. 2 captured the upper ocean sound speed minimum between 150 and 300 m in the region south of the Gulf Stream. This subsurface acoustic duct feature persisted throughout the study, but varied significantly in strength and vertical structure. The observed sound speed profiles also exhibited strong tidal oscillations as well as near surface effects from the Gulf Stream, both of which could impact acoustic propagation.

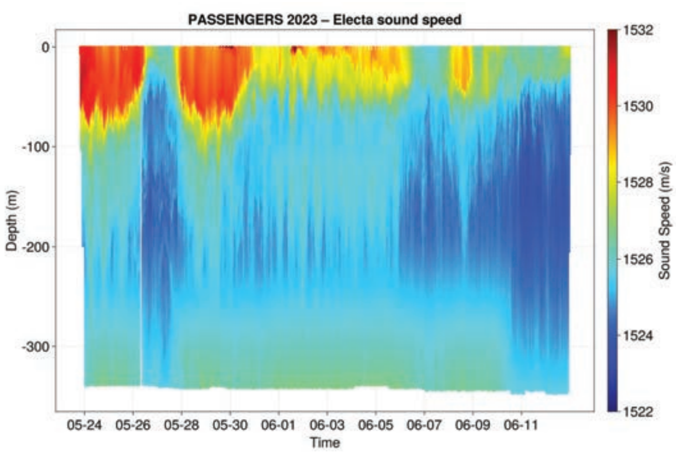

Fig. 2. Time series of the sound speed profiles observed by glider Electa during May/June 2023

Three gliders (RU30 with 1000 m profiles, RU36 with 1000 m profiles, and Angus with 200 m profiles) were deployed to attempt station keeping at fixed distances from WHOI TR. Two other gliders (NRL639 with 200 m profiles and NRL640 with 200 m profiles) were deployed near SIO N and were set to track areas of highest sound speed variability. These two gliders were recovered on June 1st in preparation for a redeployment near the MIT LL acoustic source planned for the second leg of this cruise. However, NRL640 was extremely corroded due to a battery fault and could not be redeployed.

For the June portion of the field work the MITT LL acoustic source was deployed after its repair. The MF (3-10 kHz) source was moored at a nominal 450 m depth and transmitted for 96 hours. The signal schedule was 1-second length, 6-second PRI broadband signals, repeated throughout the duration of the source deployment, to achieve vertical resolution of glider acoustic receptions of about 0.9 m (assuming glider vertical ascent/descent rate of approximately 0.15 m/s). The signals were a mix of full band LFM up and down sweeps and multi-tone frequency-shift keyed sequences (FSKs). NRL639 along with a new glider teammate (Sylvia with 200 m profiles) were deployed upstream in the Gulf Stream on coordinated paths planned to take them nearby the MIT LL source located on the Caldera. In addition, NRL641, RU30, and RU36 gliders were recovered and re-positioned on coordinated paths planned to also take them past the MIT LL source. Gliders Electa and Angus continued to gather data, now relatively far to the southeast of WHOI TR. In total for the May/June 2023 field experiment, 3,186 glider CTD profiles, 60 deep ship CTDs, and 71 Underway CTDs were collected. The hydrophones on the eight gliders recorded more than 110 days duration of sound, primarily in the vicinity of WHOI TR and profiling through subsurface acoustic ducts.

B. PASSENGERS Modeling

PASSENGERS field work was supported by an ocean forecasting system that assimilated both project glider observations and routinely collected observations distributed through the World Meteorological Organization's Global Telecommunication System (e.g., sea surface height anomaly data, sea surface temperature data, ARGO profile data). The numerical core of the forecasting system was the Navy Coastal Ocean Model (NCOM) [5] and data was assimilated via three-dimensional data assimilation in the Navy Coupled Ocean Data Assimilation system (NCODA) [4]. NCOM was configured with 2 km horizontal resolution and 50 vertical levels. The domain extended from 31°N to 43.2°N and from the US East Coast offshore to 54.50°W. Boundary conditions were from the Navy's Global Ocean Forecasting System (GOFS, version 3.1). Because GOFS 3.1 does not have tides, barotropic tides (eight major constituents) were applied at the boundary and sourced from the Oregon State University TPXO Tide Model [6]. GOFS is also the source of initial conditions (Nov. 1, 2022). Atmospheric forcing is from the Navy Global Environmental Model (NAVGEM) [7]. A global model was used due to the relatively large and remote extent of the NCOM domain.

Daily results from the NCOM ocean forecasting model were used in multiple ways during the PASSENGERS experiments. The results were sent to the PASSENGERS and other NESMA scientists at sea to inform adaptive sampling daily plans. NCOM forecasts were also used in the Guidance for Heterogeneous Observation SysTems (GHOST) to generate glider pilot assistance maps by predicting the path of a glider if directed to swim towards a particular waypoint [8]. GHOST can also compare predicted sampling results between different waypoints to allow a glider pilot to select waypoints that are predicted to be optimal for particular sampling goals. GHOST guidance was run daily for many of the PASSENGERS gliders to support their different sampling goals and provide waypoint suggestions for possibly implementation. Glider observations of temperature and salinity profiles were in turn assimilated back into NCOM [4] to improve future glider pathway forecasts.

NCOM results were also used to generate acoustic forecasts using the Bellhop acoustic ray tracing model along the glider transects. Bellhop was set up to model transmission loss for a source frequency of 6 kHz using a range-dependent sound speed section provided by the daily NCOM forecast. Bathymetry was from NOAA Okeanos Explorer (EX1303): New England Seamount Chain Exploration. The transmission loss results from Bellhop were used to determine the acoustic convergence zone or location of highest predicted signal/lowest transmission loss for each transect for the day. These acoustic positions of importance were then used as target goals in GHOST for glider sampling for one glider on each transect in November when possible.

C. Gulf Stream Background Flow

As expected, the Gulf Stream played a prominent role for both the November 2022 and the May/June 2023 experiments as it crossed close by the Atlantis II Seamount. Fig. 3 shows shipboard Acoustic Doppler Current Profiler (ADCP) data gathered by the R/V Atlantic Explorer during a crossing of the Gulf Stream on November 11, 2022 and on May 26-28, 2023. The latter crossing was slower than the former because the ship stopped to take 2000 m CTD casts every 10 km along the track.

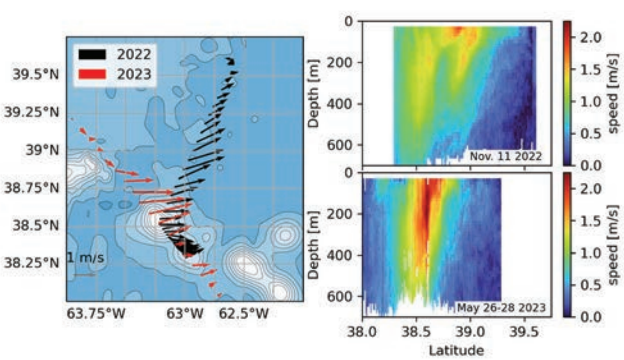

Fig. 3. Left-hand panel shows map of Gulf Stream currents for Nov. 2022 (black) and May 2023 (red) as measured by the shallowest depth bin (27 m) of R/V Atlantic Explorer's shipboard ADCP. The right-hand panels show the measured speed depth structure for Nov. (top) and May (bottom) versus latitude.

There were notable differences in Gulf Stream strength, position, and structure between the two field campaigns. In May 2023, the peak observed speed of the Gulf Stream was 2.22 m/s compared to only 1.86 m/s in November 2022. The core of the Gulf Stream was located directly over the northern flank of the Atlantis II Seamount on May 27. It was located further north on November 11 with a somewhat broader area of strong flow compared to the peaked but narrow core observed in May. Some of the apparent broadening of the flow could be due to different crossing angles, but it is clear that the Gulf Stream was more compact in May than in November. There is also a big difference in the current shear profiles between the two crossing with the May crossing showing very little current shear down to a depth of 600 m. In contrast, the November crossing had areas of high shear in the upper 200 m right under the core and relatively high shear between 200 and 400 m north of the core. Shear was relatively weak directly over the seamount (about 38.5°N) in both cases.

III. Results

Analyses are ongoing for the PASSENGERS data collected in November 2022 and May/June 2023. Here we summarize some of our early results from this field work with a focus on glider operation and measurements.

A. November Glider Speed Tests

Several strategies were tested in November to experiment with glider settings and thruster modes of operation for maintaining station in extreme ocean current conditions for acoustic sampling. Normally such strategies are not tried in the field as typical goals for glider sampling are to maximize duration of sampling and avoid high-battery use settings. However, objectives of acoustic sampling may not require multiple months of observations and it could be more important to maintain position close to a sound source mooring for acoustic monitoring than have an extended mission that is far from the sound source and unable to observe it despite retaining battery reserves.

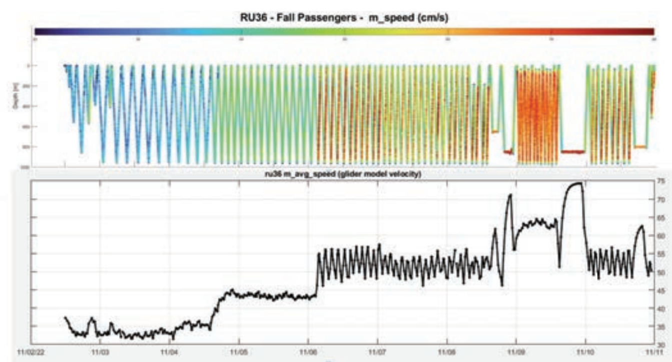

Fig. 4. Top panel shows the time/depth position of the RU36 glider during the PASSENGERS November 2022 field experiment. Bottom panel shows the segment averaged speed (cm/s) through water of the glider versus time. Instantaneous horizontal speed (cm/s) through water is also shown in color on the top panel. Both are calculated onboard the glider using depth rate of change and pitch angle, assuming a nominal 0° angle-of-attack.

Fig. 4 shows the progressively faster speeds through water achieved by RU36 during the November 2022 experiment. From Nov 2 through midday on Nov 4, typical glider settings were used and the speed through water was about 0.35 m/s. RU36 is a generation 3 glider with an expanded capacity buoyancy engine. Therefore, from Nov 4 midday to Nov 6 the buoyancy engine capacity was increased from ± 200 cm^3 of a typical glider to its full expanded capacity of ± 400 cm^3. The resulting speed through water increase was about an additional 9 cm/s to 0.44 m/s. RU36 was equipped with a thruster, which can be used to assist with surfacing through a freshwater plume or to increase the speed of the glider (at the cost of higher energy usage) in either thrusted profiling or hover thrust modes. From Nov 6 to midday on Nov 8, the thruster was turned on during the upcast portion of the glider profile leading to about an additional 8 cm/s speed through water increase to 0.52 m/s. On Nov 9 for about 12 hours, the thruster was used during both the upcast and downcast leading to about an additional 12 cm/s speed through water increase to 0.64 m/s.

On November 9 for 8 hours a hover thrust mode was tried with RU36. This mode sends the glider to depth (in this example to 800 m) and runs the thruster with the glider oriented horizontally (0°) rather than at its typical 26° tilt from horizontal. This use led to a further 10 cm/s increase in speed through water from the case of using the thrusters while profiling. The 0.74 m/s speed through the water was replicated when the Electa glider also was run in a hover thrust mode. This mode has the distinct disadvantage of taking no measurements when used, but has some advantages. In addition to having the highest overall speed through water, it also can take advantage of current shear with depth so that its speed over ground would be, e.g., 0.74 m/s minus the current speed at 800 m depth rather than 0.52 m/s minus the average current speed between 0 and 1000 m as would be the case for using the thruster on the upcast. Running a hover thrust mission continuously is not practical because of its high energy usage and lack of measurements. However, strategies that include hover thrust missions combined with regular profiling should be considered for station keeping in strong currents, especially ones with high levels of vertical current shear.

Theoretical calculations were conducted using the measured ADCP currents from the ship in November and we predicted that using a hover thrust mode for 8 hours per day would have allowed gliders to station keep on the southern boundary area of the Gulf Stream over the Caldera in November 2022. However, in May/June 2023 the Gulf Stream flow over the Caldera was much stronger than in November 2022 and had little shear with depth (Fig. 3). This lack of shear made hover thrusting in May/June less advantageous and therefore the glider thrusters were primarily used during upcast sampling to increase speed during the 2023 experiment. Experimenting with glider thruster modes in November paid off as the strategies practiced then led to better glider performances in May/June (Fig. 1) with no gliders being caught in the Gulf Stream and advected far away.

B. Glider Team Flyby of the MIT LL Acoustic Source

The MIT LL acoustic source was repaired during a port stop in the May/June 2023 PASSENGERS research cruise and the acoustic source mooring (MITLL Fig. 1) was deployed on the Caldera on June 8 at the beginning of the last leg of the cruise. The source was programmed to acoustically broadcast from June 8 to the morning of June 13 (about 4 days) and then programmed to stop transmissions for safety of recovery. Two gliders (NRL639 and Sylvia) were also prepared during the port stop for dedicated acoustic sampling of this source. The Gulf Stream was still flowing close to the Caldera (Fig. 3) as verified by glider RU30 operating just to the south and currents at the Caldera were too strong for glider station keeping even if using the methods of section III-A. Therefore, we planned the deployments of NRL639 and Sylvia for areas of highest predicted sound speed gradients that increased with depth at 300 m and which occurred 160-180 km upstream of the Caldera. If these 200 m gliders lost ground to the Gulf Stream at a rate of 1 m/s, then such a deployment would bring them to the Caldera in about 2 days' time and allow them to sample for 2 days upstream of the acoustic source and for 2 days downstream of the acoustic source before it turned off.

Runs of GHOST predicted that the gliders would both stay south of the acoustic source over their closest 72 hour course approaches, but a northward shift of their deployment positions by 30 km would allow them to make a closer approach. Therefore the gliders were deployed at these northward shifted positions (Fig. 5). Actual deployments were 149 km (NRL639) and 177 km (Sylvia) distant from the source. NCOM predicted southeastward currents between the gliders and the Caldera, so the initial assigned waypoints were to the northeast (blue and green squares in Fig. 5) in order to track a eastward path (dashed lines are the predicted pathways). This turned out to be an over-prediction of the southward component of flow and both NRL639's and Sylvia's true paths (blue and green lines) over the course of the first day were north of the predicted ones.

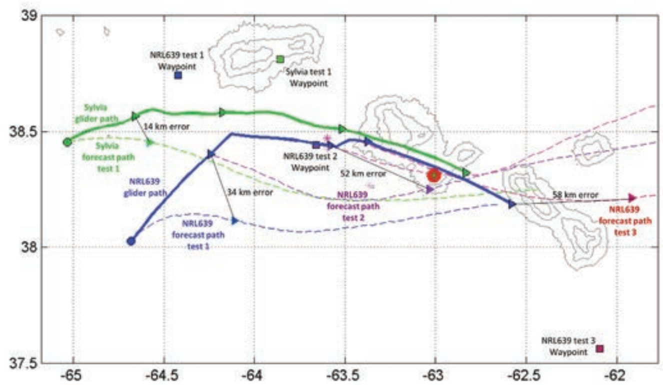

Fig. 5. Map of upstream deployments of Sylvia (solid green line) and NRL639 (solid blue line) for June 9-13, 2023. The red circle is the MITLL acoustic source mooring. Triangles show positions for GHOST glider path forecast initializations and dashed lines show forecast tracks as labeled. GHOST waypoints that were used for tests are shown as squares and labeled. Waypoints used for the glider but not for tests are shown as stars. The pink dashed line is a GHOST forecast path between test 2 and test 3, but was excluded from the test count as waypoints (light purple stars) other than the GHOST one (purple star) were used for that day.

On the second day of the flyby approach with these two gliders it was decided to have Sylvia aim for a waypoint directly on the Caldera. NRL639 continued to use GHOST selected waypoints after vetting by glider pilots. Using the next-day's NCOM forecast and accounting for a new starting position of the glider, the new GHOST recommended waypoint (purple square in Fig. 5) was shifted to be directly east and only slightly north of the day 2 starting point. NRL639's path was predicted to dip southeastward before returning northeastward and passing close by the acoustic source in 28 hours' time (purple dashed lines). This second waypoint was sent to the glider 8 hours later than what GHOST had simulated as can be noticed in NRL639's abrupt turn to the east in its path. NRL639 did not dip southward as predicted and was able to directly fly towards this new waypoint, even passing directly over it. Ghost's new guidance on day 3 kept the waypoint (purple star) near the same location as on day 2. This successfully slowed NRL639 progress much more than predicted (compare the pink dashed line to the distance between the two blue triangles near 63.5°W) and several other waypoints were tried by the piloting team (light purple stars) to try and speed up progress to the acoustic source.

On Day 4 there was a drastic change in GHOST's recommended waypoint as it was shifted far to the southeast (red square in Fig. 5). The path that NRL639 took passed very close to the acoustic source as desired and followed the GHOST predicted path quite closely. However, its progress along this path was much slower than predicted, ending 58 km west (final blue triangle) of its predicted end point (red triangle). Table I summarizes the distance, angle, and speed errors between the predicted pathway and actual pathways of the gliders during these tests. Day 3 guidance for NRL639 is excluded due to the changing waypoints. Timing delays in implementation of the waypoints are not treated separately so a portion of these errors could be attributable to those delays. It is clear that NCOM over-predicted the Gulf Stream flow on June 9-13 for this region with stronger southward and eastward flows than the gliders actually experienced. The average over-predicted speed was 0.48 m/s for these experiments. Despite this, with daily course corrections, GHOST guidance did succeed in the mission of bringing a glider for a very close flyby of the PASSENGERS acoustic source mooring. However, the benefit of flying in the Gulf Stream with GHOST is unclear as Sylvia also succeeded in a close flyby of the source by placing a waypoint at that location.

TABLE I
GLIDER PATH FORECAST ERRORS

experiment	distance error	angle error	duration	avg. current error
Sylvia test 1	14.2 km	150°T	16 hours	0.25 m/s
NRL639 test 1	33.5 km	160°T	22 hours	0.42 m/s
NRL639 test 2	51.7 km	114°T	28 hours	0.51 m/s
NRL639 test 3	57.9 km	87°T	24 hours	0.67 m/s

Glider RU30 was directed to swim towards the MIT LL acoustic source mooring after the mooring was deployed on June 8, but Gulf Stream currents soon swept it far to the east and south (note southeastward extent of pink line in Fig. 1). Therefore, we recovered this glider along with RU36 and NRL641 which were far south of the source mooring, and redeployed them on June 11 (local ADT time) within 55 km of the Caldera (Fig. 6). NRL641 was directed by GHOST to run a straight eastward track in-between the MIT LL and WHOI TR acoustic source moorings. RU36 was directed by pilots to run a southeastward track staying southeast of the topography of Atlantis II and the Caldera. RU30 was directed by pilots to run a parallel southeastward track but passing directly over Atlantis II and the Caldera. All three of these planned tracks were successfully executed even in Gulf Stream currents. Together with Sylvia and NRL639 tracks that had been staged earlier, this formed a five glider team flyby of the MIT LL acoustic source mooring from June 11-13 with appropriate glider spacing for planned future data assimilation studies. On June 13, just before the acoustic source mooring was programmed to stop transmitting, both the R/V Atlantic Explorer and the R/V Armstrong (one of our collaborating partner ships) stopped operations and lowered hydrophones on their CTD profiles to also record the transmissions of the MIT LL source simultaneous to what was being recorded by the 5 glider mobile receiving array that we had formed (Fig. 6).

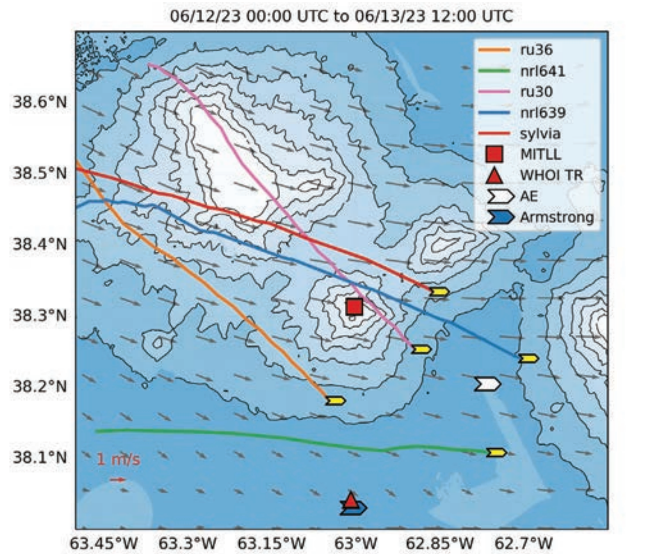

Fig. 6. Map of glider flyby mobile receiving array experiment conducted on June 12-13 (UTC), 2023. Bathymetry is shaded in blue with contours drawn in gray to show the seamounts. Gray arrows are surface current predictions from NCOM. Colored lines show glider tracks with ending positions indicated as yellow symbols. Acoustic source moorings (MITLL and WHOI TR) and research vessel R/V Atlantic Explorer (AE) and R/V Armstrong positions on June 13 are also shown and labeled in the key.

C. Gliders as Mobile Acoustic Receivers

One focus of PASSENGERS was using buoyancy gliders as shallow-water mobile acoustic receivers. Due to the proximity of WHOI TR and MIT LL acoustic sources, gliders that passed between them during favorable acoustic conditions were able to simultaneously capture sound from both. Fig. 7 is a spectrogram from acoustic data recorded on RU30 when it made its first attempted approach towards the MIT LL source on June 9 and the glider was 42 km from the MIT LL source and 46 km from the WHOI TR source. While the MIT LL acoustic source was transmitting throughout this time, the glider was descending and the vertical acoustic refraction was most favorable during the 25-45 s window. RU30 also captured the WHOI TR LF (500-600 Hz) and MF (2.75-4.25 kHz) upchirps starting at the top of the hour, which is around 70 s into this recording section. Overlapping the WHOI TR MF source is broadband glider self-noise from 2.5-4 kHz. The broadband (0-10 kHz) glider self-noise is from the glider's rudder.

Fig. 7 also shows the glider observed sound speed profile recorded at the same time as the acoustic transmissions shown in the spectrogram. The presence of a subsurface acoustic

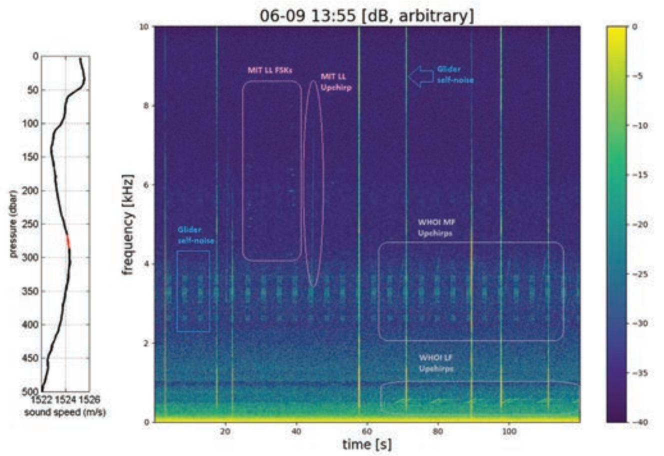

Fig. 7. Left panel shows the sound speed profile in the upper 500 m observed by RU30 glider on 6/9/2023 from 13:35-14:12 UTC. Right panel shows the spectrogram from RU30 glider PAM simultaneously capturing MIT LL and WHOI TR acoustic sources and self-noise. Red highlights on the left panel graph show the depth location (266-286 m) of the glider when the acoustic data was collected as analyzed in the right panel.

duct is clearly indicated by the local sound speed minimum at 136 m depth and the glider was within the duct (above the local sound speed maximum) when the MIT LL and WHOI TR transmissions were heard. Such ducts were routinely observed by all the gliders operating south of the Gulf Stream and in this case may have helped facilitate recording of the acoustic source mooring transmissions.

IV. Summary

PASSENGERS collected a large physical oceanography and acoustic propagation dataset that successfully resolved some of the multiple-scale dynamic processes associated with the Gulf Stream crossing over the Atlantis II and neighboring seamounts. This dataset will facilitate our future work on improving acoustic forecasting for such regions using teams of buoyancy gliders. The November pilot study showed the possibilities for enhancing glider performance with strategic thruster use and the lessons learned allowed us to keep a fleet of 7 gliders of varying capabilities sampling within a 130 km by 110 km box at the edge of the Gulf Stream for the majority of a three week concentrated experiment in May/June (Fig. 1). Results from PASSENGERS illustrate the need for improvements in forecasting the Gulf Stream position and currents for glider path planning and other purposes (Table I). Our future plans include using this PASSENGERS dataset in a multi-scale data assimilation research effort to improve both the physical oceanography and acoustic forecasting capabilities of our real-time modeling systems.

Acknowledgment

This work would not have been possible without many long days from dedicated teams aboard the R/V Atlantic Explorer and on-shore piloting gliders. The offshore team included Leslie Birch, Emily Busch, Angel Diaz, Breana DiRenzi, Anthea Empson, Rhyan Grech, Ian Martens, Jason Noel, Andrew Quaid, Annat Sonion, and Jon Wood. Frank McQuarrie served ashore on one leg and offshore on two others while Karen Dreger did the opposite. Brian Buckingham served offshore during every leg of PASSENGERS. The onshore team also included David Aragon, James Bird, Drew Vincent, and Nicole Waite. Port Captain Rick Verlini was very helpful with all our customs issues and even filled in at the last minute during one leg at sea. Ruth Curry and Jonny Chapman very generously allowed our team use of their glider facilities for ballasting, calibration, and other glider work. Bermuda Institute of Ocean Sciences hosted us during our time preparing for these efforts. The crew of the R/V Atlantic Explorer were exceptional and we would like to especially thank Marine Science Technicians Rory O'Connell, Lydia Sgouros, and Oban Jones, and Captains George Gunther and Patrick Redmond.

Abstract*— The presence of offshore wind infrastructure in the Northeast U.S. ocean is rapidly increasing to achieve the national goal of 30 gigawatts power by 2030. With varying foundation configurations and grid layouts, construction of offshore wind farms will impact several state and federal surveys that provide invaluable insight to stock management and the impacts of climate change on marine species, habitats, and ecosystems. In addition to the risk of active and derelict gear entanglement from vessels engaged in bottom trawling or dredging with offshore wind infrastructure, alternative non-extractive survey methods (e.g., autonomous underwater vehicles such as ocean gliders) share the risk of entanglement and interacting with infrastructure highlighting the need for careful operational planning and risk mitigation strategies. Our study aims to assess the risk of interaction between ocean gliders and offshore wind turbines within the Wind Energy Areas (WEAs) OCS-A 0498, OCS-A 0499, and OCS-A 0512 using a decade of historic glider track data in a simulated environment of turbine pylons. We utilized 142 historical glider deployments from 2013 to 2023, incorporating an interaction algorithm that accounts for varying buffer zones (0, 2, 4, 20, and 30 meters) beyond monopile foundations to model potential interaction scenarios. It was found that about 1 interaction per deployment occurred across our 142 deployments where no avoidance routines were used. The analysis revealed that risk varies across different WEAs and buffer zones. Simulated interactions were more frequent in larger buffer zones and WEAs that had an increased number of deployments, with a noticeable difference in interaction rates between turbine structures and substations. Specifically, simulated interactions with turbines at depth were more prevalent than surface and substation interactions. While surface interactions are less common, they may pose greater risks due to environmental conditions near the surface (e.g., waves, winds, currents, storms, etc.). Additionally, the infrequent substation interactions could pose a greater risk to the glider due to its foundation type (i.e., piled jacket) which has more underwater structure to interact with. The study highlights a trend where increased time spent in WEAs translates to higher interaction frequencies and reduced time between interactions. This study highlights the baseline interaction rates and thus importance of enhanced operational strategies, vehicle vulnerability awareness, and real-time monitoring to mitigate interaction risks in areas of active offshore wind development.

Keywords—Underwater Glider, Turbines, Wind Energy Area, Interaction

I. Introduction

With a national goal of 30 gigawatts of power coming from offshore wind by 2030, the Northeast U.S. ocean is rapidly under development [1]. Offshore wind structures serve different purposes and come in various configurations, including but not limited to monopiles, jackets, and tripods, as well as substations and other support infrastructure. They are designed for use at different depths, encompassing both bottom-fixed and floating foundations. Bottom-fixed foundations and the anchors for floating foundations interact with the soil and water characteristics such as depth, current velocity and direction, waves, and tides in the surrounding area which can elicit erosion of the seabed. To counteract this effect, scour protection, which involves placing an armor layer such as coarse rock material, is installed around the structure [2, 7-9].

The construction of offshore wind farms along the Northeast U.S. coastal shelf will impact several federal and state surveys that are paramount to understanding the effects of climate change on marine species, habitats, and ecosystems [3]. Offshore wind farms can present a risk of gear entanglement with turbine structures and cables for both derelict and active survey gear. The likelihood of entanglement increases for vessels engaged in bottom trawling or dredging when turbines are spaced less than 1 nautical mile apart [4]. Due to safety concerns and gear loss, non-extractive survey methods are being considered as alternative data collection methods to mitigate the impact to these traditional surveys. One platform that could support this non-extractive data collection are autonomous underwater vehicles (AUV) equipped with active acoustic sensor payloads.

AUVs, such as ocean gliders, are considered low-energy, long-endurance, and relatively cost-effective vehicles. These mobile sensor platforms propel themselves vertically and horizontally in a triangle pattern by changing buoyancy, enabling the collection of spatial and temporal data throughout the water column [5]. The modular ability to incorporate sensors for physical, biological, and chemical data collection is integral to filling observational gaps where ships and remote sensing could not succeed. Additionally, this capability aids in the validation and data assimilation of models [5-6]. For these reasons, gliders have become a staple in oceanographic and ecosystem monitoring surveys, from the deep ocean to nearshore coastal environments including the regions identified for offshore wind development.

OCEANS 2024 - Halifax | 979-8-3315-4008-1/24/$31.00 ©2024 IEEE | DOI: 10.1109/OCEANS55160.2024.10754184

Sharing the ocean with large vessels and hardened static structures such as buoys, moorings, or oil platforms has presented interaction risks such as collision, entanglement, and sensor damage that can lead to vehicle loss. This has led to diligent monitoring and piloting to minimize these risks. The offshore wind environment may introduce increased hazard to oceanographic gliders as well as any vehicles with limited amounts of control to avoid interactions. We intend to 1) assess the risk of glider-turbine interaction occurring, 2) estimate the potential impact if the risk were to occur, and 3) suggest mitigation behaviors. We use a decade of historical glider tracks within the New Jersey/New York Bight (NYB) region as well as simulated glider behaviors to explore these topics.

II. Methods

A. Study Area

The Rutgers University Center for Ocean Observing Leadership maintains several operational survey lines off New Jersey. Therefore, this study focused on the near shore Wind Energy Areas (WEAs) off New Jersey (Fig. 1) to evaluate the feasibility of maintaining these historic survey lines. WEAs of focus include OCS-A 0499 (Atlantic Shores Offshore Wind Projects 1 and 2), OCS-A 0498 (Ørsted Ocean Wind 01), and OCS-A 0512 (Empire Wind). This study was limited to the WEAs that overlap with historic glider deployments and have publicly accessible turbine layouts. While Ocean Wind 01 was terminated in October of 2023, we used the proposed turbine design to help inform piloting behavior if development in OCS-A 0498 does occur in the future. Publicly available shapefiles for offshore wind farms designated as WEA borders, proposed and operational turbine locations, and proposed and operational substation locations in the NYB were retrieved from https://marinecadastre-noaa.hub.arcgis.com/ and/or directly from developer.

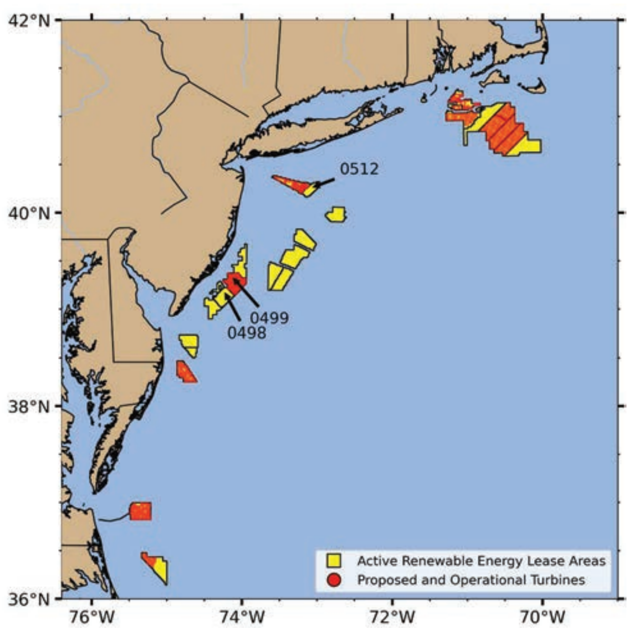

Fig. 1. Map of active renewable energy lease areas (yellow) with proposed and active turbine locations (red) in the Mid-Atlantic region. Arrows pointing areas in the NYB used in this analysis: OCS-A 0512, OCS-A 0499, and OCS-A 0498. Data retrieved from https://marinecadastre-noaa.hub.arcgis.com/.

The terminated Construction and Operations Plan (COP) for OCS-A 0498 spanned 75,525 acres with 98 turbines and 3 substations, featured monopile turbine and piled jacket substation foundation diameters of 11.3 meters and 4.5 meters, respectively, with a grid layout of 1 nautical mile by 0.8 nautical miles. Scour protection was likely rock placement, with a diameter of 55.8 meters [7] and possible 2-meter height [8]. The COP for OCS-A 0499 covers 102,124 acres with 200 turbines and 3 substations, featuring monopile turbine and piled jacket substation foundation diameters of 15 meters and 5 meters, respectively, with a grid layout of 1 nautical mile by 0.6 nautical miles. Scour protection is also likely rock placement, with diameters of 82 meters for monopile foundations and 30 meters for piled jackets – each having a 2-meter height [8]. The COP for OCS-A 0512 spans 79,350 acres and includes 147 turbines and 2 substations, with monopile turbine and piled jacket substation foundation diameters of 11 meters and 2.5 meters, respectively, with a grid layout of 1 nautical mile by 0.65 nautical miles [9]. Scour protection is likely rock placement, with a diameter of 63 meters [9] and possible 2-meter height [8].

On average, this area experiences generally weak southwestward alongshore flow, with current magnitudes typically ranging from 10 to 20 centimeters per second. During strong storms, velocities can exceed 50 centimeters per second. The surface flow in this region is influenced by topography, large-scale circulation, wind, fresh water input, and turbulent dissipation [10-11]. Seasonal variability is governed by the intensity of stratification and the prevailing meteorological conditions that either promote upwelling or downwelling [10]. The largest variability in surface currents was seen in the winter and fall with a standard deviation of 15.4 centimeter per second while summer showed the least variability with a standard deviation of 11.9 centimeter per second [11].

B. Gliders

One decade of historic glider tracks from 2013 to 2023, totaling 142 deployments, in the NYB were retrieved from https://slocum-data.marine.rutgers.edu/erddap/. Most of these deployments have taken place before knowledge of turbine's locations were acquired, and none were designed or piloted to avoid future turbine placement, thus the trajectories are mostly science and operations focused. That means this analysis quantified how many glider-turbine interactions would occur if we carried out without consideration of turbine and substation locations. Each glider track was interpolated to 4 second intervals, based on the assumption of a glider's approximate length of 2 meters and horizontal speed of 0.5 meters per second. This approach maintains high-resolution data (i.e., each point along the track was spaced the length of the glider), preventing any misinterpretation by the algorithm that the track skipped over turbine and substation locations. While the exact position of a glider underwater is not known, the best estimate of position was interpolated position between GPS fixes which take place before submerging and after surfacing. Furthermore, each track was clipped to capture only the part that traversed inside of the of the WEA and thus subject to monopile interactions.

C. Interaction Algorithm

The algorithm to identify interactions is a simple geometry union between the glider's location and circle with a varying radius. Buffer radii of 6, 8, 10, 26, 36 meters were selected as analysis points for an interaction and placed as a buffer around the turbine and substation locations. The initial buffer radius of 6 meters represents the turbine or substation foundation diameter and was chosen based on turbine sizes detailed in each WEA COP [7-9], which detailed foundations ranging from 11 to 15 meters in diameter. The 8- and 10-meter buffer radii account for extensions beyond the foundation such as ladders and anode cages, and potentially derelict debris (nets, line, etc.). The larger 26- and 36-meter buffer radii encompassed entanglement risk due to longer fishing debris and for knowledge on the glider's general proximity to underwater structures. We feel it was helpful to think of the buffer zone beyond turbine in terms of glider size or units. It is assumed a typical glider size is about 2 meters by length (and width) and thus in terms of glider units the interaction buffer zones beyond the foundation are 0, 1, 2, 10, 15 glider units. Furthermore, it is important to differentiate the risk associated with turbines and substations at depth and at surface. Interactions that occur at the surface may impose a higher risk due to intense environments where waves or currents would allow interactions at higher velocities and frequencies (Fig. 2; 1A and 2A). Communications and musings regarding underwater interactions and the velocities involved (10-30 centimeters per second) suggest that the glider should be able to resist damage in a simple interaction, but limited data is available (Fig. 2; 1B). It is unknown what additional interactions with fishing gear or other debris entangled on the foundations might do to a glider aside from entrapment. If a glider were to encounter a piled jacket foundation that could pose a greater risk of the glider getting stuck, causing external sensor appendage damage, or at worse a forced hull breach (Fig. 2; 2B). All these scenarios can potentially lead to vehicle or data loss.

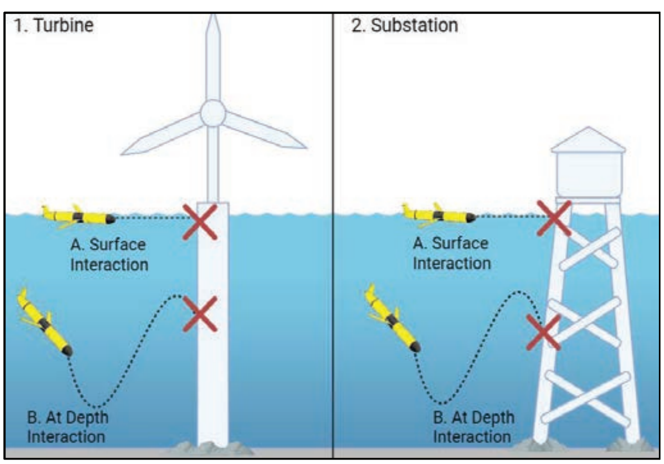

Fig. 2. Schematic of surface (1A) and at depth (1B) interactions with a monopile foundation and surface (2A) and at depth (2B) interactions with a piled jacket foundation.

The algorithm identified glider-turbine interactions defined as all points of intersection, where each glider track overlapped with the range of buffers around each turbine and substation location within the WEA. A glider track was defined as interpolated position between GPS positions. Knowledge of a glider's location underwater is uncertain so any method here results in unknown errors. As a result of the interpolation, consecutive points within the buffer zone separated by a time delta of 4 seconds were categorized as one interaction segment. If the time delta between points in the buffer zone was greater than 4 seconds, a second interaction segment was identified. This approach helped to distinguish multiple encounters with the same turbine, accounting for scenarios where the glider track intersected the turbine buffer zone at different times.

The output is a list of timestamps and locations of the turbines or substations that the track intersects. Each interaction segment was assumed to be a single interaction, and the results were broken down into turbine or substation interactions and if the interaction occurred at depth or at the surface.

Special consideration has been taken for interactions that occur when the glider is drifting at or near the surface. A coastal glider is typically underwater anywhere from 1 to 6 hours per segment with our average segment being about 2 hours. This duration is bookended by GPS positions at the dive and surfacing position and this duration is the amount of time a glider will be dead reckoning navigating underwater. Each underwater duration is also a single data segment or file stored by the glider which helped characterize a surfacing interval without the data burden of depth record. We extrapolated out the start and end times of a surfacing and apply a buffer each end of + 5 minutes to account for variances in surfacing and surfacing departure rates. Applying these surface drift bounds to the interaction output described above allowed for the identification of surface interactions within the buffer zones around turbine and substation locations.

We calculated several metrics for each WEA and buffer zone to analyze glider interactions. Total deployments were defined by each unique glider mission having any part of its track enter a WEA. Total interactions refer to the aggregate of all interaction types—such as at-depth turbines, at-depth substations, surface turbines, and surface substations—that occurred during each deployment within the WEAs. A subset of total interactions included total surface interactions, which specifically accounts for interactions occurring at the surface, and total substation interactions, which focuses on those involving substations. We also computed the average interactions per deployment by dividing the total number of interactions by the number of deployments. Total days in WEA represents the cumulative duration of data collection (or glider presence) within each WEA, calculated by cumulative summing of time spent within the WEA. Finally, days per interaction was derived by dividing the total days in the WEA by the total number of interactions (all types), providing the average time interval between interactions. This metric was also calculated specifically for surface interactions, including both turbines and substations.

III. Results

For all three WEAs, we analyzed buffer zones consisting of 0, 2, 4, 20 and 30 meters (i.e., circle radii of 6, 8, 10, 26, and 36 meters, respectively) (Table 1), which are distances beyond the standard footprint (e.g., 12-meter diameter for a monopile). Out of the 135 tracks in the NYB, lease areas OCS-A 0498, OCS-A 0499, and OCS-A 0512 contained 54, 75, and 8 glider tracks, totaling 123.61, 151.16, and 6.4 days inside the WEA,

TABLE I. SUMMARY METRICS FOR EACH WEA AND EACH BUFFER ZONE. VALUES IN PARENTHESES DENOTE VARIABLES AT THE SURFACE ONLY, THE VALUES OUTSIDE OF THE PARENTHESES ARE INCLUSIVE OF ALL INTERACTION TYPES.

WEA	Buffer Zone (m)	Total Deployments	Total Interactions(surface)	Total Substation Interactions	Average Interactions per Deployment (surface)	Total Days in WEA (surface)	Days per Interaction (surface)
0498	0	54	4 (1)	0	1 (1)	123.61 (37.3)	30.9 (123.61)
0498	2	54	7 (1)	2	1.4 (1)	123.61 (37.3)	17.66 (123.61)
0498	4	54	16 (2)	2	1.33 (1)	123.61 (37.3)	7.73 (61.81)
0498	20	54	37 (11)	2	1.54 (1.2)	123.61 (37.3)	3.34 (11.24)
0498	30	54	50 (11)	4	1.85 (1.1)	123.61 (37.3)	2.47 (11.24)
0499	0	75	14 (5)	0	1 (1)	151.16 (69.1)	10.8 (30.23)
0499	2	75	23 (6)	0	1.10 (1)	151.16 (69.1)	6.57 (25.19)
0499	4	75	26 (8)	0	1.18 (1)	151.16 (69.1)	5.81 (18.9)
0499	20	75	58 (14)	0	1.57 (1)	151.16 (69.1)	2.61 (10.8)
0499	30	75	93 (21)	2	1.94 (1.2)	151.16 (69.1)	1.62 (7.2)
0512	0	8	1 (0)	0	1 (0)	6.4 (2.8)	6.4 (inf)
0512	2	8	3 (0)	0	1 (0)	6.4 (2.8)	2.13 (inf)
0512	4	8	3 (0)	0	1 (0)	6.4 (2.8)	2.13 (inf)
0512	20	8	5 (1)	0	1 (1)	6.4 (2.8)	1.28 (2.8)
0512	30	8	6 (1)	0	1.2 (1)	6.4 (2.8)	1.07 (2.8)

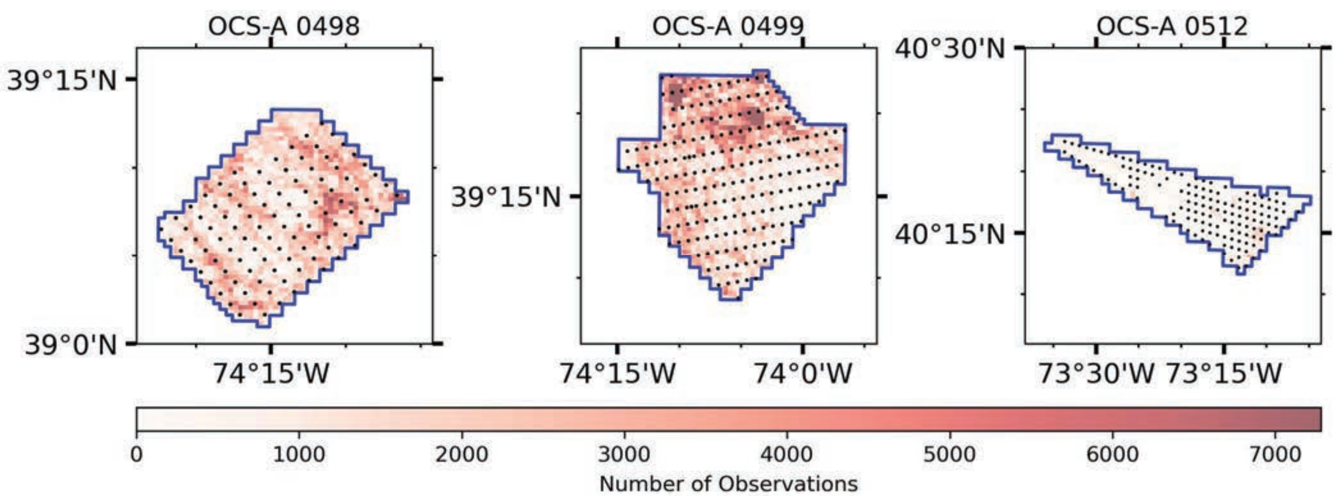

Fig. 3. Utilization of WEAs by historic glider missions using the interpolated tracks. The blue outline represents the area of each WEA, and the black dots represent proposed turbine and substation locations. The colormap represents the number of observations at each grid point.

respectively (Fig. 3). Historic tracks utilized southern WEAs (OCS-A 0498 and 0499) more than OCS-A 0512 due to avoidance of the shipping lanes surrounding the WEA. Both OCS-A 0489 and OCS-A 0499 had tracks available from 2013-2023, while OCS-A 0512 only had tracks available from 2019-2023. The larger number of tracks within OCS-A 0498 and

OCS-A 0499 produced a greater number of total interactions ranging, from a total of 4 to 50 and 14 to 93, respectively, compared to OCS-A 0512 which only had 1 to 6 total interactions as buffer zones increased in size. Across all areas, average interactions per deployment were 1.1 interactions per deployment with approximately 0.6 interactions per deployment at the surface (based on 8-meter radius).

The analysis showed that surface interactions were the minority out of the total interactions, indicating that most interactions occurred at depth, with only 37.3 (OCS-A 0498), 69.1 (OCS-A 0499), and 2.8 (OCS-A 0512) days spent at or near surface. For instance, in OCS-A 0498, out of 50 total interactions in the 30-meter buffer zone, only 11 were surface interactions, demonstrating a lower frequency of surface incidents. Additionally, substation interactions were less frequent than turbine interactions, only occurring in OCS-A 0498 and OCS-A 0499, and zero occurred at the surface. This pattern is consistent across the datasets and demonstrates that while surface and substations interactions do occur, they are relatively infrequent compared to interactions at depth with turbines.

Another metric to define rate of interaction would be days per interaction. A common measure of glider flight time is days deployed or days in mission. Total days was counted only when a glider was inside a WEA. It can be assumed that as days increase, so does hazard or risk [12]. Across all areas, the average days per interaction was about 9 days and 123 days for surface (based on 8 m radius). Days per interaction inversely varied with buffer zone size in all WEAs. Days per interaction, decreased with larger buffer sizes for all WEAs, meaning that the average time between interactions decreased. From buffer zone 0 to 30 meters, days per interaction decreased in OCS-A 0498, OCS-A 0499 and OCS-A 0512 from 30.9 to 2.47 days, 10.8 to 1.62 days, and 6.4 to 2.13 days, respectively. Days per interaction for surface interactions only followed the same trend, but with higher values, as surface interactions are a small subset of total interactions. These trends indicate that, as expected, larger buffer zones lead to more frequent interactions and fewer days between them.

IV. Discussion

Our analysis provides insights into the interaction risk faced by underwater gliders navigating near offshore wind turbines in the NYB region. The results indicate varying levels of interaction between gliders and turbine infrastructure across different WEAs and buffer zones. Buffer zones were determined based on glider length and turbine size. The determination of buffer radii considers the glider's length and the turbine's radius, ensuring that buffer zones reflect realistic interaction distances. The data reveal a clear trend of increased interaction frequency with larger buffer zones and days spent at sea. This can also be assumed in terms of risk for an interaction of a glider in a wind farm: the more time spent in the WEA the higher the chance of interaction. Shown here (Fig. 4) are the layout of turbines in WEA and whether there was a surface or at depth interaction. It is important to note that even if there are very few deployments that enter the WEA, interactions still may occur, as was seen for OCS-A 0512.

Research and monitoring missions are currently underway and being planned within WEAs prior to, during, and after turbine construction. Gliders included, it remains to be seen how underwater vehicles (gliders, propeller-AUV, etc.) and surface vehicles (sailing drones, etc.) will handle these interactions. We generally feel at typical ocean and glider velocities (10-30 centimeters per second, about 0.4 miles per hour) that an underwater interaction should be benign. The larger risk would be for entanglement with sub-structure or derelict marine debris such as fishing gear, ropes, or fouling. We consider a surface interaction to be of higher risk than whilst underwater due to wave action and in our experience of previous glider interactions with fixed sea structures at the surface. This increased surface risk should be considered by other AUVs that operate at or near the surface. Perhaps protection or shielding can be added to current vehicles to ensure science sensor and glider integrity as well as minimized entanglement risk in terms of an interaction.

Given the interaction risk outlined above, we aim to propose strategies for turbine avoidance. Several solutions or approaches are capable in the current software set, others are

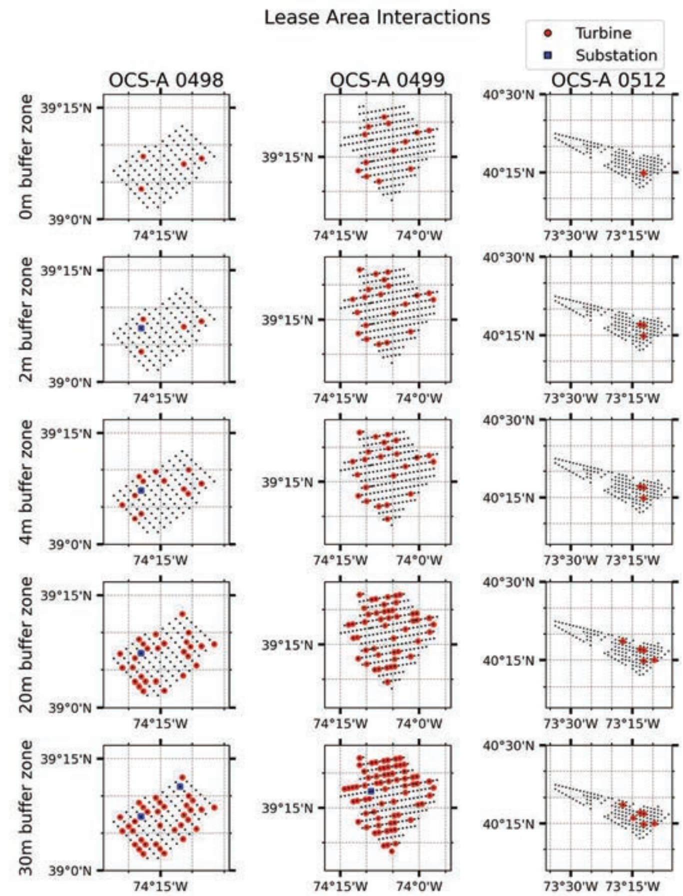

Fig. 4. Interactions with turbines (red) and substations (blue) on proposed turbine and substation location grids (black), which are spatially to scale.

more advanced and would require development. Two approaches that are capable now are: 1) navigate more accurately in between turbines (which would require shorter surfacing intervals and thus more surface hazard) or 2) navigate between turbines with less regard for accuracy in exchange of minimizing surface interaction risk. Additional considerations must be taken for different velocity environments. Areas with small tidal and mean currents may offer safer conditions for navigational accuracy (avoidance), whereas high current and tidal conditions may better be suited for surface avoidance (accepting underwater interaction risk). Variable environmental conditions could impose further risks associated with not only fixed infrastructure, but also mobile infrastructure such as vessel operations which could lead to vessel strikes [13]. Limiting surface time may lower risk of an interaction.

Solutions, including the aforementioned and beyond, will require more accurate dead reckoning capabilities. This often is determined by the ability of the glider to estimate, predict, and implement accurate knowledge of local current fields. Abilities such as tidal predictions or model forecasts could be combined with local knowledge of currents, as determined by the glider, to create a more accurate estimate of currents [14]. Fortunately, the Slocum glider control software has the capability to be piloted locally by an onboard computer utilizing backseat driver control [15]. This will allow rapid development of such current estimating algorithms as well as the initial implementation of such estimates applied over time underwater while the glider is dead reckoning. This will allow solutions that rely on perhaps a pre-programmed turbine field location list to have the glider more accurately determine if it is too close to a known location and to 'turn away' from it – avoiding an interaction.

To help evaluate these two approaches, additional analysis will be conducted to characterize physical forcings using high-frequency radar (HFR) surface currents observations (https://tds.marine.rutgers.edu/thredds/cool/codar/cat_totals.html) in each WEA, in conjunction with field testing mitigation strategies. This will assess the current dead reckoning capability in observed current conditions and help infer which conditions would allow for safe operation in WEAs. Efforts are being made to quantify if active avoidance piloting techniques reduce interaction rates.

Acknowledgment

From Rutgers University, we would like to thank John Kerfoot, Lori Garzio, and Laura Nazzaro for their data management and Joseph Gradone and Nicole Waite for providing glider expertise. We would like to thank Emily Shumchenia for supplying the turbine locations from the marine cadastre. We would like to thank Teledyne Webb Research for discussing glider-turbine interaction risk outcomes with us.

OCEANS 2024 - Halifax | 979-8-3315-4008-1/24/$31.00 ©2024 IEEE | DOI: 10.1109/OCEANS55160.2024.10754275

Abstract*— Marine Technology Society is developing a series of Ocean Technician Microcredentials to facilitate both traditional and alternate routes to the Blue Economy workforce. This Microcredential plan consists of skillset tiers for various oceanographic technologies, including autonomous underwater vehicles. Ocean gliders are autonomous underwater vehicles used for an array of science and research applications, such as climate change, tropical storm intensification and model data assimilation, water quality and ocean acidification, and fisheries management. Gliders allow for safe, affordable, and around-the-clock data collection and can be deployed inexpensively, for months at a time in a variety of ocean conditions. Rutgers University Center for Ocean Observing Leadership and the Marine Technology Society host a week-long hands-on workshop on underwater glider technologies each June. Participants are introduced to the Teledyne Webb Slocum glider through experiential learning opportunities including preparing, ballasting, deploying, and piloting the glider. The workshop maximizes the active learning for all participants, while also ensuring comprehension of the essential basics applicable to Slocum gliders and many other AUVs. The goal of the workshop is for participants to gain an introductory knowledge of and justification for underwater glider principles and their associated science applications that can be built upon in future experiences. This workshop's authentic, introductory approach to AUVs, specifically Slocum gliders, fundamentally aligns with MTS's ocean technician microcredential plan at the Foundational tier for a Glider Trainee, meant for core knowledge and experience relevant to the specific technologies. The seamless overlap between MTS's endeavor and RUCOOL's Glider Workshop benefits all participants by providing assessed certification of participant skill and knowledge that will accelerate employment in the New Blue Economy.

***Keywords*— gliders, autonomous observations, ocean observing systems, workforce development, blue economy**

I. Introduction

The National Oceanic and Atmospheric Administration (NOAA) released its Blue Economy Strategic Plan [1] in January 2021 to outline the advancement of America's Blue Economy followed by its New Blue Economy plan in 2022 [2]. The New Blue Economy is a knowledge-based, data-enhanced ocean economy. Skilled workers in multiple areas of the blue economy (e.g. research, infrastructure, fisheries, ports and shipping, national security, renewable energy, tourism, etc.) are needed globally. Engaging, innovative, agile and equitable educational opportunities are needed to prepare this workforce. Training opportunities should encompass a range of workers and experience levels and foster pathways for life-long learning. Stackable microcredentials and professional certificates provide the competency-focused training required and should promote self-development, adapt to technological changes, and maximize opportunities within the New Blue Economy [3].

To address this need, the Marine Technology Society (MTS) is developing a series of stackable microcredentials to create accessible and flexible pathways to learning and vocational training [3]. The microcredentials will address core competencies required for employment in the ocean/marine/blue economy and capture learners entering the workforce from high school; applying skill sets acquired during military service; recognition of skills acquired in a professional capacity; and as a vehicle for employment retraining. Microcredential competency is organized into foundational, intermediate, and advanced levels. The Marine Technology Society is organizing

979-8-3315-4008-1/24/$31.00 ©2024 IEEE

communities around the world to establish a marine technology microcredentialing framework and pilot foundational level content. Here we present activities at Rutgers University to offer students foundational level content and assessment for ocean gliders.

Ocean gliders are increasingly useful and important tools for studying the ocean environment. These autonomous underwater vehicles (AUVs) use buoyancy changes as the primary means of movement through the water column. This unique propulsion method allows several advantages described later. Several types of gliders are available for use by researchers. One type of ocean glider is the Slocum glider AUV, built by Teledyne Webb Research Corporation (North Falmouth, MA). The Slocum glider is an integrated instrument platform designed to operate in the coastal oceans up to 1000 m depth, often with no propeller. It is designed to adjust its volume via a ballast engine, allowing it to dive and climb in a triangle pattern. The result is a low cost, highly adaptable autonomous underwater vehicle with a very low power requirement [4]. While traversing the glide path, the vehicle slowly travels horizontally at about one kilometer per hour, with a fin steering the glider towards continuously adjustable waypoints.

AUVs allow for safe, affordable, and around-the-clock data collection in all conditions. AUVs can be deployed inexpensively for months at a time in a variety of ocean conditions: from coastal shallow waters (10 m) and open ocean environments to the center of a hurricane or ice-adjacent zones of Antarctica. Gliders are equipped with an increasing array of instrumentation to gather ocean conditions, including temperature, salinity, pH, oxygen, zooplankton biomass, marine mammal calls, wave heights, and current speeds. These remote vehicles are well poised for an array of science and research applications, such as climate change, tropical storm intensification and model data assimilation, water quality, ocean acidification, and fisheries management.

II. Rutgers Glider Workshop

A. Workshop Goals

Rutgers University Center for Ocean Observing Leadership (RUCOOL), sponsored by the MTS, hosts a hands-on workshop on underwater glider technologies for one week every June, with a focus on the Teledyne Webb Slocum glider. RUCOOL has hosted 15 glider 'training sessions' over the last 19 years, with six MTS sponsored 'glider workshops', beginning in 2017. The workshop is structured as an informal 'glider camp' with meals provided to allow and encourage interactions between instructors, students, scientists, and RUCOOL technical staff. MTS Workshops, in collaboration with Rutgers University, provides scholarships for students interested in attending this workshop.

The Rutgers-MTS Glider Technology Workshop is designed as an experiential learning opportunity that allows participants to learn about underwater gliders and interact directly with the equipment to gather data. Participants are introduced to the Teledyne Webb Slocum glider including communicating, preparing, ballasting, preparing, deploying, and piloting the AUV. The goal of the workshop is for participants to gain an introductory knowledge of and justification for underwater glider principles and their associated science applications that can be built upon in future experiences. The five-day workshop is structured around maximizing the active learning for all participants, while also ensuring comprehension of the essential basics applicable to Slocum gliders and many other AUVs.

B. Target Audience/Participants

The Rutgers-MTS Glider Technology Workshop is designed to be an introductory workshop for anyone interested in Slocum gliders. No prior work or knowledge with gliders is required. Prior knowledge of density, basic oceanography, and command-line operating systems is helpful though not required. The workshop is largely geared toward undergraduate and graduate students, however, has also had participants in early-career positions from organizations such as the NOAA, US Navy Naval Oceanographic Office, and other research institutions. International participants are also welcome.

C. Workshop Format and Agenda

The workshop is a combination of classroom lectures and demonstrations (Fig. 1a,b), hands-on sessions working with the gliders (Fig. 1c,d), and an 'on the water' day in Raritan Bay, NJ on the R/V Rutgers research vessel to deploy and recover a glider (Fig. 1e,f). Participants spend the week preparing a glider for deployment, deploying and recovering that glider, and analyzing at glider data. The context of the preparation is for operating the glider for a test flight in an estuarine environment. Basic goals are structured for each day so that the students have enough knowledge to operate safely and reference resources properly. Throughout the week, best practices for ocean technology and gliders are introduced and demonstrated. Worksheets are completed by participants at the end of each day to highlight key lessons.

The agenda (Table 1) begins on Monday with an overview of gliders, glider command and control, and an introduction to some scientific research applications of gliders at RUCOOL. Students learn the parts of a glider, basics of how a glider operates, how to communicate with a glider and where to locate information about glider sensors and settings. Beginning on Monday afternoon, students are hands-on in the lab (Fig. 1c) practicing issuing commands and glider communication and opening and closing gliders. The primary goal from day 1 is to be able to interact (communicate) with a glider safely and confidently as well as understand their purpose for ocean monitoring.

Day 2's sessions focus on glider ballasting techniques, glider hygiene, in-water practices, and practical rules for effective weight adjustment (Fig. 1d). Classroom lectures explain the basics of ocean density, density units, and glider ballasting theory (Fig. 1a). Heavy emphasis on density and glider operation round out Tuesday's lessons allowing the participants to fully understand how to ballast a glider reliably.

Final ballasting continues into Wednesday, while also emphasizing the software, hardware, and scientific sensor steps of the checkout procedure. An outdoor compass calibration involving suspending the glider and rotating in as many angles allowed in 3D space begins to show the importance of a properly navigating robot remotely deployed. Classroom sessions on Wednesday cover glider mission structure and defining control

Fig. 1. Glider workshop participants in classroom lectures and demonstrations (a,b), working hands on with the gliders (c,d), and deploying and piloting the gliders during the boat day of the workshop (e,f). Photo credit: b,c,d - Jacqueline Southby; a,e,f - RUCOOL.

TABLE I. AGENDA AND TOPICS TAUGHT IN THE RUTGERS-MTS GLIDER TECHNOLOGY WORKSHOP.

Day	Theme	Topics Covered
Monday	Glider Introduction Command and Control	• Parts of a glider and functions • How to communicate with a glider • General understanding of software behavior • MASTERDATA • How to open and close a glider
Tuesday	Ballasting and Hardware	• Ballasting theory (from grams to cc to kg/m3) • Ballasting rule of thumb • Open/Closing hygiene and practices • Glider checkouts
Wednesday	Ballasting Glider Checkouts Software Introduction	• Glider Checkouts • Compass tests and calibrations • Glider Mission operation • SFMC Operation
Thursday	Glider Deployment and Recovery – Boat Day	• Glider in water command and control • Glider deployment • Deployment analysis • Glider recovery
Friday	Piloting and Data	• Piloting practices and tools • Data QA/QC • Simulation

files which essentially define how a glider operates when deployed. Wednesday concludes with a glider that is prepared and checked-out for deployment. Some aspects of data analysis and collection are introduced at this point in preparation for actual in-water sensor and engineering acquisition.

Thursday relocates from lab to research vessel to highlight ship safety practices, pre-deployment procedures, followed with an actual glider deployment with analysis, and lastly recovering the glider. Participants practice deploying and recovering the glider with a couple of methods for small boat operations (Fig. 1e). Participants also pilot the glider (Fig. 1f), practicing safe in-ocean operations, issuing commands to run missions, and transfer data files to determine glider performance.

The workshop opens on Friday with a debrief of the in water tests as well as the preceding week's knowledge. Switching focus to deployed glider operations (piloting), an overview of piloting best practices, glider diagnostics, available piloting tools, and resources like a flight simulator are introduced (Fig. 1b). Special focus is given to Teledyne's Slocum Fleet Mission Control software and Google Earth with their GIS capabilities and navigational assistance imagery. The workshop concludes with an introduction of glider data publishing and Quality Assurance/Quality Control (QA/QC).

III. MICROCREDENTIALS

The Ocean Technician Microcredential framework being developed by MTS consists of skillset tiers for various oceanographic technologies (Table 2), including AUVs. Microcredentials are designed to be competency-based

TABLE II. EXAMPLES OF GLIDER MICROCREDENTIALS COMPETENCIES FOR A TRAINEE OR STUDENT FOR THE THREE COMPETENCY LEVELS IN THE TRAINEE SERIES: FOUNDATIONAL, INTERMEDIATE, ADVANCED.

Foundational (camp)	Intermediate	Advanced
Knowledge and Justification for:	***Guided Experience with:***	***Supervised Experience with:***
Hardware: opening/closing, o-ring etiquette, battery maintenance	Hardware: replacing/repairing connectors, replacing components, swapping assemblies	Hardware: integrating new instruments, calibrating actuators
Ballasting: density theory, density rule of thumb, ocean densities	Piloting: autoballast, low power operations, abort handling, shoreside handling scripts	Software: mission writing, control file maintenance, telemeter data control
Operations: boat safety, glider deployment protocols boatside	Operations: shore side deployment protocols	Piloting: hover missions, under ice, extreme currents

recognition for mastery in targeted knowledge and skills. Microcredentials are awarded as a digital badge, are modular, and can be stacked to gain more comprehensive certifications. Please see Hotaling et al., 2024 OCEANS paper for more details on the microcredential development [3].

The Foundational Microcredential for a glider trainee focuses on core knowledge and experience relevant to the specific technology. Requirements for this level include 30-40 training hours, technology fundamentals, beginning and introductory concepts, knowledge of uses and applications, and demonstration of basic knowledge of the technology [3]. The glider workshop's authentic, introductory approach to AUVs, specifically Slocum gliders, fundamentally aligns with the foundational microcredential level of the Glider Trainee series.

Participants completed an anonymous survey following the June 2024 Rutgers-MTS Glider Technology Workshop to provide feedback on the workshop structure and glider training received. Completion of the survey did not affect participants' ability to earn microcredentials. Survey results indicate that this glider workshop effectively introduces the Slocum glider, providing participants the foundational knowledge and experience required by the microcredential program and the competency for future work and training with gliders. In their own words, participants described the workshop and their experience as:

> *"I appreciated the time and care that the workshop developers put into building this camp. The camp began at a comfortable level for both inexperienced and experienced participants. The pace and schedule at which the instructions/lessons were given were ideal and holistic, without being over complicated and mundane. The camp developers grouped individuals by experience level to provide more in-depth instruction for the attendees' specific needs, which allowed for more one-on-one examples and discussions. The boat day was appreciated as it*

allowed the students to translate what had been taught and discussed in class into real world applications/scenarios."

"This was an amazing experience and despite me not knowing anything about these machines the speed and detail was fantastic and very insightful."

"They were thorough, professional, not too dry (but not too casual), provided excellent Q&A opportunities with real-world applications towards my specific glider missions.… I think the resources that were provided are going to be INCREDIBLY useful to my personal research and will be the basis for all future deployments and laboratory configurations."

Prior glider experience varied among participants, with 40% having little to no prior experience, 20% having some experience, and 40% having a good amount of experience. Regardless of prior experience, 80-90% of participants felt confident or very confident in their ability to explain the core topics covered in the workshop (Table 3). Additionally, all participants reported feeling prepared (50%) or very prepared (50%) to intern working with gliders. Participants further reported the workshop structure, including hands-on experiential learning, demonstrations, and classroom lectures, as helpful or very helpful to their training and ability to serve as an intern (Table 4).

TABLE III. SURVEY RESULTS FROM PARTICIPANTS IN THE JUNE 2024 RUTGERS-MTS GLIDER TECHNOLOGY WORKSHOP ON THEIR ABILITIES TO EXPLAIN THE CORE TOPICS COVERED.

After completing this workshop, how confident are you in your ability to EXPLAIN the following?						
Learning Objectives	***Mean rating***	***Very***	***Confident***	***Some-what***	***A little***	***Not at all***
How to open and close a glider safely	4.5	60%	30%	10%	0%	0%
How to deploy a glider and recover it safely	4.5	60%	30%	10%	0%	0%
How to communicate and interact with gliders	4.0	20%	60%	20%	0%	0%
How density and ballasting works	3.9	20%	60%	10%	10%	0%

The seamless overlap between MTS's endeavor and RUCOOL's Glider Workshop benefits all participants by providing assessed certification of participant skill and knowledge that will accelerate employment in the Blue Economy. At the completion of the Glider Workshop, participants can apply for a Foundational Tier microcredential in the Glider Trainee series. The first microcredential certificates for this level were issued to participants in June 2024. As Rutgers University is a partner school in the MTS microcredentials program, Rutgers instructors supply MTS with a list of learners who successfully demonstrated the competencies needed to earn microcredentials. MTS directly issues microcredentials to the learners for use on their resumes and social media channels to represent their new skill sets.

TABLE IV. SURVEY RESULTS FROM PARTICIPANTS IN THE JUNE 2024 RUTGERS-MTS GLIDER TECHNOLOGY WORKSHOP ON HOW HELPFUL THE WORKSHOP FORMAT AND ACTIVITIES WERE TO THEM.

How helpful were the following activities in preparing you to intern on a team deploying gliders?						
Instructional strategies	***Mean rating***	***Very***	***Helpful***	***Some-what***	***A little***	***Not at all***
Guided practice in operating the technology	4.9	90%	10%	0%	0%	0%
Working in small teams	4.9	90%	10%	0%	0%	0%
Overview of the technology and its applications (lecture)	4.8	80%	20%	0%	0%	0%
How the technology works and how to operate it (lecture)	4.8	80%	20%	0%	0%	0%
How to operate the technology (demonstration)	4.8	80%	20%	0%	0%	0%
How to interpret data (demonstration)	4.7	70%	30%	0%	0%	0%

ACKNOWLEDGMENT

MTS microcredential development is funded by National Science Foundation grant number NSF OCE-2308556. The authors thank the faculty and staff of RUCOOL and Captain Chip Haldeman that assist in organizing and running the Rutgers-MTS Glider Technology Workshop. We further acknowledge and thank the glider workshop attendees for their participation and providing valuable feedback on the workshop.

ABSTRACT

Polar systems are experiencing major changes that has significant implications for ocean circulation and global biogeochemistry. While these changes are accelerating, access to polar systems is decreasing as ships and logistical capabilities are declining. Autonomous underwater buoyancy gliders have proven to be robust technologies that are capable of filling sampling gaps. Gliders have also provided a more sustained presence in polar seas than ships are able. Along the West Antarctic Peninsula, one of the most rapidly warming regions on this planet, gliders have proven to be a useful tool being used by the international community to link land research stations without requiring major research vessel ship support. The gliders are capable of adaptive sampling of subsurface features not visible from satellites, sustained sampling to characterize seasonal dynamics, and they increasingly play a central role in the management of natural resources. Future challenges to expand their utility include: (A) developing robust navigation under ice, which would allow gliders to provide a sustained bridge between the research stations when ship support is declining, and (B) expanding online resources to provide the international community open access to quality data in near real time. These advances will accelerate the use of gliders to fill critical sampling gaps for these remote ocean environments.
Keywords: gliders, polar, ocean observing, climate

History

Polar oceans are remote, harsh, and unique environments characterized by extreme winds and large ocean-atmosphere heat fluxes, seasonal variability in sea ice extent, infestation by icebergs, and a limited ship presence. Polar marine ecosystems are regions of high seasonal biological productivity supporting unique organisms adapted to extreme conditions, and are driven by local, regional, and remote physical forcing. Over the past 200 years, these ecosystems have provided society with food, fuel, and fiber (Ainley & Pauly, 2013; Chapin III et al., 2005) and play a disproportionately large role, relative to their size, in global biogeochemical cycles (Gruber et al., 2019; Hauck et al., 2015; Moore et al., 2018). For example, the Southern Ocean alone is responsible for 40% of the annual global ocean uptake of anthropogenic CO_2 from the atmosphere (Gruber et al., 2019). These unique systems are regulated by complex interactions between the ice, atmospheric, and oceanic forcing that are difficult to sample using traditional sampling approaches given the limited number of ships in these remote locations.

The limited data collected in polar oceans is problematic as they are among the most rapidly changing on Earth, with changes to temperatures (Meredith et al., 2019; Schmidtko et al., 2014), eddy energy (Hogg et al., 2015), and biological systems (Brown & Arrigo, 2012; Morley et al., 2020; Schofield et al., 2010). These systems are sentinels of climate and ecosystem change, with charismatic species (penguins, polar bears, etc.) serving as public symbols of global change. Therefore, developing a coherent sampling strategy is critical to documenting changes in polar ocean systems and the regional to global consequences of those changes. While satellites have long proven to be an effective tool for documenting surface dynamics of polar systems (Arrigo et al., 2017, 2015; Crawford et al., 2020), these regions are often cloudy (Wang & Key, 2005; Wood, 2012), which often requires data averaging over weeks to months to provide full images. Moorings can provide high-resolution time series of great value (Brearley et al., 2017; Dickson, 2006; Martinson & McKee, 2012; McKee & Martinson, 2020; Mikhalevsky et al., 2015; Yang et al., 2021) and are important in the collection of physical, chemical, and biological data. However, moorings do not provide spatial data, and systems with near-surface measurements can be damaged by the passage of icebergs or the presence of heavy sea ice.

By the late 1990s, underwater autonomous gliders transitioned from a concept first imagined by Stommel (1989) to being a robust tool for conducting oceanographic research (Davis et al., 2002; Schofield et al., 2007), filling data gaps in subject areas ranging from boundary current dynamics to ocean-atmosphere interactions during storms to ecological dynamics in coastal shelves (Rudnick, 2016). In northern high latitudes, gliders have quantified the hydrography and circulation between the Nordic and Atlantic Ocean waters (Beaird et al., 2013; Fraser et al., 2018; Hoydalsvik et al., 2013; Ullgren et al., 2014). Additionally, sustained sampling with repeat surveys helped quantify fluxes through the Davis Strait (Curry et al., 2014) and is being integrated into marine mammal research (Aniceto et al., 2020; Baumgartner et al., 2020). In the Arctic, gliders have also been operated as a central part of a sea ice ocean observing network (Lee & Thomson, 2017; Lee et al., 2019). Using gliders to sustain sampling has been a focus in the Southern Ocean as well (e.g., du Plessis et al., 2019; Nicholson et al., 2022), and this article will highlight the range of applications that gliders have addressed specifically along the West Antarctic Peninsula (WAP) by the international community.

Glider Technology and Capabilities

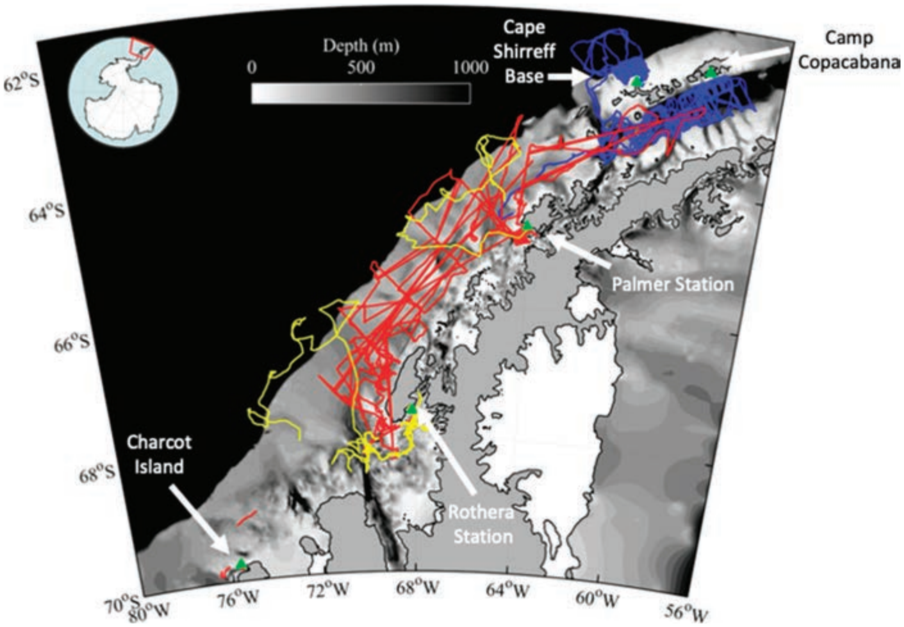
Gliders are 1- to 2-m-long autonomous underwater vehicles (AUVs) that maneuver vertically through the water column at a forward speed of 20–30 cm/s (Davis et al., 2002). The vertical motion of the platform is regulated by changing the buoyancy of the platform, and wings translate the forward motion providing the ability to sample the full water column ranging from 15- to 1500-m depths. The primary navigation system is an on-board GPS/iridium receiver coupled with an attitude sensor, depth sensor, and altimeter to provide dead-reckoned navigation, with backup positioning and communications provided by an Argos transmitter. Given this, communication is only possible when the vehicle is at surface. The mission duration of a glider is limited by battery life and is largely a function of the number of sensors and the water depth. The largest power drain in the glider involves the operation of the buoyancy pump, and, therefore, the battery life is shortest in shallow seas. Several of the gliders are modular, allowing sensor packages to be customized depending on the specific science mission. The glider duration is variable and largely a function of the number and type of sensors being carried. For gliders that have low sensor payloads Conductivity-Temperature-Depth (CTD) sensor, they have conducted missions for over a year; however, it should be noted that overall battery lifetime is dependent on the water temperature. Customized lithium batteries can extend the duration of the mission. The recent development of rechargeable lithium batteries offers the potential for rapid redeployment of systems not requiring significant ballasting efforts; however, currently, these systems have a shorter battery life.

Spatial/Temporal Coverage Provided By Gliders in the WAP

Gliders have become a critical tool for sampling polar systems. Along the WAP over the last 15 years, gliders have maintained a sustained presence in the field (Figure 1). These platforms have been used to study a variety of processes (see below) when ships are unavailable or when the region of interest is out of the safety limits of small boats launched from shore stations. To date, gliders have conducted over 75 missions over 1000 days at sea and spanning > 20,000 kilometers of the WAP (Figure 2). Given their semi-Lagrangian sampling capabilities, these platforms are filling critical data gaps spanning mesoscale circulation, biological dynamics, and storm-ocean interactions (cf. Rudnick, 2016). Shore-based field stations are maintained by the international community along the WAP with ocean sampling conducted from small vessels (Figure 1). These smaller vessels have limited spatial coverage (measured in tens of kilometers) in large part for safety considerations because weather in the WAP is subject to rapid change and it is not rare for wind intensity to increase by an order of magnitude on time scales of less than an hour. Gliders have provided a unique tool

FIGURE 1

Deployments of gliders along the West Antarctic Peninsula. Yellow lines indicate glider missions from the British Antarctic Survey, red lines indicate the surveys of Rutgers University, and blue lines indicate the missions from the National Oceanic and Atmospheric Administration. The green symbols indicate gliders' locations anchored by land-based stations or ships.



to maintain a sustained spatial presence in the coastal regions surrounding these shore stations.

The Palmer Long Term Ecological Research (LTER) program is focused on how long-term change associated with climate will ripple through the food webs. Figure 2 shows the multi-year presence of gliders deployed from the United States Palmer Station collected as part of the National Science Foundation LTER program. Sampling at Palmer Station is focused on understanding how biophysical interactions influenced by an irregular seafloor topography (especially associated with the Palmer Deep sea floor canyon, Figure 2A) support a biological hotspot with high primary productivity and abundant higher trophic levels (whales, seals, penguins). The sustained sampling in this region (Figure 2B), despite strong local currents (Oliver et al., 2013), is possible given the ability of the glider to remain for long periods in location. The glider presence is allowing for the first time the construction of a summer season climatology of phytoplankton biomass showing an initial summer phytoplankton bloom and then a secondary bloom in the late summer months (Figure 2C).

Further south along the peninsula at the UK Research station of Rothera (Figure 1), small boat-based year-round CTD and biological observations have occurred since 1998 as part of the Rothera time series (RaTS) (Venables et al., 2023). While these measurements take place within a deep coastal embayment (520 m), knowledge initially remained limited around the physical and biological connectivity of the coastal station with the wider WAP shelf, in particular its relationship with the deep Marguerite Trough (up to 1400 m) that provides a pathway between the open Southern Ocean and the inner shelf up to George VI ice shelf. Since 2012, gliders have formed an important part of the RaTS sampling, providing a clearer understanding of this connectivity and its implications for both ocean circulation and near-surface productivity (Venables et al., 2017).

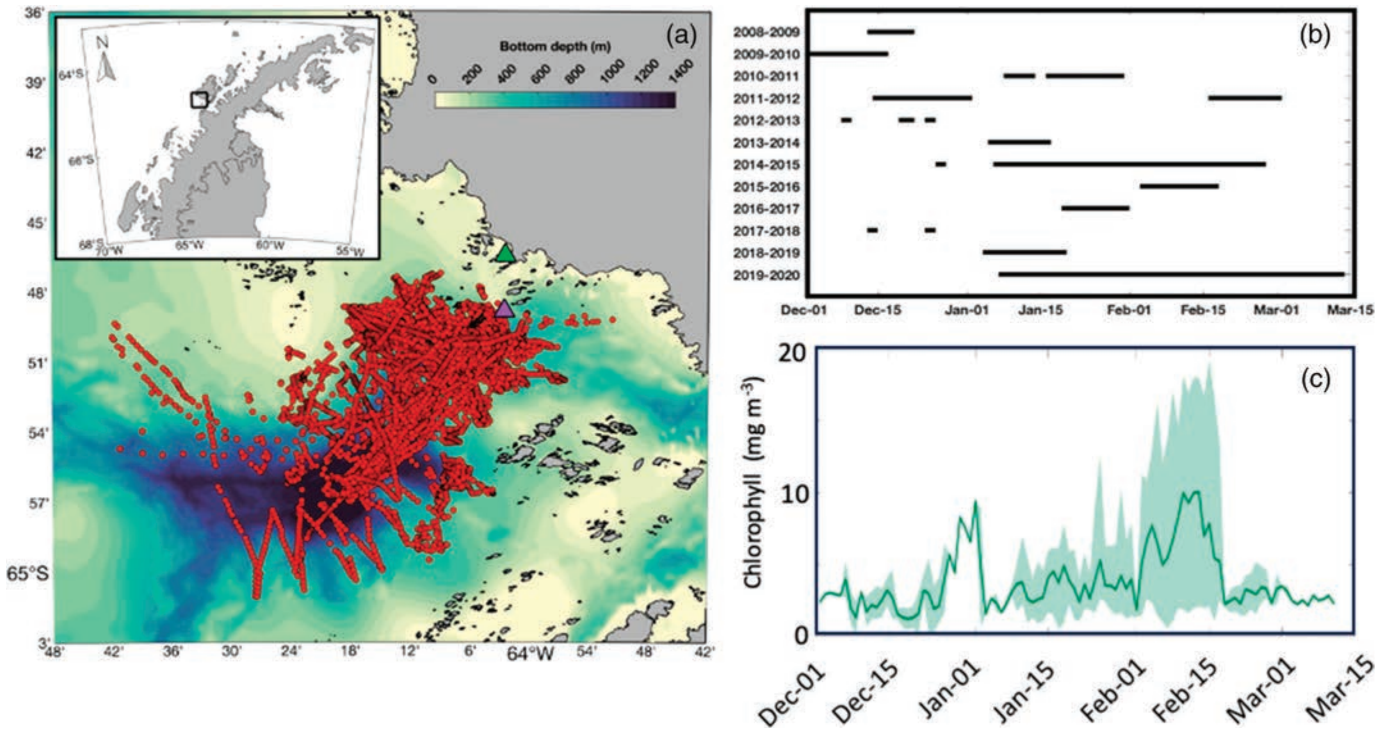
While ship-based sampling is a critical tool for mapping regional biological patterns, efforts chronically under sample of the system, reflecting the relatively low availability of research vessels for these remote locations. One strategy to overcome these limitations is to combine gliders from the numerous field stations spanning the WAP. This offers the unique opportunity for developing an international robotic network. The strategy is based on flying gliders between the shore-based field stations where they can be recovered, rebatteried, and redeployed to then fly back to the original field station. This provides a means to map broad swaths of the WAP continental shelf without significant ship support for sustained periods of time. The potential of this approach was demonstrated when a glider was launched from the United States Palmer Station and flown to and recovered by the United Kingdom Rothera research base (Figure 3). Given that the number of available research vessels is decreasing with the United States moving from a two research vessel operation to a single research operation, this strategy will provide an opportunity to maintain a sustained presence in a remote region.

Adaptive Sampling of Mobile Subsurface Features

The WAP is one of the fastest winter warming locations on the

FIGURE 2

Glider coverage at Palmer Station. (A) Spatial sampling at Anvers Island located over the Palmer Deep sea floor canyon, which is critical for penguin ecology (Schofield et al., 2013). The triangles indicate the long-term time series locations collected using traditional zodiac water sampling. (B) The temporal glider coverage of 12 years at Anvers island. (C) The fluorescence-derived chlorophyll climatology for the region (black line) with the green shading representing the maximum and minimum around the mean.

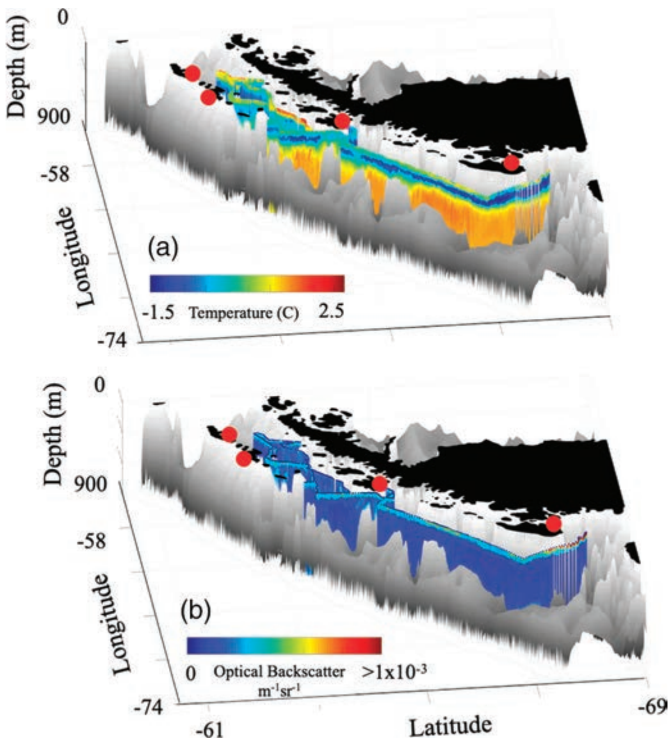


planet with the majority of glaciers in full retreat (Cook et al., 2005) and the annual sea ice exhibiting decadal declines (Stammerjohn et al., 2008). One dramatic example of this was that Rothera had no period of fast ice in the winter of 2022, which is the first time since recording started in the mid-1990s. These changes have been linked to a warming atmosphere and ice melting from below with the heat associated with onshore transport of offshore water (Cook et al., 2016; Couto et al., 2017; McKee et al., 2019; Pritchard et al., 2012; Rignot & Jacobs, 2002). The Upper Circumpolar Deep Water (UCDW) is the largest source of heat to the WAP continental shelf (Hofmann et al., 1996). While upwelling has been suggested as the potential delivery mechanism of UCDW (Dinniman et al., 2011; Martinson et al., 2008), higher resolution data (Martinson & McKee, 2012; Moffat et al., 2009) and models (Graham et al., 2016) suggest the delivery is associated with coherent eddies that move onto shelf and dissipate heat as they move onshore. These subsurface eddies are small with diameters of 10–15 km, cannot be detected by satellite, and move across the shelf, making them difficult to resolve using traditional oceanographic sampling approaches.

Gliders have proven unique tools for studying these dynamic subsurface features. Warm-core, subpycnocline, primarily anticyclonic eddy-like features have been observed and modeled several tens of kilometers from the shelf break, particularly in the vicinity of Marguerite Trough (Brearley et al., 2019; Couto et al., 2017; Graham et al., 2016; McKee et al. 2019; St-Laurent et al., 2013). Glider surveys were designed to sample these dynamic features by first documenting gradients along the axis of advection for any eddies encountered along the way, and then identifying and tracking an eddy in real time through data-adaptive sampling using the warm modified UCDW temperature as a hydrographic fingerprint. This allowed, for the first time, high-spatial and temporal resolution transects directly through some of these eddies and a real-time quantification of the attenuation of their core properties. The transects revealed a composite vertical structure, lateral size, and rotation consistent with theoretical instabilities. To quantify attenuation, a glider occupied a "fence" perpendicular to the

FIGURE 3

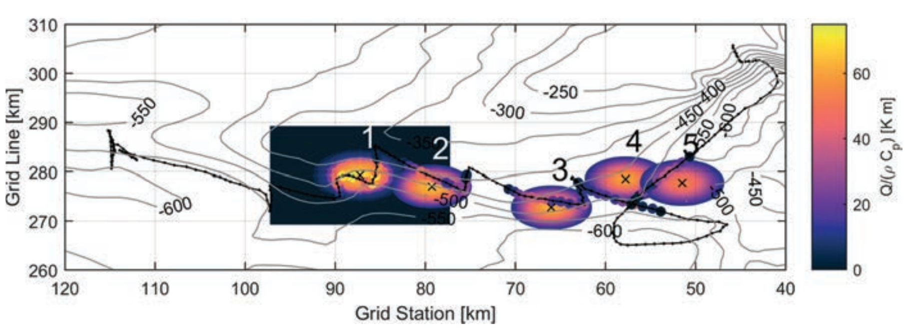
Gilder survey of the West Antarctic Peninsula. Panel A shows temperature with the characteristic winter water structure. Panel B shows the optical backscatter with particles largely found in the surface layer. Red circles indicate the land-based field station. The glider was launched from Palmer Station and was remotely piloted to the British Rothera Base in the south.



eastern wall of Marguerite Trough (Figure 4) and, when it encountered a feature with the warm signature of the UCDW, the glider sampled the water until the hydrographic feature was no longer detected. The glider was then directed to fly shoreward in the trough to move ahead of the eddy and resample it again. This adaptive sampling strategy was able to look at the heat loss of these eddies for almost 4 days, finding the rate agreed well with that of a simple diffusion model initialized with the eddy's initial structure and governed by diffusivity coefficients parameterized from historical density and velocity data (McKee et al., 2019, Figure 4). The results suggest eddies lose heat both laterally and vertically downward, which preserves the subsurface heat capable of melting marine-terminating glaciers (McKee et al., 2019). Closer to those marine-terminating glaciers, Scott et al. (2021) have used a microstructure instrument on a glider to quantify directly the turbulent diffusivity and vertical heat fluxes out of the CDW layer. While these heat fluxes were low (~1.3 Wm^{-2}), significant enhancement was observed during strong wind events and over a shallow sill linking Ryder Bay (where RaTS is based) with Marguerite Bay.

FIGURE 4

Glider-adaptive sampling of Marguerite Trough. The black line indicates glider trajectory, and dots indicate profile locations, with larger dots indicating presence of modified circumpolar deep water and their color indicating integrated heat content. Color contours indicate vertically integrated heat content from a numerical diffusion model initialized with the eddy's initial condition (box shows domain size), with eddy location at each time step (1–5) determined by grid search algorithm as the location that minimized mismatch between glider sampling of the real and modeled fields. The inferred trajectory (along-isobath) and speed are consistent with regional currents.

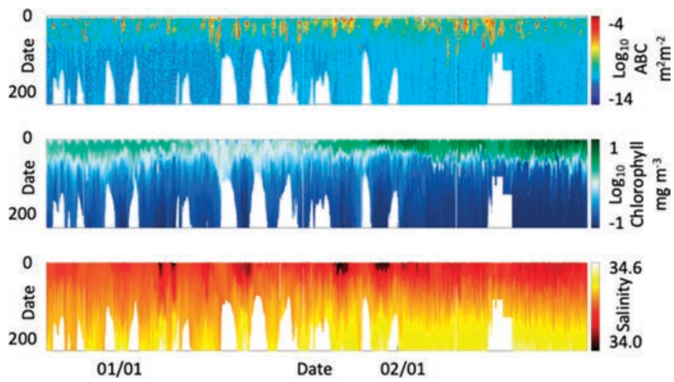


Providing Ecosystem Data to Support Management Requirements

Polar systems are very productive with rich biological resources that have provided great value to society and will continue to do so (Ainley & Pauly, 2013). Managing these resources is difficult given the extreme locations, and many of the key fishing regions are in remote international waters. Management practices are critically important given the historical evidence that humans can overexploit the natural resources. Antarctic krill (*Euphausia superba*) is the principal meso-zooplankton and is critical to Southern Ocean ecology, and it is the target of a large commercial fishery

FIGURE 5

Contour plot of (A) $\log_{10}$ acoustic backscatter coefficient (ABC $m^2\ m^{-2}$), (B) $\log_{10}$ chlorophyll-a fluorescence (mg m^{-3}), and (C) salinity during typical seasonal (mid-December through mid-February) glider deployments off Cape Shirreff Livingston island, Antarctica. Krill aggregations are visible in the upper 100 m of the water column in Panel A, with few large aggregations observed at depth. Glider-based echosounders provide opportunity to examine fine-scale water column relationships between krill, primary production, and the physical environment throughout the water column over deployments spanning multiple months.



(Nicol & Endo, 1997). This fishery is expanding given the growing demand for krill to supply the increasing demand by fish aquaculture and krill oil/nutraceutical industries (Meyer & Kawaguchi, 2022). This is increasingly important as many regions of krill fishing are exhibiting significant change that includes warming temperatures, declining sea ice, and retreating glaciers (Schofield et al., 2010).

Biological resources in the Southern Ocean, including Antarctic krill, are managed using ecosystem-based approaches, through the Convention for the Conservation of Antarctic Marine Living Resources. For krill, this effort has been historically anchored by ship-based surveys combining net tows with acoustic surveys conducted by research or fishing vessels (Fielding et al., 2014; Hewitt & Demer, 2000; Krafft et al., 2021; Reiss et al., 2008). Globally, the costs for traditional fisheries independent surveys have become prohibitive and there have been efforts to conduct resource surveys autonomously (De Robertis et al., 2021; Reiss et al., 2021). The adaptation of both single frequency (Ainley et al., 2015; Guihen et al., 2014, 2022) and multi-frequency (Chave et al., 2018; Taylor & Lembke, 2017), single-beam or wideband (Benoit-Bird et al., 2018) echosounders onto gliders provides new opportunities to acoustically estimate the biomass of meso-zooplankton, specifically Antarctic krill (Reiss et al., 2021) across time and space scales required to manage resources and to link trophic scales from primary production through secondary production.

Modeling studies have demonstrated that gliders sampling with their sawtooth pattern can effectively recover the time series of biomass density of krill (Kinzey et al., 2022; Figure 5), though some observational evidence exists of avoidance behavior by krill to AUVs, which needs due consideration when designing sampling campaigns (Guihen et al., 2022). Ten years of ship-based acoustic survey data collected in the Antarctic were resampled by flying a virtual glider through the data and then calculating the mean biomass density for each of the ship surveys. A single glider diving to 150 m and acoustically sampling a further 100-m range recovered the temporal pattern of krill biomass density observed in ship-based surveys, and these estimates fell within 1 *SD* of the ship-based estimates nearly 100% of the time. Increasing the number of gliders decreased the variability, while increasing the glider dive depth increased the variability as fewer profiles through the krill swarms in the surface layer are conducted. The results of these simulations provide a roadmap for developing more robust sampling strategies that can be used to provide input in resource assessments.

The use of scientific echosounders to conduct ecosystem or resource surveys requires identification of acoustic targets in order to allocate acoustic energy to targets of interest and to convert acoustic energy to biomass density using appropriate target strength models. Gliders, with the capacity to sample the pelagic ecosystem autonomously for months at a time (Figure 6), are unlikely to always sample with information about the size and composition of planktonic targets. Using multi-frequency or broadband echosounders allows differencing models to be used to discern targets of interest from other acoustic scatters, where the difference in the return strength from different acoustic frequencies are used to provide information about the likely targets (Kang et al., 2002). However, as battery life increases, the addition of optical systems to verify the acoustic targets should become integral to the use of gliders in remote locations, like polar environments where

FIGURE 6

other ecosystem surveys are less likely to be performed.

Challenges and Steps Moving Forward

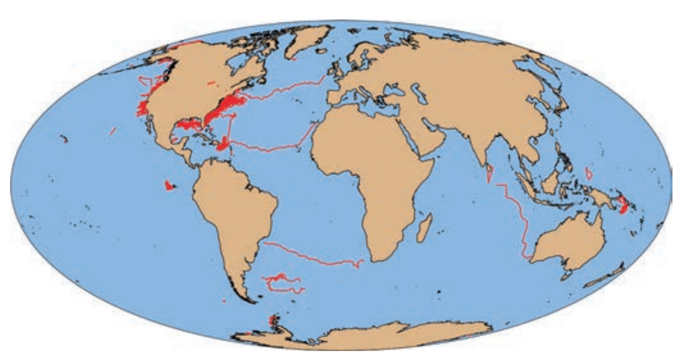
Under-ice navigation. Many changes in polar systems are associated with critical processes occurring under sea ice and ice sheets. As these ice-covered regions represent ~12% of the world's ocean, it is imperative to sample them for improved understanding of physical circulation, ecosystem structure, vertical mixing, and changes associated with long term anthropogenic change. Unfortunately, these are among the most difficult regions in the ocean to sample. Under-ice navigation has been achieved using fully capable AUVs (see Barker et al., 2020; Norgren et al., 2014) with strategies using acoustics from low-frequency sound sources, or multiple sound sources, and/or a surface vessel directing the robots. These approaches unfortunately are difficult for gliders given their long missions (hundreds of kilometers, multiple month missions), that the platforms undulate and the doppler navigation logs are not gimbled, and that ice complicates the use of surface vehicles.

There are generally two strategies for under-ice navigation by autonomous vehicles. One strategy is based on internal navigation sensors (inertial navigation, doppler velocity log) that estimate the location of the vehicle by tracking the velocity and accelerations. Navigation accuracy over time degrades as long under-ice missions can experience significant navigational drift associated with inertial sensors. Additionally, the types of navigational aids are limited on gliders due to constrained energy budget associated with gliders. The second strategy is based on external signals that often use sonar imaging or acoustic positioning to determine the vehicle position relative to geographic features (Claus & Bachmayer, 2015; Webster et al., 2015). This is a difficult problem given the relatively poor sea floor maps for most polar regions, the relatively low contrast features of ice compared to terrestrial systems, and because features, such as sea ice/icebergs, move (Bandara et al., 2016). Despite these challenges, ice-tethered acoustic navigation beacons have been able to coordinate under-ice missions of Seagliders for up to 12 days (Webster et al., 2015). A high priority and continuing efforts will expand these capabilities. Strategies include the potential use of fixed location beacon "runways" leading to land-based field stations for recovery. This could involve the placement of bottom, or ice, mounted navigation beacons, allowing the glider to track into location. This strategy will benefit from improved onboard processing and adaptive control of the systems (Duguid & Camilli, 2021).

Community cyberinfrastructure. The accelerating use of gliders has fueled the need to develop international open access data systems, allowing the wider community to utilize

FIGURE 7

The glider deployments that are currently available in the NOAA Glider DAC.



the data. This model of open access has been a hallmark and critical to the global success of the Array fir Real-Time Geostrophic Observatory (ARGO) network. The development of these systems is rapidly evolving. In the United States, the Glider Data Assembly Center (DAC) began development in 2013 and has been maturing over time driven by investments from the Integrated Ocean Observing System. Initial implementation of the DAC focused on physical data for submission to Global Telecommunication System, but in 2017, it began to accept submission of full deployments. Currently data flows to the National Centers of Environmental Information for permanent archiving. The system is also expanding the range of the data types available through the DAC. Use of the Quality Assurance/Quality Control of Real-Time Oceanographic Data protocols is a requirement for inserting data into the DAC. The system is open to anyone willing to provide the correct formats and required metadata. Currently, the DAC has 1,539 total data sets (1,059 real-time and 480 delayed mode data sets) (Figure 7). While the number of data sets is growing, it represents just a subset of the available glider deployments, and future efforts should collate and provide the full data sets as it is possible. A second major data system is the European Gliders for Research Ocean Observation and Management (GROOM). This system is designed to provide a multi-faceted cyberinfrastructure system designed to serve a wider range of autonomous systems and capabilities including system control and optimized links to operational numerical models. It is being developed to provide an integrated system supporting operations-maintenance, data sharing and harmonization, and piloting infrastructure. As systems such as the DAC and GROOM mature, a major challenge will be to ensure wide community adoption to provide a few centralized portals that leverage engineering, methods, and scientific analysis by the distributed community.

In conclusion, gliders are and will increasingly become an indispensable tool for studying polar systems. Given the rapid and accelerating changes in these regions, gliders will be a central tool to filling data and informational gaps. This comes at a critical time as polar systems are exhibiting accelerating change. These changes include hemispheric declines in sea ice (Eayrs et al., 2021) as was evidenced by the 6.4-sigma event in sea ice decline observed in 2023 (Cassella, 2023). The ramifications of these changes on the ocean biogeochemistry and ecology remain an open questions. Gliders will be a critical tool to addressing these important questions. Additionally, the open access data developments will provide a means to engage the wider science community in science discoveries as access to these remote locations is likely to decline in the near term with the declines in the available ship time.

Acknowledgments

These efforts have been supported by a range of programs. The Palmer LTER program (PLR-1440435). Since 2017, the RaTS has been supported by Natural Environment Research Council (NEFRC) award "National Capability – Polar Expertise Supporting UK Research" (NE/R016038/1) and supplemented by Brearley's NERC Independent Research Fellowship (NE/L011166/1). Darren McKee was supported by National Science Foundation Grant PLR-2026045.

***Abstract*—The Slocum glider's long-duration and cost-effective data collection capability, coupled with remote operation from shore, makes them ideal platforms for oceanographic research. However, once submerged in standard operation, instrument operation, waypoints, behaviors, and more are fixed until the vehicle surfaces. This lack of underwater adaptive control can lead to limitations in scientific sampling, limiting the glider's ability to meet the mission's scientific goals. In this work, we present a manual for implementing the Slocum Backseat Driver (BSD) architecture on a G3S Slocum glider. It contains examples for configuring an external controller (a Raspberry Pi 4 Model B), managing file transfers, incorporating real-time sensor data for decision-making, and advancing the ocean simulation capability of a glider simulator using a Slocum Fleet Mission Control (SFMC) script. Four simulations were ran, two utilizing the Slocum BSD architecture to autonomously navigate with a heading orthogonal from the Depth-Averaged Current (DAC) value calculated by the glider. The missions utilizing the BSD architecture updated the heading less frequently and did so with a more optimal average heading. Through using the Slocum BSD architecture, we can fully realize the glider's true capability for long-duration and cost-effective persistent oceanographic sampling presence in challenging regions throughout the globe. This research and accompanying manual provide a starting point for glider pilots, technicians, scientists, and others when working through how to use the Slocum glider's BSD architecture.**

Keywords—Slocum Glider, Backseat Driver, External Controller, Slocum Fleet Mission Control, Real-Time Onboard Processing

I. INTRODUCTION

Slocum gliders are well suited to sample the world's oceans. They are highly cost-effective and capable of multi-month missions gathering thousands of vertical casts of oceanographic data [1]. Slocum gliders' capabilities coupled with their remote programmability makes them ideal platforms for oceanographic research. However, like any system purely reliant on onboard power, operators of Slocum gliders must make energy consumption decisions causing tradeoffs between scientific sampling, communication with shore for near-real-time data telemetry, and flight trajectory. The interplay between these variables must be accounted for by glider pilots as they ensure ample data collection for a successful scientific mission. Balancing these trade-offs is further complicated by the limits of Iridium satellite communications.

During an ocean deployment, the standard operating procedure is to have the glider communicate with the shore via the Iridium satellite network. This method is bandwidth limited and connections are lost as the glider is submerged. Therefore, pilots ashore cannot make decisions for an underwater glider in real-time while the glider is submerged: mission parameters about sampling and waypoints are only configurable during surface events. While Slocum gliders have enabled a persistent oceanographic sampling presence in challenging regions ranging from polar oceans [2], beneath tropical cyclones [3], [4], and across ocean basins [5], the lack of adaptive control between vehicle surfacings can limit scientific sampling.

The implementation of a Backseat Driver (BSD) onboard the autonomous underwater vehicle (AUV) can help meet this gap in capability. A system with a BSD can help answer questions ranging from detecting and mapping the extent of oil spills [6], [7], mapping the underwater portion of icebergs [8], following thermoclines [9], coastal upwelling fronts [10], haloclines [11], processing ADCP [12] or side-scan data [13], and optimizing the flight of a glider as it navigates ocean currents, as described in this work. Each of these examples requires optimizing the AUV's flight path intelligently and adaptively, allowing more data collection in scientifically rich areas. To address this desired increase in vehicle capability, the Slocum glider BSD architecture has been in development for over ten years, with significant development efforts in recent years. Its use has been

979-8-3315-4008-1/24/$31.00 ©2024 IEEE

limited by availability of resources and expertise on the subject, resulting in limited end-user implementation.

II. Required Hardware and Software

There are three main components to this work: a G3S Slocum glider or a shoebox glider simulator, an external controller, and the hardware and software connection between the two. A fourth component, a Slocum Fleet Mission Control (SFMC) script was made to verify proper external controller operation.

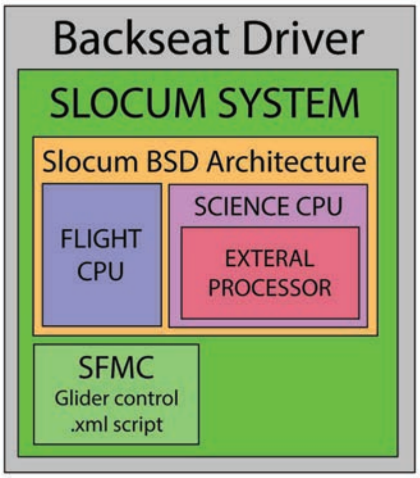

Fig. 1. The layout of the Slocum Backseat Driver architecture and associated system parts within the framework of a Backseat Driver. The SFMC glider control script is external to the glider system, but is within the Slocum system.

A. Slocum G3S Glider Simulator

Termed the "shoebox" due to its oblong rectangular shape, Teledyne Marine makes a dedicated G3S glider simulator. It has a flight computer and science computer with all standard science ports allowing for connection of sensors in the typical manner.

B. External Controller

The external controller must exist within the size and energy consumption constraints that come from being inside a Slocum glider on long-duration missions. Therefore, the external controller should be an energy-efficient small form factor single-board computer. This has led to the adoption of common external controllers such as a BeagleBone Black [14] or a Raspberry Pi 4 Model B [12].

For this work, the external controller selected was a Raspberry Pi 4 Model B due to accessibility of resources and ease of beginner use, making it well suited for educational purposes. Additionally, its Wi-Fi capability is not only useful for the lab setting, allowing remote access through the secure shell protocol (SSH), but its ability to generate its own Wi-Fi connection makes it is also possible to connect to the Raspberry Pi while it is in a glider.

That said, there are many other computers that could be used as an external controller. Selecting the proper external controller comes from the perspective of the science mission. Excess computing power increases power consumption, along with size and/or shape, connection ports, communication protocols, and weight considerations.

C. Simulating a Western Boundary Current with a Slocum Simulator and an SFMC Script

The Slocum BSD architecture program made in this work changes the glider's heading mid-mission based on the vehicles calculated values for ocean current speed and direction; however, in the standard glider simulation the ocean conditions are set once at mission start and remain static throughout. Thus, in order to test this application, we first developed a way to update the glider simulator's water direction and magnitude mid-mission by using a SFMC script.

SFMC is the web application used to manage a Slocum glider in real-time [16]. One of SFMC's capabilities is user-configurable scripts to control the glider, freeing a human pilot from directly issuing commands during every surfacing. A typical script will read the surfacing output from the glider and issue commands for sending and receiving files before commanding the glider to resume the mission and dive. Utilizing this system for our simulation glider, we created a script that reads the glider's longitude from the surface dialog. The script then issues two commands (!put s_water_speed and !put s_water_direction) based on a user defined representation of an ocean current environment. Once the simulated ocean variables are updated, the glider simulator resumes flight using the new values, creating the effect of glider traversing a changing current field (Figure 2).

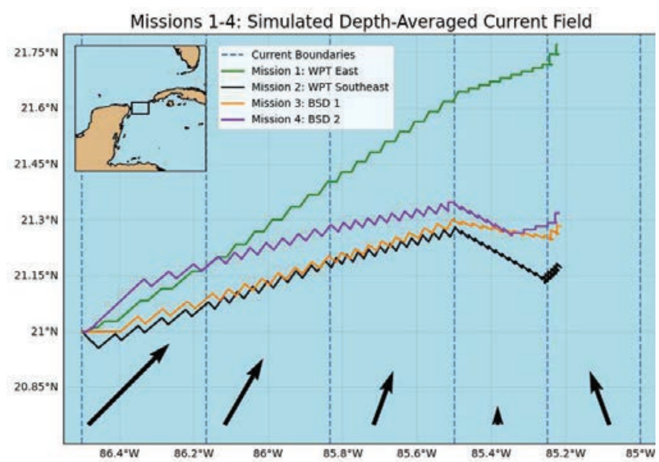

Fig. 2. Blue dashed lines delineate the boundaries between changing currents, with the arrow in each vertical slice of longitude indicating the magnitude and direction of currents within. All gliders started at 21° N, 86.5° W and proceeded east. Four missions were ran in this current field: (1) Green has a waypoint due east of the start location near Africa; (2) Black has a waypoint due southeast of the start location, between South America and Africa; (3) Orange is controlled with the Slocum BSD architecture setting the heading 90° to the right of the DAC; (4) Purple also uses the Slocum BSD architecture to control the heading based upon the DAC, with the addition of calculations to pick the heading that should result in the smallest theoretical northward deflection distance. The sawtooth pattern is due to the time underwater vs time on the surface. The simulated vehicle is subject only to currents (there is no wind forcing).

III. Backseat Driver Concept and Implementation

This paper treats the term BSD as the conceptual context of adding an additional processor onboard a vehicle for improved adaptable capability. Thus, the Slocum BSD architecture is the hardware and software required to implement the BSD concept onboard the Slocum glider (the physical cable connections, communication protocols, and the like). The external controller is the additional computer added to the existing glider control structure.

A Slocum glider has a flight computer and a science computer. The flight computer handles all behavior characteristics and communication protocols with the shore. The science computer handles all scientific sensor and data collection protocols. Although different, the two computers talk with one another via a logic pathway called the clothesline. However, the flight computer typically does not adapt its behaviors based on what the science computer "sees" of the ocean. Like the clothesline between the two glider computers, the science computer and external controller have another physical connection. This is accomplished with a USB to RS232 to Molex connector.

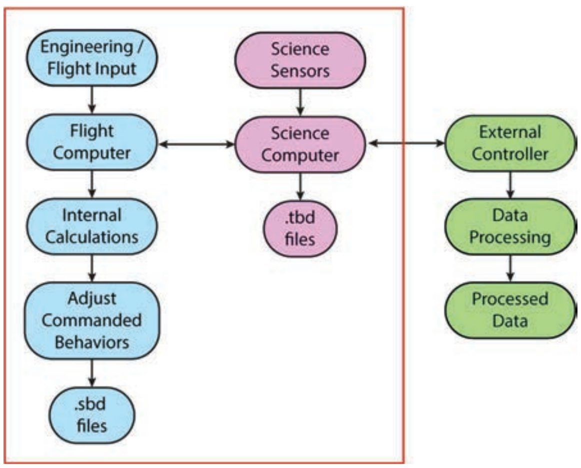

Fig. 3. The external controller is external to the standard Slocum glider's flight and science computer (red box), but still within the physical gider.

Using the connector, we attach the external controller to a science port on the science computer. To the glider, the external controller functions like a typical science sensor where specific commands about when to sample (in this case when to be powered on) are determined by the glider. Standard behavior arguments (b_args) are set once at mission start by the values throughout the glider files and on the surface mid-mission by pilots altering the files via Iridium. The Slocum BSD architecture allows for b_args to be dynamic while under the surface of the ocean by giving the external controller the ability to request and overwrite certain b_arg values stored in glider memory, allowing for in-situ autonomous adaptive control.

The external controller is used and/or controlled in multiple files on the glider. When a mission begins, the glider initializes values from onboard files and stores them in the flight computer's random-access-memory. The external controller then actively overwrites these values as the glider is flying, altering the behavior at that point in time. By allowing the b_args to be dynamic, new glider behaviors can be actualized through the external controller's dynamic controllability and potential increase in computing power, if greater processing is required.

IV. Backseat Driver Manual

To further enhance communities' resources, in this work I have written a manual which provides numerous use-cases of how to use the Slocum BSD architecture: Implementing the Backseat Driver Architecture on a G3S Slocum Glider: A Manual for Operators [15]. The manual is intended as a starting point for anyone to leverage the BSD architecture on a Slocum glider for their own specific use-case.

The manual contains background, practical guidance, and examples for configuring an external controller, integrating real-time glider sensor data, datafile transfer and management, simulating scientific sensors for validating proper external controller behavior, and more. All the glider files and Python code to implement the external controller onboard the glider are in the manual.

V. Simulations

Using the shoebox simulator, the Raspberry Pi 4 Model B as the external controller, and the associated wiring and programming, four simulated missions were run in an SFMC controlled current field roughly approximating the Yucatán Channel's Depth Average Current (DAC). All four began at the same location just offshore the Yucatán Peninsula and represent 22 days and 7 hours of simulation time.

Two missions were run using the goto_list behavior: Mission 1, with a waypoint due east of the start location, and Mission 2, with a waypoint due southeast of the start location. Both waypoints were extremely distant, on the same longitude as the westernmost part of Africa, a common practice to effectively program the glider to fly on a constant heading. Two missions (3 and 4) were run utilizing the Slocum BSD architecture with the set_heading behavior using the external controller to control the glider's heading based upon the glider's calculated DAC. When the glider surfaced and updated its DAC calculation, the external controller would read the new DAC value and update the glider's heading.

Given acceptable time and deflection distance constraints, the missions controlled with the Slocum BSD architecture crossed the fast moving currents in less time and with less northward deflection than when using standard practices for piloting gliders in areas of fast-moving current. Although Mission 2 had the shortest northward deflection distance it took an excessive amount of time. Mission 3 and 4, with headings between Mission 1 and 2, crossed the currents at a more optimal angle, better meeting the time vs distance trade-off (Figure 5A).

Missions 3 and 4 demonstrate the viability of operating an external controller for a total of 8.59 days. While this is not conclusive for weeks-long or multi-month missions, this indicates an external controller is capable of proper operation for the extended periods of time required for a glider mission. That said, the external controller's script run time is not always predictable.

For the duration of Mission 3, the same Python script ran with an execution time ranging from 18.46 seconds to 43.19 seconds. Glider sensor vales are sent to the external controller only when they are updated onboard the glider, causing the external controller to wait to receive all values. This lead to the inconsistent script runtime. Teledyne Marine is addressing this in future versions of the Slocum BSD architecture by working to allow the external controller to actively request a specified glider sensor value.

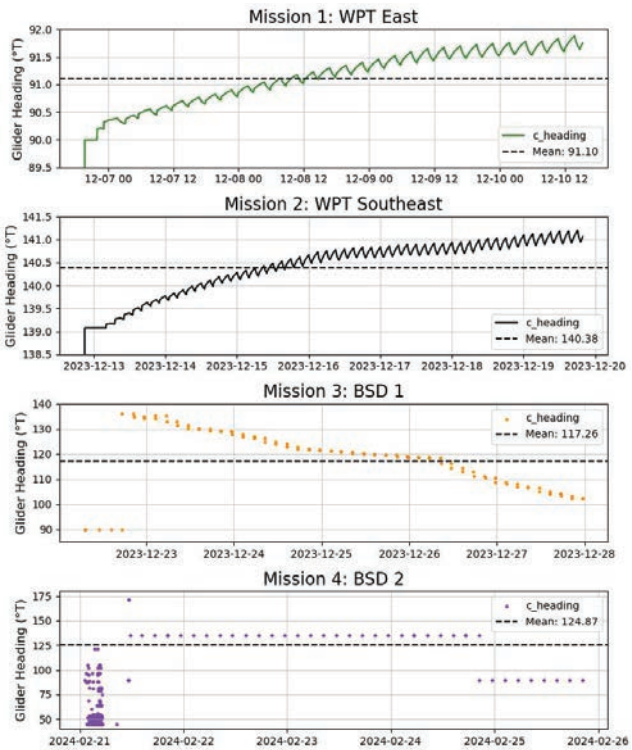

Fig. 4. Mission 1 and 2 are waypoint missions; thus c_heading yaws back and forth as the glider flies towards a distant waypoint. Mission 3 and 4 utilize the BSD architecture updating the set_heading behavior with c_heading only changing when m_water_vel_dir is updated at the surface. At the start of Mission 4 m_water_vel_dir improperly represented s_water_direction causing the external controller to update the heading often and not accurately.

Although setting a distant waypoint could result in the more optimal mean heading of 117°T, doing so would continually update the heading while submerged. In contrast, the two missions utilizing the BSD architecture did not update the heading as often (Figure 4). This is due to the external controller reading the DAC upon surfacing, changing the set_heading behavior's c_heading before diving and resuming the mission. While underwater, the glider's c_heading does not yaw towards a distant waypoint; instead, it remains at the fixed value set by the external controller during the surfacing.

VI. Discussion

The presence of the external controller enables the fine-tuning of the desired cross-current heading to optimize deflection distance versus time, balancing the trade-offs of spending more time for a lower deflection. This also shows the capability for the external controller, via the Python script, to adapt a behavior on a glider as the end-user sees fit.

There are many ways to implement a BSD in a given system; this is but one. However, it is worth remembering that there is no "set" way to utilize the Slocum BSD architecture. Choice of external controller, type of control and glider sensor values are all use-case specific questions that must be decided upon. Also, this work has one main limitation: the glider simulator is not designed to accurately represent a real-life ocean environment, requiring the SFMC script and simulated science sensor work-around. With further development, the SFMC script could integrate latitude for a higher-resolution simulated ocean current and more simulated sensors could be made; however, the simulator's present capabilities place restrictions on lab-based testing, necessitating in-situ ocean missions to properly validate glider characteristics.

The time involved with tests of this nature, simulating glider missions, is long, and there is at present no way to speed up the glider's simulation. Moreover, only one simulation can be run at a time, necessitating thorough testing, debugging, and verification before committing to a multi-day, or longer, test.

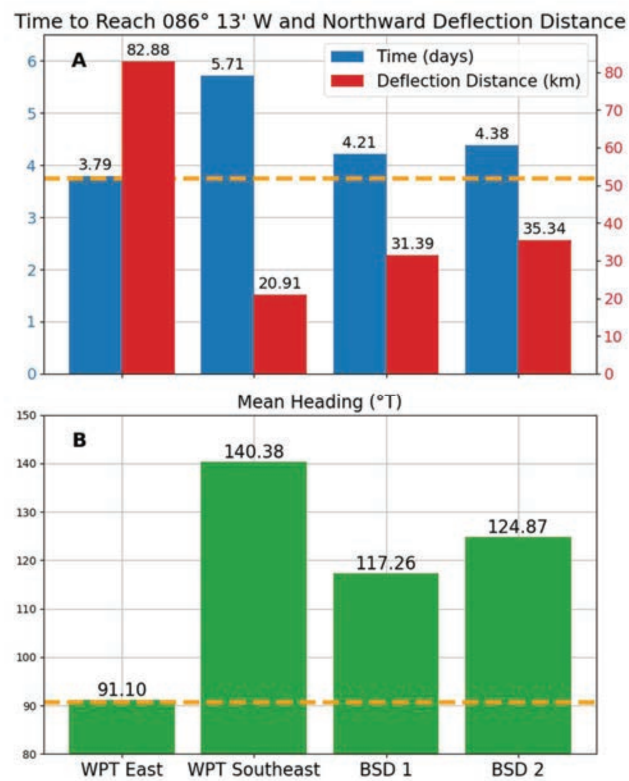

Fig. 5. A: Mission 3 and 4's times and northward deflection distance is more optimal. B: Mission 3 and 4's average heading is between the two waypoint mission heading extremes.

VII. Conclusion

While this work and operational manual created is one step as we continue towards ever greater capability for answering our science questions, there are far more possibilities within the BSD concept than anyone can possibly hope to cover in one work. As the true strength of using a BSD is the creativity in unique vehicle control it can afford, we must continue to leverage and expand upon our existing structures to better capture relevant data. Thus, using the Slocum BSD architecture should be paramount.

To realize this expansion of the Slocum glider's potential, education and outreach is required. Greater collaboration between the engineers creating these systems, scientists desiring data, and the pilots operating the vehicle is necessary.

Translation between the different groups and mindsets to leverage the strengths of each towards the common goal of furthering oceanographic data collection, and ultimately humanities relationship with our planet, is in dire need.

Using the knowledge gained from everyone's backgrounds, we can better implement this incredibly powerful method to enhance the Slocum glider's capabilities for data collection. The Slocum BSD architecture is limited only by our imagination, and our ingenuity.

Lagrangian coherent structures influence the spatial structure of marine food webs

Check for updates

Jacquelyn M. Veatch[1,2] ✉, Matthew J. Oliver[3], Erick Fredj[4], Hank Statscewich[5], Kim Bernard[6], Ashley M. Hann[6,7], Grant Voirol[3], Heidi L. Fuchs[1], William R. Fraser[8] & Josh T. Kohut[1]

The patchy distribution of prey in marine environments has a large effect on upper trophic level foraging strategies and distributions. While currents can disperse or concentrate low-motility plankton into patches that reflect the dynamic fluid environments they inhabit, it remains unclear whether surface flows affect motile zooplankton. Here, we used an in-situ optical dataset to detect phytoplankton patches, active acoustics to observe krill, and GPS-tagged penguins to observe three levels of the food web. These data allowed us to investigate whether the local food web overlaps with small-scale surface transport patterns as evidence that dynamic flows structure marine food webs. In Palmer Deep Canyon, Antarctica, we deployed High Frequency radars to measure hourly ocean surface currents, which were subsequently applied to estimate attractive Lagrangian Coherent Structures. We found that phytoplankton patches, Antarctic krill (*Euphausia superba*), Adélie penguins (*Pygoscelis adeliae*) and gentoo penguins (*Pygoscelis papua*) were preferentially located in attracting Lagrangian Coherent Structure features. These results provide evidence that Lagrangian Coherent Structures act as hotspots for prey and associated foraging predators, thus spatially focusing the food web. Results highlight the role of small-scale currents in food web focusing and the importance of transport features in maintaining the Palmer Deep Canyon ecosystem.

Distributions of planktonic and nektonic marine organisms are continuously shaped by the dynamic ocean environments in which they reside and are typically patchy in space and time. Phytoplankton and zooplankton are both known to form discrete patches[1,2], with predators that seek out these patches of prey[3], which leads to a form of spatial control on the ecosystem known as food web focusing[4], where small scale fluid flows (hours-days and 1–100 km) structure the relationship between different trophic levels. Here, we are using the term "food web focusing" to describe transient and spatially variable prey patches, as opposed to prey aggregations associated with fixed spatial structures like seamounts[4]. Understanding the mechanisms that control "patchiness" seen in primary producers, primary consumers, and their predators requires integrating environmental observations of physical processes and community structure at relevant temporal and spatial scales[5,6]. These interactions between marine organisms and physical ocean processes are crucial to understanding their distribution within and reliance on the dynamic ocean habitat in which they reside.

Low-motility plankton with low and intermediate Reynolds numbers (Re ~10^{-2}–10^{3})[7], such as phytoplankton and zooplankton, are transported by ocean currents[8]. (Here, Reynolds numbers (Re) refer to how the fluid flows around the animals rather than how the fluid flows on its own). Foraging species with high Reynolds numbers (Re ~10^{6})[7] and greater mobility can employ various foraging strategies to seek out their zooplankton prey, which swim more slowly and are less able to move independently of ocean currents. The transport of low-motility plankton is particularly noticeable in areas with strong currents, often associated with features such as ocean fronts and eddies[9]. In order to understand distributions of phytoplankton, zooplankton, and top predators, we must investigate patterns in ocean transport.

Patterns in ocean transport can be elucidated through particle release experiments within observed ocean velocity fields. By integrating over Lagrangian particle trajectories, attracting structures are quantified within evolving velocity fields using an analysis known as Lagrangian Coherent Structures (LCS)[10]. Several types of LCS exist with different definitions of

"attraction" and "repulsion" to quantify the strength of transport features. In this study, we use Finite Time Lyapunov Exponents (FTLE) as a metric to identify attracting LCS, and test if these attracting LCS are acting as a hotspot for low-motility plankton. FTLE were chosen as they provide flexible integration time, allowing for the identification of ocean features at the scale of interest, and have been shown to identify transport features associated with increased phytoplankton patch presence in our study area[11]. LCS can quantify transport patterns in ocean velocities that cannot be seen by studying Eulerian velocity fields alone, allowing for the investigation of the role of transport in food web focusing.

LCS have been shown to overlap with bioactivity on different levels of the marine food web, shaping large phytoplankton blooms[12–15], correlating with the presence of middle trophic levels (fishes)[16], and appearing along the tracks of top predators[17,18]. Much of this previous work has been conducted on larger, geostrophic currents characteristic of open ocean (pelagic) ecosystems. On these scales, satellite-observed ocean color is often used to track the evolution of large phytoplankton patches and Global Positioning System (GPS) tags are used to track movements of large marine animals in relation to LCS calculated from satellite altimetry[12] or long range radars[14]. However, predator and prey patches likely interact at much smaller scales than measured by these systems.

Distributions of zooplankton affect prey availability for many higher trophic level predators[6] including whales[19] and commercially important fishes[20]. Therefore, a major interest in marine spatial ecology has been understanding and quantifying the factors that affect the preyscape of a marine ecosystem. While both phytoplankton and predators have been associated with attractive LCS features, the relationship between zooplankton and LCS are more difficult to obtain as they require in-situ acoustic measurements and/or net tows, and the factors that influence their distribution can be driven by both zooplankton behavior and advection.

Many of the studies linking LCS to top predators assume that, similarly to phytoplankton, zooplankton are also concentrated by attractive LCS features, though these assumptions are typically made without coincident zooplankton measurements. The few studies that have linked zooplankton to LCS were conducted over relatively large scales using data from mesoscale ocean model output[21,22] and long-range (low frequency) radars[23]. These findings suggest links between zooplankton biomass and the presence of LCS at scales of days to weeks and tens of kilometers. Other studies have associated zooplankton distributions with mesoscale eddy kinetic energy[24], tidal cycles phases[25,26], and wind events[25,27] suggesting connections between ocean dynamics and zooplankton swarms. Larger top predators such as whales have also been shown to select for LCS-identified prey concentrating features over larger scales[23]. However, predators likely seek prey patches on much smaller scales[28,29], meaning these coarser-scale associations between LCS and predators could be averages of finer scale processes. Using an Antarctic submarine canyon as our natural laboratory, we resolved the food web at scales of hours to days across spatial scales of hundreds of meters to kilometers and observed transport features experienced by near-shore patches of phytoplankton, zooplankton and associated predators. To our knowledge, the following study is the first, to the best of our knowledge, to include concurrent high-resolution observations of zooplankton, phytoplankton and upper trophic predators in relation to LCS-identified ocean features.

For this study, we focus on the local food web of Palmer Deep Canyon along the Western Antarctic Peninsula (WAP). Here, Antarctic krill (*Euphausia superba*, hereafter referred to as krill) serve as a keystone species and a major food source for marine predators including whales, seals, and penguins[27,30–34]. Local Adélie (*Pygoscelis adeliae*) and gentoo (*Pygoscelis papua*) penguins are both central place foragers, meaning they return to a nest after each foraging trip, with overlapping foraging areas centered over Palmer Deep Canyon (Fig. 1b). Penguin populations in Palmer Deep Canyon have persisted for hundreds of years[35–37], their diets dependent at least in part on the elevated biomass of krill[38] that persists here in relation to neighboring regions[37,39,40], establishing Palmer Deep Canyon as a "biological hotspot". Consequently, Palmer Deep Canyon's ecosystem hinges on the availability of krill as the trophic link between phytoplankton at the base of the food web and higher predators[41]. In this study, we investigate current-driven controls on the distributions of phytoplankton patches and krill

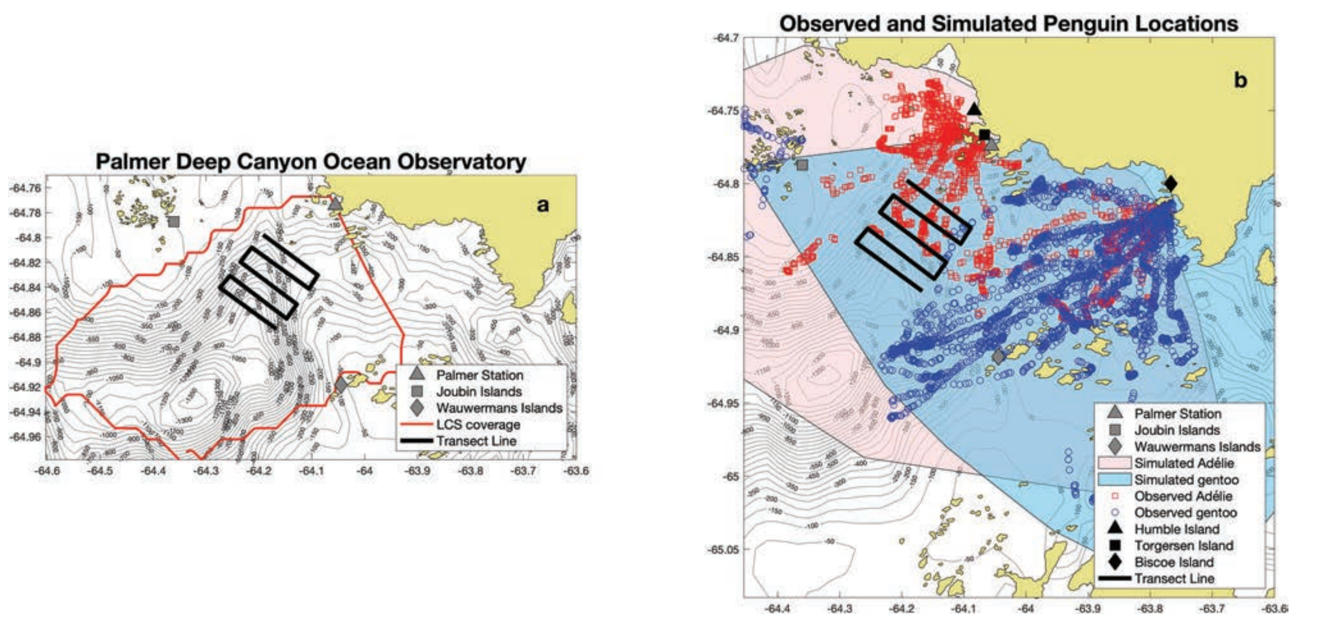

Fig. 1 | Ocean observatory around Palmer Deep Canyon. **a** Palmer Deep Canyon study region with the location of the three High Frequency Radars shown with polygons and the area of LCS results contoured. Within the LCS footprint is the transect line of the active acoustic survey used to detect krill and optical survey used to detect phytoplankton patches. Canyon bathymetry is contoured in 50 m isobaths. **b** Penguin positions observed with GPS tags for Adélie (red squares) and gentoo (blue circles) penguins. Convex hulls of simulated Adélie and gentoo penguins are shown in red and blue respectively, the smallest convex polygon that contains the set of points produced by the simulated penguin tracks. Penguin nests are shown in black polygons. Adélie breeding colonies are located on Humble Island, Torgerson Island, and Biscoe Island, and gentoo breeding colonies on Biscoe Island. Transect line for the surveys that observed krill swarms and phytoplankton patches is shown with a solid black line. Canyon bathymetry is shown in contours of 50 m isobaths. Note that the seemingly strait penguin tracks are likely penguins returning to their nests after satiation.

swarms at the scales of penguin foraging through the use of a multi-platform ocean observing system (Fig. 1a). Integration of multiple observing platforms provides the rare opportunity to analyze the overlapping physical processes and trophic interactions on time and space scales relevant to understanding the physical mechanisms that concentrate high density patches of prey that predators use to efficiently forage.

When integrating both biological and physical observations of an ecosystem, it is important to investigate them at the appropriate space and time scales[42]. Palmer Deep Canyon is a coastal system, characterized by submesoscale ocean currents, strong tidal influences, and short (2–7 days) surface residence times[43]. Similarly, phytoplankton patches have been shown to move through this system quickly (6 h decorrelation)[11], and most penguin foraging trips are between 6 and 24 h[44]. Previous work has established Palmer Deep Canyon as a fast-moving oceanic habitat, characterized by dynamic physical conditions and a similarly variable biological ecosystem. In this study, we determine if the distribution of krill and foraging penguins at these shorter time and space scales show similar association with LCS-identified transport features as previously observed with phytoplankton[11], suggesting small-scale and current-driven controls on food web focusing. The present study maps each level of the food web onto dynamic ocean currents at resolutions that resolve interactions between near-shore creatures and complex coastal flow, providing a unique opportunity to deepen our understanding of potential small-scale physical mechanisms of spatial ecology.

Results

Dynamic feature mapping with Lagrangian Coherent Structures

In this study we used a high-resolution High Frequency Radar (HFR) network to calculate attracting FTLE, projected at the temporal and spatial resolution of inputted HFR data (1 h, 1 km). FTLE is a metric used to characterize the Lagrangian structure in fluid flows. It measures the rate of separation of initially close particles over a finite time interval, providing insights into the stability and chaotic behavior of the flow (see section 5.7 for details). FTLE maps were calculated each hour with a 1 km spatial resolution (Fig. 2 and Supplementary Movie 1), the same spatial and temporal resolution as the HFR velocity field data. Higher values of LCS indicated a higher influence on the attraction of nearby drifting particles. This analysis produced a time resolved 2-dimensional field of attracting features.

Phytoplankton patches occuring in transport features

Phytoplankton patches were observed with an ACROBAT, a towed instrument that undulates between the surface and ~50 m depth (see Section 5.3 for details), outfitted with a Wetlabs Ecopuck optical sensor (chlorophyll-a, CDOM fluorescence, and optical backscatter at 700 nm) and a fast-sampling (16 Hz) Seabird 43 FastCAT CTD (conductivity, temperature, and pressure) following transect lines within the HFR footprint (Fig. 1a). MLD was calculated as the depth of maximum buoyancy frequency for each profile[11,45] using data collected via the towed ACROBAT. Phytoplankton patches were determined following methods in Veatch et al.[11] as profiles with an integrated mixed layer backscatter greater than a threshold, and re-analyzed in this study for direct comparison with krill and penguin foraging observations (Section 5.3, Supplementary Fig. 2).

Previous results found phytoplankton patches were associated with higher FTLE values (indicative of stronger attracting features) than a null model[11]. The distribution of FTLE values associated with phytoplankton patches are shifted towards higher FTLE values, peaking around 0.3 hr^{-1} while the distribution of FTLE values associated with randomized phytoplankton patches (null model) were more symmetrical, peaking around 0.22 hr^{-1} (Fig. 3). Randomized phytoplankton patches were created by generating survey transects in random locations and associating them with LCS (see section 5.6 for details). The distribution of FTLE values associated with observed phytoplankton patches were significantly higher than those of randomized phytoplankton patches (Fig. 3a), according to a one-sided Kolmogorov-Smirnov (KS) test ($p = 0.01187$) which tests whether one sample distribution tends to have greater values than the other. Results were the same when the null model was confined to the area of the observed transect (see section 5.6 for details) passing a one-sided KS test ($p = 2.54e{-}11$).

Krill swarms occuring in transport features

Krill swarms (Fig. 4) were concurrently mapped using active acoustics during small boat surveys within the HFR footprint (Fig. 1a) during daytime surveys. The small boat was equipped with a hull-mounted EK80. Krill were acoustically detected and parameterized following methods previously used in Palmer Deep Canyon[28,46–48]. Mixed layer depth (MLD) was also observed using a CTD aboard a towed ACROBAT instrument (see Sections 3.2, 5.3). Of the 1749 total krill swarms detected, 687 (~39%) were observed above the MLD. A null model representing random distribution of krill aggregations across the survey area was created to compare to observations.

Observed krill swarms as well as randomized krill swarms from a null model were matched in space and time with FTLE. The density distributions of FTLE for krill swarms (above the MLD, below the MLD, and total) are skewed towards higher FTLE with the peak around 0.35 hr^{-1} for krill above the MLD, 0.33 hr^{-1} for krill below the MLD, and 0.35 hr^{-1} for all krill swarms (Fig. 3b). In contrast, the density distributions of FTLE for randomized krill swarms is relatively symmetrical in shape, peaking at a lower value around 0.25 hr^{-1}. A KS test between density distributions of FTLE for observed and randomized krill swarms showed that the distribution of true krill swarms is skewed toward higher FTLE values compared to randomized krill swarms. There was a significant difference between total krill swarms and randomized krill swarms ($p = 9.57e{-}14$). This was also true for krill swarms both above and below the MLD ($p = 0.0028$ and $p = 5.56e{-}12$, respectively) (Fig. 3b). When all krill swarms were compared to null model confined to the area of the observed transect (see section 5.6 for details) results were the same, passing a one-sided KS test ($p = 7.16e{-}39$).

Adélie and gentoo penguins selecting for transport features

Penguin diving locations, tracked using Fastloc GPS archival tags, showed preference for higher values of FTLE. Similar to the krill swarms, density distributions of FTLE associated with observed Adélie penguin diving locations indicated that Adélie penguins tended to forage in regions with higher FTLE compared to the simulated Adélie penguin tracks (KS test, $p = 2.7e{-}5$). Adélie locations with dives less than 10 m deep (KS test, $p = 2.2e{-}15$) and locations with dives greater than 10 m deep (KS test, $p = 0.0017$) both showed higher density distributions of FTLE compared to null models, with 10 m representing the average MLD calculated from the towed ACROBAT instrument. Like Adélie penguins, the density distributions of FTLE associated with observed gentoo penguin diving locations was shifted towards higher FTLE values compared to randomized gentoo penguin foraging locations (KS test, $p < 1.66e{-}15$). Observed gentoo penguin foraging locations were also associated with higher FTLE values compared to randomized foraging locations for dives with maximum depths above and below 10 m ($p < 1.15e{-}13$ and $p < 9.6e{-}12$, respectively). The density distributions of FTLE for Adélie and gentoo penguins are shifted towards higher FTLE (Fig. 3c, d). In contrast, the density distributions of FTLE for simulated Adélie and gentoo penguins are relatively symmetrical in shape. For all three of these comparisons (all dives, dives shallower than 10 m, and divers deeper than 10 m), we systematically removed one penguin from the analysis and recomputed the KS test, as each sampling group was O10 penguins. The resulting distributions showed that no individual penguin was driving the shift of Adélie or gentoo penguins toward higher FTLE values (see the grey shaded area in Fig. 3c, d).

Discussion

In this study, we observed that food web focusing by small-scale currents shapes the spatial ecology of a coastal marine food web at the patch scale of foraging (hours and 100 s of meters to kilometers). Our results show that phytoplankton, krill, and penguins are found in higher attracting FTLE features (LCS), suggesting aggregation of plankton from horizontal ocean

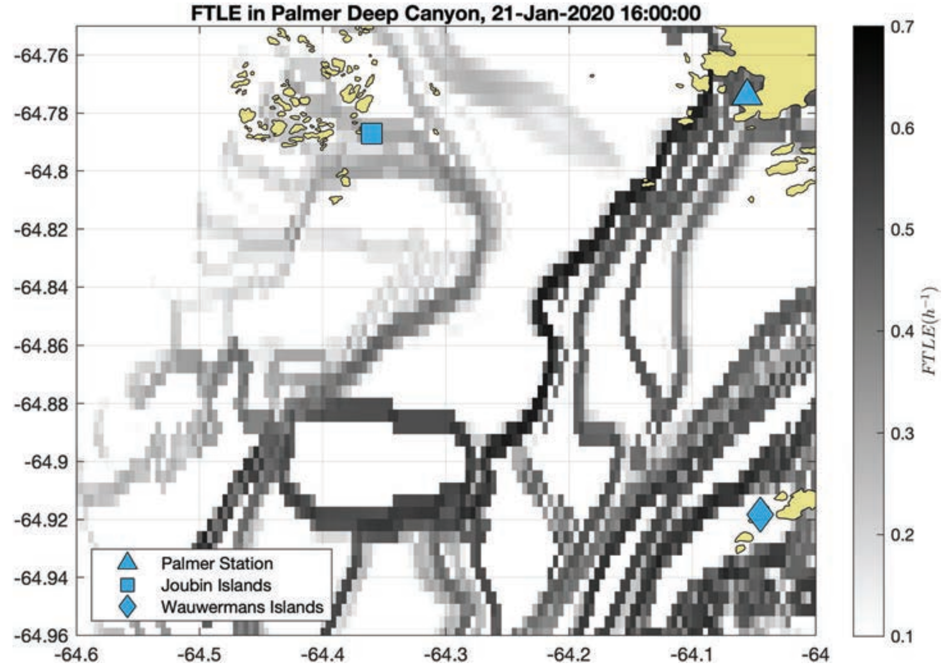

Fig. 2 | Example FTLE results calculated from High Frequency Radar observed surface currents. Locations of three HFR stations are denoted with polygons. FTLE results on January 21st 2020 at 16:00 GMT are shown in greyscale with higher FTLE values corresponding with stronger attracting ocean features.

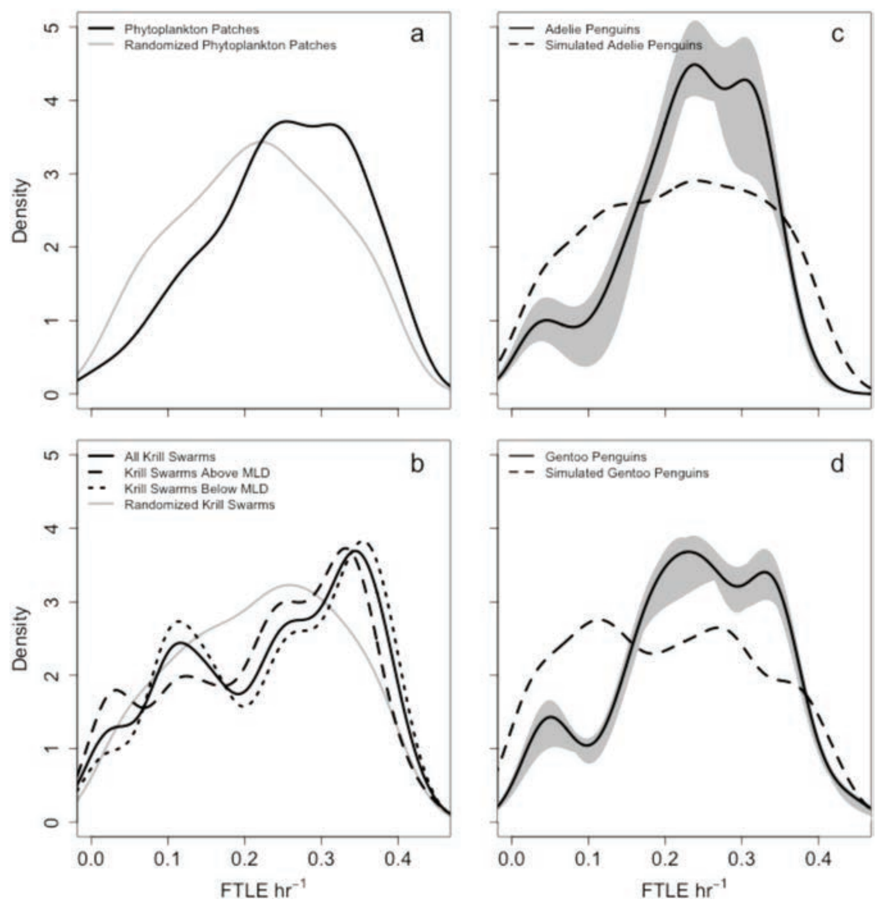

Fig. 3 | Density distributions of FTLE. a Density distributions of FTLE associated with observed phytoplankton patches (black line) and randomized phytoplankton patches (grey line) previously published in Veatch et al.[11]. Phytoplankton patch FTLE value density distribution were skewed toward higher values compared to randomized phytoplankton patches (KS test, $p = 0.01187$). **b** Density distributions of FTLE associated with observed krill swarms (solid line) above (dashed line) and below (dotted line) the mixed layer depth. All three of these distributions are skewed toward higher FTLE values than randomized krill swarms (grey line) (KS test, $p = 9.57e{-}14$, 0.0028, 5.56e−12). **c** Adélie and (**d**) gentoo tagged penguin FTLE values shown in solid line and randomized penguin FTLE values with dashed line. Grey regions represent the distributions of either Adélie or gentoo penguins if individual birds were systematically excluded from the analysis. This was done to determine if an individual bird was driving the results. Both Adélie and gentoo FTLE distributions were skewed toward higher values compared to FTLE values with simulated penguins (KS test, $p = 2.7e{-}5$, $p < 1.66e{-}15$). All curves are kernel density estimates computed with a density function within the statistic package of R[86], with the bandwidth of the kernel smoother set to 0.03. These density curves visualize the frequency of the underlying data.

transport is an important factor in the spatial ecology of Palmer Deep Canyon and providing the first evidence, to the best of our knowledge, of LCS selection at these scales across primary producers, primary consumers, and predators.

Interactions with ocean transport from each trophic level

The three trophic levels tested in this study span a wide range of Reynolds numbers with significant differences in their behavior and in the dependence of their movement on ocean currents. The passive particles used in

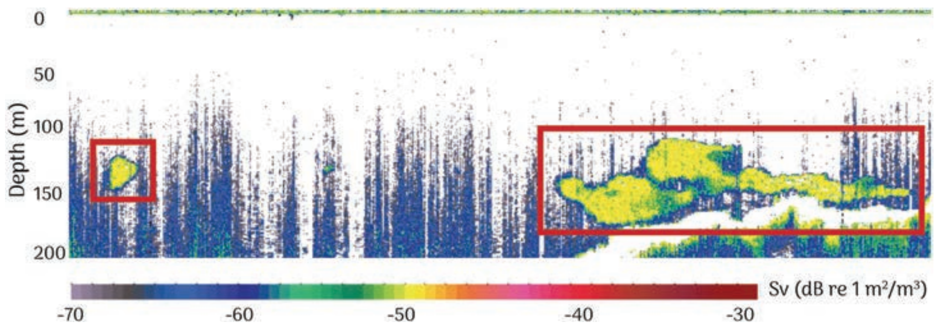

Fig. 4 | Example of acoustic detection of krill swarms. Echogram from survey (see Fig. 1a for survey path) with ACROBAT deployment. Dense yellow regions outlined in red boxes were detected as krill using a threshold of −70 to −30 dB. Raw acoustic data was processed in Echoview software, following methods of Tarling et al.[47,48] to identify krill swarms from all other backscatter.

LCS calculations most closely approximate the non-motile characteristics of phytoplankton at the scales of this study (Re ~10^{-2}, estimated from length scale[7]). The correlation between phytoplankton patches and LCS, their immobility, and their slow growth rates compared to local surface residence time[43] suggests that these patches are formed through horizontal ocean transport.

Unlike the largely passive phytoplankton cells, krill exhibit movement behavior relative to local ocean currents (Re ~10^3) and migrate vertically based on the sun angle[49], which means they can both be transported by ocean currents and swim somewhat independently of them. Our analysis used only passive particles and current velocities at the surface, yet surprisingly, high FTLE values indicated that krill both above and below the MLD were preferentially associated with surface concentrating features. Dynamics below the mixed layer are outside the scope of this study, but we can speculate why krill below the MLD would have higher FTLE values than a null model using surface particles. Krill below the MLD may have recently migrated down from within the mixed layer, and have not yet become decorrelated with surface currents. It is also possible that the velocity field below the MLD may be similar to that in the mixed layer, concentrating sub-surface krill in similar patterns to those reflected in the surface. Similarities between the surface and the sub-surface velocity fields could be driven by this region's barotropic tides[50], creating similar concentrating features in the sub-surface as in the surface velocities used to calculate FTLE. Finally, krill may be attracted to locally concentrated phytoplankton in higher FTLE values, indicating that both advection and behavior explain their affinity for LCS features with high FTLE values. Regardless of the mechanism, these results suggest that the distribution of krill in Palmer Deep is affected by food web focusing driven by small scale currents.

Foraging penguins have very high Reynolds numbers (Re ~10^6), indicating that they may move independently of currents. As a result, their distribution is expected to be most unlike the passive particles used in the LCS calculations. Results from this study show that penguin foraging behavior leads to spatial distribution in which there is more frequent penguin dives around locations with strong concentrating features (high FTLE). This suggests that while penguins may not actively seek out LCS, they are more likely to dive once they reach these features and find concentrated prey. Similar conclusions were drawn by a previous study investigating elephant seals interacting with larger scale currents[51], showing that elephant seals increase their foraging dives when at distinct oceanographic features. Unlike the elephant seals, Adélie and gentoo penguins will return straight to their nests once satiated, which creates the directed return journeys in the penguin tracks (Fig. 1b).

Penguin dives above and below the MLD, associated with stronger FTLE values, suggest that while penguins may use surface cues to initiate dives, they do not limit their foraging to the surface layer. This result is consistent with findings in krill distributions, where krill swarms both above and below the MLD were associated with strong FTLE. Penguins and other marine mammals transit near the ocean surface from where they dive to search and forage for their prey, exhibiting a variety of movement modes[52–54]. Although dive location and frequency can be quantified, little is known about the selective interactions of animals during their foraging trips that produce these patterns[55], including whether animals actively search for prey or use environmental cues associated with prey[56]. Emerging theories suggest that selection for environmental cues is likely[57], but it is unknown if Adélie or gentoo penguins respond to prey or environmental cues. Further research is needed to identify the surface cues Adélie and gentoos use to decide when to dive for prey.

Despite the wide range in the Reynolds numbers of our study species, each species showed selectivity for horizontally concentrating features (LCS) derived from passive particle trajectories. As species size and Reynolds number increases, so does the complexity of their relationship to LCS. Phytoplankton have low Reynolds numbers, and their distributions are likely dominated by ocean transport. Krill have intermediate Reynolds numbers, and their selection for LCS likely reflects a combination of physical concentration by attractive features and behavioral attraction to phytoplankton patches. Lastly, Penguins have high Reynolds numbers and behavior-driven distributions, so their selection for LCS is likely dominated by foraging behavior concentrated at krill patches. Such selectivity across species with varying Reynolds numbers demonstrates the importance of ocean transport to multiple levels of the food web.

Observations of small-scale ocean transport with Lcs

Selection by multiple levels of the food web for LCS quantified by FTLE at a 6-h integration suggests that FTLE capture transport patterns that create small-scale (sub-tidal) food web focusing. FTLE is a paired particle tracking technique, meaning that it uses relative distances between neighboring particles to quantify attraction and repulsion. This allows FTLE to quantify attracting features with little influence of the particle's starting position, unlike the single particle tracking methods[11]. FTLE also assigns scalar quantities to attracting features based on separation rate of neighboring particles (backwards in time, particle accumulation rate), allowing FTLE to account for rate of change of particle position rather than position alone. Additionally, FTLE integrate over particle trajectories, adding "memory" of particle position to the calculation of attracting features. Yet another strength of this method is the integration over time, which pairs well with the high temporal resolution of the HFR velocity data. The incorporation of relative particle motion and integration over particle trajectories makes FTLE a powerful tool for quantifying small-scale transport compared to the use of particle trajectories on their own.

FTLE patterns at these scales are highly variable in space and time, yet ubiquitous throughout the study system (Supplementary Movie 1 and Fig. 1). The null model sensitivity test showed similar results when the null model was constrained to the area closer to the observed transect rather than the entire LCS bounds (Fig. 5). Therefore, FTLE are not concentrated over the observed transect but throughout the study region. It is unknown whether penguins select their colony locations based on proximity to heightened LCS features. This study sets the groundwork for future investigations into whether coastal regions on the WAP near persistent penguin colonies have heighted FTLE activity compared to regions without such colonies.

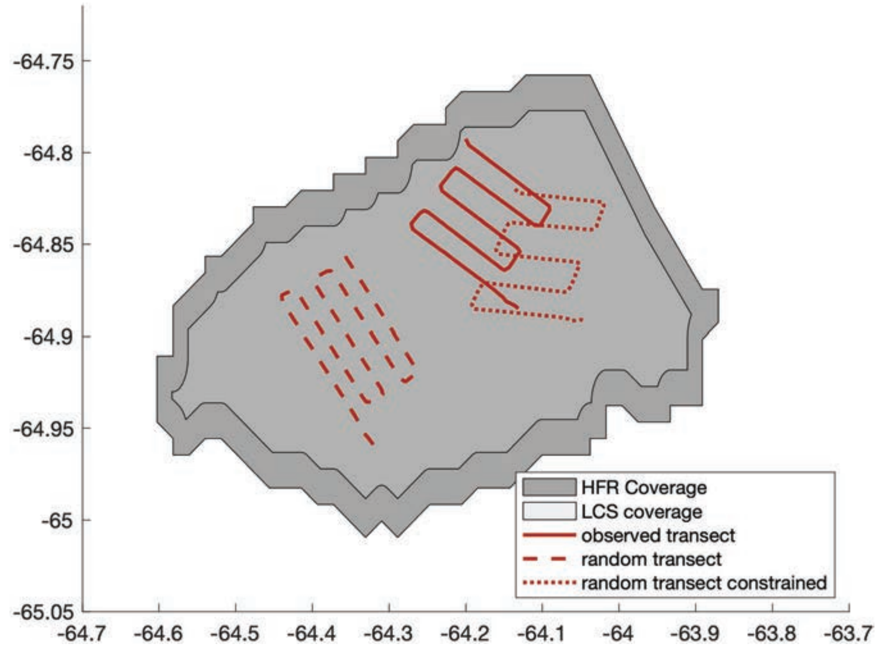

Fig. 5 | Example of null model. The area of LCS coverage is plotted in light grey, shrunk from HFR coverage (dark grey) to exclude edges of data. The transect where phytoplankton patches and krill swarms were observed is plotted with a solid red line, and one of the randomly rotated and translated transects is plotted with a dashed red line. A sensitivity test was conducted on the null model, constraining "randomly generated" transects to the northeast of the solid black line. A randomly rotated and translated transect confined to northeast of the black line is plotted with a dotted red line. Figure modified from Veatch et al.[11] Fig. 3.

In addition to identifying areas of attraction, strong FTLE will appear as horizontal transport barriers, which manifest as horizontal buoyancy gradients (fronts and edges of eddies) in ocean velocity fields. This makes areas of high FTLE oceanographically distinct from areas with low FTLE values. While attractive transport is likely to be a large reason why phytoplankton and zooplankton are associated with high FTLE values, it is unclear if Adélie and gentoo penguins are able to select for areas of high FTLE based on a learned oceanographic cue or if they are able to perceive large krill swarms and those happen to be at areas of high FTLE. Future work is needed to investigate penguin (and other forager) behavior that leads to their association with areas of high FTLE.

Limitations and caveats

There are several biological processes that limit the conclusions that can be made with these observational data. Mapping of prey, which was conducted through small boat surveys twice weekly, provides a snapshot in time of a prey field that is constantly evolving. The timing of observation within the process of food web focusing is unknown. For example, an area where there was an LCS-identified transport feature could have been observed shortly after a predator fed on a krill swarm. Our observations would show that an LCS-identified transport feature was there without presence of food web focusing, when in fact there was. Our observations could have also occurred before the ecosystem was able to respond to the presence of the LCS, perhaps showing high phytoplankton but no krill, or krill swarms but no penguin foraging. Additionally, far fewer predators (penguins) exist than prey (krill), making it more difficult to correlate predators to food web focusing events. With these caveats in mind, the patterns that were observed likely underestimate the food web focusing effect of small-scale transport.

Local and global implications

Results and conclusions from this study increase our understanding of how a coastal biological hotspot is maintained in the context of a larger marine ecosystem. Palmer Deep Canyon was once considered to be a location where phytoplankton production is driven by local upwelling[40]. Recent studies provide evidence against this, showing instead almost no stratified summertime occurrence of nutrient-rich Upper Circumpolar Deepwater in the photic zone[58]. Further, production is light limited rather than nutrient limited[59], suggesting little reliance on locally upwelled nutrient rich waters. Furthermore, a deep, recirculating eddy driven by the bathymetry of Palmer Canyon has the ability to trap krill performing diurnal vertical migration[60]. This feature may provide a seasonal reservoir of krill, which migrate to the surface, and are then aggregated in surface LCS structures. Emerging theories propose that high concentrations of phytoplankton[40] are advected from the shelf break where upwelling of nutrient-rich Upper Circumpolar Deep Water fuels phytoplankton blooms[61,62]. Future work is needed to further investigate larger scale, regional transport that reflects climate scale impacts in the WAP region. Our results further emphasize the importance of ocean transport in this system not just for local phytoplankton abundance but throughout the food web. Oceanographic transport patterns that reliably concentrate prey could be a reason penguins colonies have persisted in this region over ecological time scales[37]. As Palmer Deep Canyon and other ecosystems along the WAP experience rapid warming[63–65], sustained observations are needed to determine if these transport patterns that local food webs rely on will change. Future work must also investigate the fate of the sources of plankton that are being delivered to the system in order to predict Palmer Deep Canyon's resistance to changing climate. A depletion of these sources could be detrimental to Palmer Deep Canyon's ecosystem even if transport patterns are maintained.

Selectivity of LCS calculated with short integrations by intermediate and upper trophic levels illustrates the importance of small-scale transport features in the spatial ecology of coastal systems. This not only supports the emerging theory of trophic focusing by physical ocean processes[4], but demonstrates that these processes occur on the sub-mesoscale. Correlations between LCS and phytoplankton, zooplankton, and top predators stress the importance of incorporating LCS as a covariate in predictions of spatial ecology in marine systems.

Our study provides a link between the preyscape of a coastal ecosystem and ocean transport. This relationship fills the gap in previous studies that link phytoplankton and top predators' distributions to ocean transport without considering the critical mid-trophic level zooplankton. Results also provide a useful tool for the marine ecological community to quantify ocean transport features, namely FTLE. FTLE, although more computationally complex than single particle tracking techniques such as Relative Particle Density[11,66], have been shown to quantify transport features that are selected by each level of the Palmer Deep Canyon food web, justifying their use in dynamic coastal environments. Connections between ocean movement and spatial ecology improve current understanding of how local populations use their ocean habitats, enabling more informed conservation strategies to protect areas of prey accumulation, mitigating anthropogenic impacts on coastal ecosystems.

Methods

An ocean observatory was deployed around Palmer Deep Canyon during January-March 2020, mapping phytoplankton, zooplankton, and penguin foraging behavior onto physical ocean processes. The following section describes the small boat surveys that were conducted along a transect twice weekly to observe phytoplankton and zooplankton as well as the HFR array observations and tagged penguin measurements that overlapped with this transect.

High Frequency radar

Three High Frequency Radars were deployed around Palmer Deep Canyon, using doppler-shifted radio waves backscattered from ocean waves to produce vector maps of surface current velocities each hour. HFRs were deployed on the Joubin Islands, Wauwermans Islands, and at Palmer Station (Fig. 1). Remote sites (Joubin and Wauwermans) were each accompanied by a remote power module, described in refs. 67,68. Radial components from each radar[69] were added together with an optimal interpolation algorithm[70] and gap filled[71] as described in refs. 11,72. The resulting data product is an evolving hourly map of ocean surface currents over a 1 km spatial grid.

Calculating mixed layer depth

On the active acoustic survey transects (Fig. 1a), an ACROBAT (Autonomous Conductivity, temperature, and depth Rapidly Oscillating Biological Assessment Towed) was towed, equipped with a fast-sampling (16 Hz) Seabird FastCAT CTD (conductivity, temperature, and pressure). This instrument undulated between the surface and about 50 m depth, profiling the upper water column about every 300 m in the horizontal. For each profile, MLD was determined as the depth with the maximum buoyancy frequency following methods in Carvalho et al.[45]. MLD measurements were used to calculated mixed layer optical backscatter (Section 5.3) and to determine if krill swarms were above or below the MLD (section 5.4). ACROBAT profiles were matched with observed krill swarms in space and time, assigning a MLD to each krill swarm. If the depth of the krill swarm was shallower than the ACROBAT observed MLD, the swarm was considered to be within the mixed layer.

Optical surveys

Towed ACROBAT surveys were conducted twice weekly collecting optical measurements of the water column along transects shown in Fig. 1a. Methods for identifying phytoplankton patches with ACROBAT optical measurements followed those in Veatch et al.[11], and are explained thoroughly there. In short, the ACROBAT profiled between the surface and about 60 m, completing a profile about every 300 m of horizontal distance traveled. Profiles were determined as “within a phytoplankton patch” or “not in a phytoplankton patch” based on a daily threshold of integrated mixed layer optical backscatter. In this system, optical backscatter is a good proxy for phytoplankton biomass and avoids the problem of non-photochemical quenching that is associated with measuring phytoplankton fluorometrically. Consecutive profiles designated as “within a phytoplankton patch” were assumed to be in the same phytoplankton patch (Supplementary Fig. 2).

Each ACROBAT profile was assigned an FTLE value based on the closest FTLE grid point to the profile in space and time. Phytoplankton patches made up of multiple profiles were assigned an FTLE value based on the average FTLE value assigned to the profiles within that phytoplankton patch.

Acoustic surveys

Active acoustic surveys were conducted twice weekly using a hull-mounted SIMRAD EK80 single-beam, single frequency (120 kHz) echosounder (Kongsberg Maritime) along transects shown in Fig. 1a. The echosounder was configured with a 1 s ping rate, 512 µs pulse duration, and 24 µs sampling duration. Calibrations of the echosounder were performed in the vicinity of Palmer Deep Canyon using a tungsten sphere (diameter = 38.1 mm) during February, 2020. Acoustic data were processed in Myriax Echoview software version 11.1 following methods from Tarling et al.[47] and Tarling et al.[48]. Raw data were processed to consider the echosounder calibration and in situ ocean acoustic conditions via incorporation of onboard CTD data, and to remove background noise and other interferences via the Background Noise Removal[73] and Impulse Noise Removal[74] algorithms in Echoview. Krill were then detected using a target strength threshold of −70 dB to −30 dB[47,48] in Echoview following similar parameterization and protocols to Nardelli et al.[28] and Reiss et al.[75] (Fig. 3).

All acoustically detected krill swarms were manually reviewed before exporting the acoustic data in Nautical Area Scattering Coefficient (NASC) values, a common proxy for organism presence in acoustic measurements. NASC values were calculated per detected swarm and exported along with depth, GPS position (longitude and latitude), swarm height, swarm length, and backscatter (Sv). These methods for acoustic surveys and processing of subsequent acoustic data follow those in Hann et al.[46].

Table 1 | Tagged penguins by colony

Colony	Penguins tagged	Trips recorded
Adélie - Humble Island	12	23
Adélie - Torgersen Island	13	24
Adélie – Biscoe Island	5	13
Gentoo - Biscoe Island	14	32

Number of individual Adélie and gentoo penguins tagged per colony.

Penguin tagging

Adélie penguin colonies were located on Humble Island (64°45'S, 64°05'W), Torgersen Island (64°46'S, 64°04'W), and Biscoe Island, (64°48'S, 63°46'W), with the latter location also including a colony of gentoo penguins (Fig. 1b). Both species were double tagged with GPS tags and time-depth recorders measuring pressure at 0.5 Hz while wet. Penguins were GPS tagged with either a Lotek FastGPS (F5G 234B, 35 g), Sirtrack Fastloc 3 loggers (30 g) or igotU GT-600 (35 g, Mobile Action Technology, Taiwan). IgotU loggers were encased in adhesive-line heat shrink tubing. The time-depth recorders were either a Lotek LAT1810 (10 g) or StarOddi DST CTD (22 g). Tags were adhered to the anterior feathers on the lower dorsal area of the penguin. All protocols were carried out in accordance with the approved guidelines of the Columbia University (Assurance #AAAS2504) Institutional Animal Care and Use Committee for the 2019–2020 season. Tags were generally deployed on individuals for 2–4 days before being removed and reattached to another penguin. We tagged 30 Adélie and 14 gentoo penguins over the course of the austral summers (Table 1).

Drift in the depth data for tags was zero offset corrected using the *calibrateDepth* function in the R package diveMove[76]. Drift was not corrected for 7 deployments, as on 6 of these deployments (all Adélies, 5 Humble Island, 1 Torgersen Island) depth recordings shallower than 1 meter were not taken, and on 1 deployment (1 Adélie, Humble Island) depth recordings shallower than 5 meters were not taken. GPS data were filtered for erroneous locations based on improbable swimming speeds (>2.8 m s^{-1}). GPS location and TDR data were time matched and dives were identified using the *diveStats* function in diveMove[76].

Penguin data collection was conducted by Polar Oceans Research Group (PORG) as part of project SWARM.

Creating null models

Distribution of LCS where phytoplankton patches and krill swarms were observed in our transects were compared to those along simulated “null model” phytoplankton patches and krill swarms. The phytoplankton and krill null models were created by randomly moving the observed distribution of phytoplankton and krill within the LCS field (Fig. 5), maintaining the observed phytoplankton patch and krill swarm size and distribution along the transect. Each of the thirteen surveys were rotated and translated 100 times, creating 100 randomized locations of each observed phytoplankton patch and krill swarm while maintaining the shape of the survey. This ensured that the survey shape did not contribute to differences found between observed and null model phytoplankton patches and krill swarms. These randomized locations make up the phytoplankton and krill null model. Methods for using the survey transect to create the null model were adapted from Veatch et al.[11].

A sensitivity study was conducted on the null model to test if the differences between the null model and observations were due to the area where the survey was conducted having more FTLE than elsewhere in the study area. A new model was created following above methodology but requiring the randomly moved transects to be within a smaller area closer to the observed transect (northeast of the black line in Fig. 5). This constrained null model produced the same results as the original null model (see Results).

Distribution of LCS selected by penguin GPS locations were compared to those along simulated "null model" penguin tracks. Penguin null models were created with simulated Brownian motion of central place foragers (simm.bb in the adehabitatLT R package)[77], having the simulated penguin tracks return to the Adélie and gentoo colonies at the end of each trip (Fig. 1b). Each day that we had overlapping penguin observed data and LCS results from HFR-observed surface currents, ten penguin trips were simulated for each species. These trips were limited to 24 h, and simulated penguin speeds were normally distributed around a mean of 4 km hr^{-1} with a maximum of 8 km h^{-1}. These limitations were set to mimic average foraging trip duration (6–24 h)[44] and swimming speeds[78] of Adélie and gentoo penguins. The Brownian motion used to create these tracks is uncorrelated. Therefore, simulated tracks represent random foragers that do not select for environmental features or remembering previous feeding locations. Simulated penguin locations were used as a null metric for all the available LCS values for non-selecting central place foragers. Methods for the creation of simulated Adélie and gentoo tracks were adapted from Oliver et al.[66].

Calculating Lagrangian Coherent Structures

LCS were calculated from the HFR observed surface currents using the FTLE metric. FTLE were calculated beginning with a velocity field over a selected time interval (in this case, 6 h). Then, from the derivative of the flow map the Cauchy-Green strain tensor field (C) and eigenvector field (λ_i) were computed to be used in Eq. (1):

$$S(x_0) = \left[\max_{i=N^{\lambda_i}}\left(C(x_0)\right)\right]^{1/2} \qquad (1)$$

where $S(x_0)$ is the maximum stretching around point x_0. FTLE is then computed over a finite time (T)[10,79–81]. The resulting FTLE field changes in space and time with inputted HFR observed velocity field. These methods follow those in Veatch et al.[11].

Matching observed presence of null models to LCS

To associate krill and penguin presence with LCS, observations were matched in both space and time. LCS results were calculated each hour and at a 1 km spatial resolution to match the resolution of inputted HFR velocity data. Krill swarms and penguin locations were matched to the nearest hour of LCS map. This means that for the LCS results computed for 13:00 on January 15th, all krill and penguin location observations between 12:30 and 13:30 on January 15th were compared to the LCS results from 13:00. To match krill and penguin presence with LCS in space, a haversine function[82] was used to find the closest LCS result grid point (using the center of the grid point) to the krill or penguin location. The LCS value in that grid point for the LCS results on the nearest hour were associated with the krill or penguin observation. The same was done for null models.

Kolmogorov-Smirnov tests

Two-sample Kolomogorov-Smirnov (KS) tests[83] were used to determine if there are significant differences between the empirical distribution functions of observations and null models. KS tests are conducted using Eq. (2):

$$D = sup_x\left|F_{n,1}(x) - F_{n,2}(x)\right| \qquad (2)$$

where D is the test statistic, $F_{n,1}(x)$ and $F_{n,2}(x)$ are the empirical distribution functions of the two samples. A small p-value from the KS test means that the two samples come from different distributions. One-sided KS tests are especially good at determining if the tails of two cumulative distributions are significantly different from each other.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

Data and code used in this study are publicly available on NSF funded project SWARM's BCO-DMO site and GitHub. High Frequency Radar observed surface currents are available in the gap-filled version used in this study on BCO-DMO[84]. Lagrangian Coherent Structure Results for FTLE metrics are available on BCO-DMO[85]. EK80 acoustic data used to detect krill swarms are available on BCO-DMO ACROBAT data used to detect phytoplankton patches are available on BCO-DMO[86] Penguin GPS tag data are available University of Delaware's public archive (http://modata.ceoe.udel.edu/public/Antarctica_2020/SWARM_Penguin_CSVs/). Any questions can be directed to Jacquelyn Veatch (jveatch@whoi.edu).

Code availability

Code used to gap-fill High Frequency Radar data are available on GitHub (https://github.com/JackieVeatch/SWARM_CODAR). The code used to produce LCS results can be found on GitHub (https://github.com/JackieVeatch/SWARM_LCS). The code was modified from open-source MATLAB library[80] for use on HFR data. All other code for analysis can be found on GitHub (https://github.com/JackieVeatch/SWARM_analysis, https://github.com/JackieVeatch/SWARM_Krillanalysis, and https://github.com/JackieVeatch/SWARM_PenguinAnalysis). Any questions can be directed to Jacquelyn Veatch (jveatch@whoi.edu).

Acknowledgements

This project was funded through the National Science Foundation, award # OPP 1745009. Many thanks to the Antarctic Support Contractor and their teams aboard the ARSV Laurence M. Gould, at Palmer Station, and headquarters in Denver, CO without whom a study of this scale would not be possible. Thank you to the students and field assistants for their valued involvement in the SWARM project in particular, Dr. Katherine Gallagher, Dr. Jerome Pinti, Dr. Thilo Klenz, Ethan Handel, and Jordi Maisch. We thank the Palmer Long-Term Ecological Research team and the Commission for the Conservation of Antarctic Marine Living Resources for their advice and collaboration, in particular the Seabird team of the Palmer Long-Term Ecological Research who were instrumental in the deployment of penguin tags.

Author contributions

J.V. contributed by writing the original draft of this manuscript, leading the formal analysis, validation and visualization of data, and contributed equally to data curation, developing methodology, and the conceptualization of this manuscript. J.K. contributed by leading the funding acquisition and supervision of this manuscript and contributed equally to the conceptualization, data acquisition, development of methodology, and reviewing and editing of this manuscript. M.O. contributed equally to data acquisition, development of methodology, analysis, and reviewing and editing of this manuscript, led the visualization of penguin tagged data, and contributed supporting supervision. H.S. contributed a leading role to the data acquisition and contributed equally to the conceptualization of this manuscript. E.F. contributed equally to the conceptualization and development of methodology in this manuscript and contributed supporting supervision. K.B. contributed equally to data validation, conceptualization, development of methodology, and reviewing and editing of this manuscript. H.F. contributed equally to conceptualization and reviewing and editing of this manuscript. W.F. contributed to penguin foraging data acquisition, conceptualization, reviewing and editing of this manuscript. A.H. led the validation of the active acoustic data and contributed equally to reviewing and editing of this manuscript. G.V. led the validation of the penguin tagged data and contributed equally to reviewing and editing of this manuscript.
